HTLV-I is not usually found in cells of the CNS but may be detected in a small population of lymphocytes present in the CSF. In general, HTLV-I replication is greater in HAM than in ATL, and patients with HAM have a stronger immune response to the virus. Antibodies to HTLV-I are present in the serum and appear to be produced in the CSF.

of HAM patients, where titers are often higher than in the serum. The pathophysiology of HAM may involve the induction of autoimmune destruction of neural cells by T cells with specificity for viral components such as Tax or Env proteins. One theory is that susceptibility to HAM may be related to the presence of human leukocyte antigen (HLA) alleles capable of presenting viral antigens in a fashion that leads to autoimmunity. Insufficient data are available to confirm an HLA association. However, antibodies in the sera of HAM patients have been shown to bind a neuron-specific antigen [heteronuclear ribonuclear protein A1 (hnRNP A1)] and to interfere with neurotransmission *in vitro*.

It is unclear what factors influence whether HTLV-I infection will cause disease and, if it does, whether it will induce a neoplasm (ATL) or an autoimmune disorder (HAM). Differences in viral strains, the susceptibility of particular MHC haplotypes, the route of HTLV-I infection, the viral load, and the nature of the HTLV-I-related immune response are putative factors, but few definitive data are available.

Other Putative HTLV-I-Related Diseases

In areas where HTLV-I is endemic, diverse inflammatory and autoimmune diseases have been attributed to the virus, including uveitis, dermatitis, pneumonitis, rheumatoid arthritis, and polymyositis. However, a causal relationship between HTLV-I and these illnesses has not been established.

Prevention

Women in endemic areas should not breast-feed their children, and blood donors should be screened for serum antibodies to HTLV-I. As in the prevention of HIV infection, the practice of safe sex and the avoidance of needle sharing are important.

Treatment: HTLV-I INFECTION

For the small number of patients who develop HTLV-I-related disease, therapies are not curative. In patients with the acute and lymphomatous types of ATL, the disease progresses rapidly. Hypercalcemia is generally controlled by glucocorticoid administration and cytotoxic therapy directed against the neoplasm. The tumor is highly responsive to combination chemotherapy that is employed against other forms of lymphoma; however, patients are susceptible to overwhelming bacterial and opportunistic infections, and ATL relapses within 4–10 months after remission in most cases. The combination of interferon α and zidovudine may extend survival. Because viral replication is not clearly associated with ATL progression, zidovudine is probably effective through its cytotoxic effects (as a chain-terminating thymidine analogue) rather than its antiviral effects. An experimental approach using an yttrium 90-labeled or toxin-conjugated antibody to the IL-2 receptor appears

promising but is not widely available. Patients with the chronic or smoldering form of ATL may be managed with an expectant approach: treat any infections, and watch and wait for signs of progression to acute disease.

Patients with HAM may obtain some benefit from the use of glucocorticoids to reduce inflammation. Anti-retroviral regimens have not been effective. In one study, danazol (200 mg three times daily) produced significant neurologic improvement in five of six treated patients, with resolution of urinary incontinence in two cases, decreased spasticity in three, and restoration of the ability to walk after confinement to a wheelchair in two. Physical therapy and rehabilitation are important components of management.

FEATURES OF HTLV-II INFECTION

Epidemiology

HTLV-II is endemic in certain Native American tribes and in Africa. It is generally considered to be a New World virus that was brought from Asia to the Americas 10,000–40,000 years ago during the migration of infected populations across the Bering land bridge. The mode of transmission of HTLV-II is probably the same as that of HTLV-I (see above). HTLV-II may be less readily transmitted sexually than HTLV-I.

Studies of large cohorts of injection drug users with serologic assays that reliably distinguish HTLV-I from HTLV-II indicated that the vast majority of HTLV-positive cohort members were infected with HTLV-II. The seroprevalence of HTLV in a cohort of 7841 injection drug users from drug treatment centers in Baltimore, Chicago, Los Angeles, New Jersey (Asbury Park and Trenton), New York City (Brooklyn and Harlem), Philadelphia, and San Antonio was 20.9%, with >97% of cases due to HTLV-II. The seroprevalence of HTLV-II was higher in the Southwest and the Midwest than in the Northeast. In contrast, the seroprevalence of HIV-1 was higher in the Northeast than in the Southwest or the Midwest. Approximately 3% of the cohort members were infected with both HTLV-II and HIV-1. The seroprevalence of HTLV-II increased linearly with age. Women were significantly more likely to be infected with HTLV-II than were men; the virus is thought to be more efficiently transmitted from male to female than from female to male.

Associated Diseases

Although HTLV-II was isolated from a patient with a T-cell variant of hairy cell leukemia, this virus has not been consistently associated with a particular disease and in fact has been thought of as “a virus searching for a disease.” However, evidence is accumulating that HTLV-II may play a role in certain neurologic, hematologic, and dermatologic diseases. These data require confirmation, particularly in light of the previous confusion regarding the relative prevalences of HTLV-I and HTLV-II among injection drug users.

Avoidance of needle sharing, adherence to safe-sex practices, screening of blood (by assays for HTLV-I, which also detect HTLV-II), and avoidance of breast-feeding by infected women are important principles in the prevention of spread of HTLV-II.

HUMAN IMMUNODEFICIENCY VIRUS

HIV-1 and HIV-2 are members of the lentivirus subfamily of Retroviridae and are the only lentiviruses known to infect humans. The lentiviruses are slow-acting by comparison with viruses that cause acute infection (e.g., influenza virus) but not by comparison with other retroviruses. The features of acute primary infection with HIV resemble those of more classic acute infections. The characteristic chronicity of HIV disease is consistent with the designation *lentivirus*. For a detailed discussion of HIV, see Chap. 90.

AIDS was first recognized in the United States in the summer of 1981, when the U.S. Centers for Disease Control and Prevention (CDC) reported the unexplained occurrence of *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia in five previously healthy homosexual men in Los Angeles and of Kaposi's sarcoma (KS) with or without *P. jiroveci* pneumonia in 26 previously healthy homosexual men in New York and Los Angeles. Within months, the disease became recognized in male and female injection drug users (IDUs) and soon thereafter in recipients of blood transfusions and in hemophiliacs. As the epidemiologic pattern of the disease unfolded, it became clear that an infectious agent transmissible by sexual (homosexual and heterosexual) contact and blood or blood products was the most likely etiologic cause of the epidemic.

In 1983, human immunodeficiency virus (HIV) was isolated from a patient with lymphadenopathy, and by 1984 it was demonstrated clearly to be the causative agent of AIDS. In 1985, a sensitive enzyme-linked immunosorbent assay (ELISA) was developed, which led to an appreciation of the scope and evolution of the HIV epidemic at first in the United States and other developed nations and ultimately among developing nations throughout the world (see below). The staggering worldwide evolution of the HIV pandemic has been matched by an explosion of information in the areas of HIV virology, pathogenesis (both immunologic and virologic), treatment of HIV disease, treatment and prophylaxis of the opportunistic diseases associated with HIV infection, prevention of infection, and vaccine development. The information flow related to HIV disease is enormous and continues to expand, and it has become almost impossible for the health care generalist to stay abreast of the literature. The purpose of this chapter is to present the most current information available on the scope of the epidemic; on its pathogenesis, treatment, and prevention; and on prospects for vaccine development. Above all, the aim is to provide a solid scientific basis and practical clinical guidelines for a state-of-the-art approach to the HIV-infected patient.

DEFINITION

The current CDC classification system for HIV-infected adolescents and adults categorizes persons on the basis of clinical conditions associated with HIV infection and CD4+ T-lymphocyte counts. The system is based on three ranges of CD4+ T-lymphocyte counts and three clinical categories and is represented by a matrix of nine mutually exclusive categories (Tables 90-1 and 90-2). Using this system, any HIV-infected individual with a CD4+ T-cell count of $<200/\mu\text{L}$ has AIDS by definition, regardless of the presence of symptoms or opportunistic diseases (Table 90-1). Once individuals have had a clinical condition in category B, their disease classification cannot be reverted back to category A, even if the condition resolves; the same holds true for category C in relation to category B.

The definition of AIDS is indeed complex and comprehensive and was established not for the practical care of patients, but for surveillance purposes. Thus the clinician should not focus on whether or not the patient fulfills the strict definition of AIDS, but should view HIV disease as a spectrum ranging from primary infection, with or without the acute syndrome, to the asymptomatic stage, to advanced disease (see below).

ETIOLOGIC AGENT

The etiologic agent of AIDS is HIV, which belongs to the family of human retroviruses (Retroviridae) and the subfamily of lentiviruses (Chap. 89). Nononcogenic lentiviruses cause disease in other animal species, including sheep, horses, goats, cattle, cats, and monkeys. The four recognized human retroviruses belong to two distinct groups: the human T-lymphotropic viruses (HTLV)-I and HTLV-II, which are transforming retroviruses; and the human immunodeficiency viruses, HIV-1 and HIV-2, which cause cytopathic effects either directly or indirectly (see below and Chap. 89). The most common cause of HIV disease throughout the world, and certainly in the United States, is HIV-1, which comprises several subtypes with different geographic distributions (see below). HIV-2 was first identified in 1986 in

CLINICAL CATEGORIES OF HIV INFECTION

Category A: Consists of one or more of the conditions listed below in an adolescent or adult (>13 years) with documented HIV infection. Conditions listed in categories B and C must not have occurred.

Asymptomatic HIV infection

Persistent generalized lymphadenopathy

Acute (primary) HIV infection with accompanying illness or history of acute HIV infection

Category B: Consists of symptomatic conditions in an HIV-infected adolescent or adult that are not included among conditions listed in clinical category C and that meet at least one of the following criteria: (1) The conditions are attributed to HIV infection or are indicative of a defect in cell-mediated immunity; or (2) the conditions are considered by physicians to have a clinical course or to require management that is complicated by HIV infection. Examples include, but are not limited to, the following:

Bacillary angiomatosis

Candidiasis, oropharyngeal (thrush)

Candidiasis, vulvovaginal; persistent, frequent, or poorly responsive to therapy

Cervical dysplasia (moderate or severe)/cervical carcinoma in situ

Constitutional symptoms, such as fever (38.5°C) or diarrhea lasting >1 month

Hairy leukoplakia, oral

Herpes zoster (shingles), involving at least two distinct episodes or more than one dermatome

Idiopathic thrombocytopenic purpura

Listeriosis

Pelvic inflammatory disease, particularly if complicated by tuboovarian abscess

Peripheral neuropathy

Category C: Conditions listed in the AIDS surveillance case definition.

Candidiasis of bronchi, trachea, or lungs

Candidiasis, esophageal

Cervical cancer, invasive^a

Coccidioidomycosis, disseminated or extrapulmonary

Cryptococcosis, extrapulmonary

Cryptosporidiosis, chronic intestinal (>1 month's duration)

Cytomegalovirus disease (other than liver, spleen, or nodes)

Cytomegalovirus retinitis (with loss of vision)

Encephalopathy, HIV-related

Herpes simplex: chronic ulcer(s) (>1 month's duration); or bronchitis, pneumonia, or esophagitis

Histoplasmosis, disseminated or extrapulmonary

Isosporiasis, chronic intestinal (>1 month's duration)

Kaposi's sarcoma

Lymphoma, Burkitt's (or equivalent term)

Lymphoma, primary, of brain

Mycobacterium avium complex or *M. kansasii*, disseminated or extrapulmonary

Mycobacterium tuberculosis, any site (pulmonary or extrapulmonary)

Mycobacterium, other species or unidentified species, disseminated or extrapulmonary

Pneumocystis jirovecii pneumonia

Pneumonia, recurrent^a

Progressive multifocal leukoencephalopathy

Salmonella septicemia, recurrent

Toxoplasmosis of brain

Wasting syndrome due to HIV

^aAdded in the 1993 expansion of the AIDS surveillance case definition.

West African patients and was originally confined to West Africa. However, a number of cases that can be traced to West Africa or to sexual contacts with West Africans have been identified throughout the world. Both HIV-1 and HIV-2 are zoonotic infections. The *Pan troglodytes troglodytes* species of chimpanzees has been established as the natural reservoir of HIV-1 and the most likely source of original human infection. HIV-2 is more closely related phylogenetically to the simian immunodeficiency virus (SIV) found in sooty mangabeys than it is to HIV-1. The taxonomic relationship among primate lentiviruses is shown in [Fig. 90-1](#).

MORPHOLOGY OF HIV

Electron microscopy shows that the HIV virion is an icosahedral structure ([Fig. 90-2A](#)) containing numerous external spikes formed by the two major envelope proteins, the external gp120 and the transmembrane gp41. The virion buds from the surface of the infected cell and incorporates a variety of host proteins, including major histocompatibility complex (MHC) class I and II antigens, into its lipid bilayer. The structure of HIV-1 is schematically diagrammed in [Fig. 90-2B](#) (Chap. 89).

REPLICATION CYCLE OF HIV

HIV is an RNA virus whose hallmark is the reverse transcription of its genomic RNA to DNA by the enzyme *reverse transcriptase*. The replication cycle of HIV begins with the high-affinity binding of the gp120 protein via a portion of its V1 region near the N terminus to its receptor on the host cell surface, the CD4 molecule ([Fig. 90-3](#)). The CD4 molecule is a 55-kDa protein found predominantly on a subset of T lymphocytes that are responsible for helper function in the immune system. It is also expressed on the surface of monocytes/macrophages and dendritic/Langerhans cells. Once gp120 binds to CD4, the gp120 undergoes a conformational change that facilitates binding to one of a group of co-receptors. The two major co-receptors for HIV-1 are CCR5 and CXCR4. Both receptors belong to the family of seven-transmembrane-domain G protein-coupled cellular receptors, and the use of one or the other or both receptors by the virus for entry into the cell is an important determinant of the cellular tropism of the virus (see below for details). Certain dendritic cells express a diversity of C-type lectin receptors on their surface, one of which is called *DC-SIGN*, that also bind with high affinity to the HIV gp120 envelope protein, allowing the dendritic cell to facilitate the binding of virus to the CD4+ T cell upon engagement of dendritic cells with CD4+ T cells. After binding of the envelope protein to the CD4 molecule associated with the above-mentioned conformational change in the viral envelope gp120, fusion with the host cell membrane occurs via the newly exposed gp41 molecule penetrating the plasma membrane of the target cell and then coiling upon itself to bring the virion and target cell together. After fusion, the preintegration complex, composed of viral RNA and viral enzymes and surrounded by a capsid

**FIGURE 90-3**

The replication cycle of HIV. See text for description. (Adapted from Fauci, 1996.)

protein coat, is released into the cytoplasm of the target cell (Fig. 90-4). As the preintegration complex traverses the cytoplasm to reach the nucleus (Fig. 90-3), the viral reverse transcriptase enzyme catalyzes the reverse transcription of the genomic RNA into DNA, and the protein coat opens to release the resulting double-stranded HIV-DNA. At this point in the replication cycle, the viral genome is vulnerable to cellular factors that can block the progression of infection. In particular, the cytoplasmic TRIM5- α protein in rhesus macaque cells blocks SIV replication at a point shortly after the virus fuses with the host cell. Although the exact mechanisms of action of TRIM5- α remain unclear, the human form is inhibited by cyclophilin A and is not effective in restricting HIV replication in human cells. The recently

described APOBEC family of cellular proteins also inhibits progression of virus infection after virus has entered the cell. APOBEC proteins bind to nascent reverse transcripts and deaminate viral cytidine, causing hypermutation of HIV genomes. It is still not clear whether (1) viral replication is inhibited by the binding of APOBEC to the virus genome with subsequent accumulation of reverse transcripts, or (2) by the hypermutations caused by the enzymatic deaminase activity of APOBEC proteins. HIV has evolved a powerful strategy to protect itself from APOBEC. The viral protein Vif targets APOBEC for proteasomal degradation.

With activation of the cell, the viral DNA accesses the nuclear pore and is exported from the cytoplasm to the nucleus, where it is integrated into the host cell

**FIGURE 90-4**

Binding and fusion of HIV-1 with its target cell. HIV-1 binds to its target cell via the CD4 molecule, leading to a conformational change in the gp120 molecule that allows it to bind to the co-receptor CCR5 (for R5-using viruses). The virus then firmly attaches to the host cell membrane in a coiled-spring fashion via the newly exposed gp41 molecule. Virus-cell

fusion occurs as the transitional intermediate of gp41 undergoes further changes to form a hairpin structure that draws the two membranes into close proximity (see text for details). (Adapted from D Montefiori, JP Moore: *Science* 283:336, 1999; with permission.)

chromosomes through the action of another virally encoded enzyme, *integrase*. HIV provirus (DNA) selectively integrates into the nuclear DNA preferentially within introns of active genes and regional hotspots. This provirus may remain transcriptionally inactive (latent) or it may manifest varying levels of gene expression, up to active production of virus.

Cellular activation plays an important role in the replication cycle of HIV and is critical to the pathogenesis of HIV disease (see below). After initial binding and internalization of virions into the target cell, incompletely reverse-transcribed DNA intermediates are labile in quiescent cells and do not integrate efficiently into the host cell genome unless cellular activation occurs shortly after infection. Furthermore, some degree of activation of the host cell is required for the initiation of transcription of the integrated proviral DNA into either genomic RNA or mRNA. This latter process may not necessarily be associated with the detectable expression of the classic cell surface markers of activation. In this regard, activation of HIV expression from the latent state depends on the interaction of a number of cellular and viral factors. After transcription, HIV mRNA is translated into proteins that undergo modification through glycosylation, myristylation, phosphorylation, and cleavage. The viral particle is formed by the assembly of HIV proteins, enzymes, and genomic RNA at the plasma membrane of the cells. Budding of the progeny

virion occurs through specialized regions in the lipid bilayer of the host cell membrane known as *lipid rafts*, where the core acquires its external envelope (Chap. 89). The virally encoded protease then catalyzes the cleavage of the gag-pol precursor (see below) to yield the mature virion. Progression through the virus replication cycle is profoundly influenced by a variety of viral regulatory gene products. Likewise, each point in the replication cycle of HIV is a real or potential target for therapeutic intervention (see below). Thus far, the reverse transcriptase, protease, and integrase enzymes as well as the process of virus–target cell binding and fusion have proven clinically to be susceptible to pharmacologic disruption (see below). Inhibitors of the maturation process of virions during the latter phase of the replication cycle are currently being evaluated in clinical trials.

HIV GENOME

Figure 90-5 illustrates schematically the arrangement of the HIV genome. Like other retroviruses, HIV-1 has genes that encode the structural proteins of the virus: *gag* encodes the proteins that form the core of the virion (including p24 antigen); *pol* encodes the enzymes responsible for protease processing of viral proteins, reverse transcription, and integration; and *env* encodes the envelope glycoproteins. However, HIV-1 is more complex than other retroviruses, particularly those of

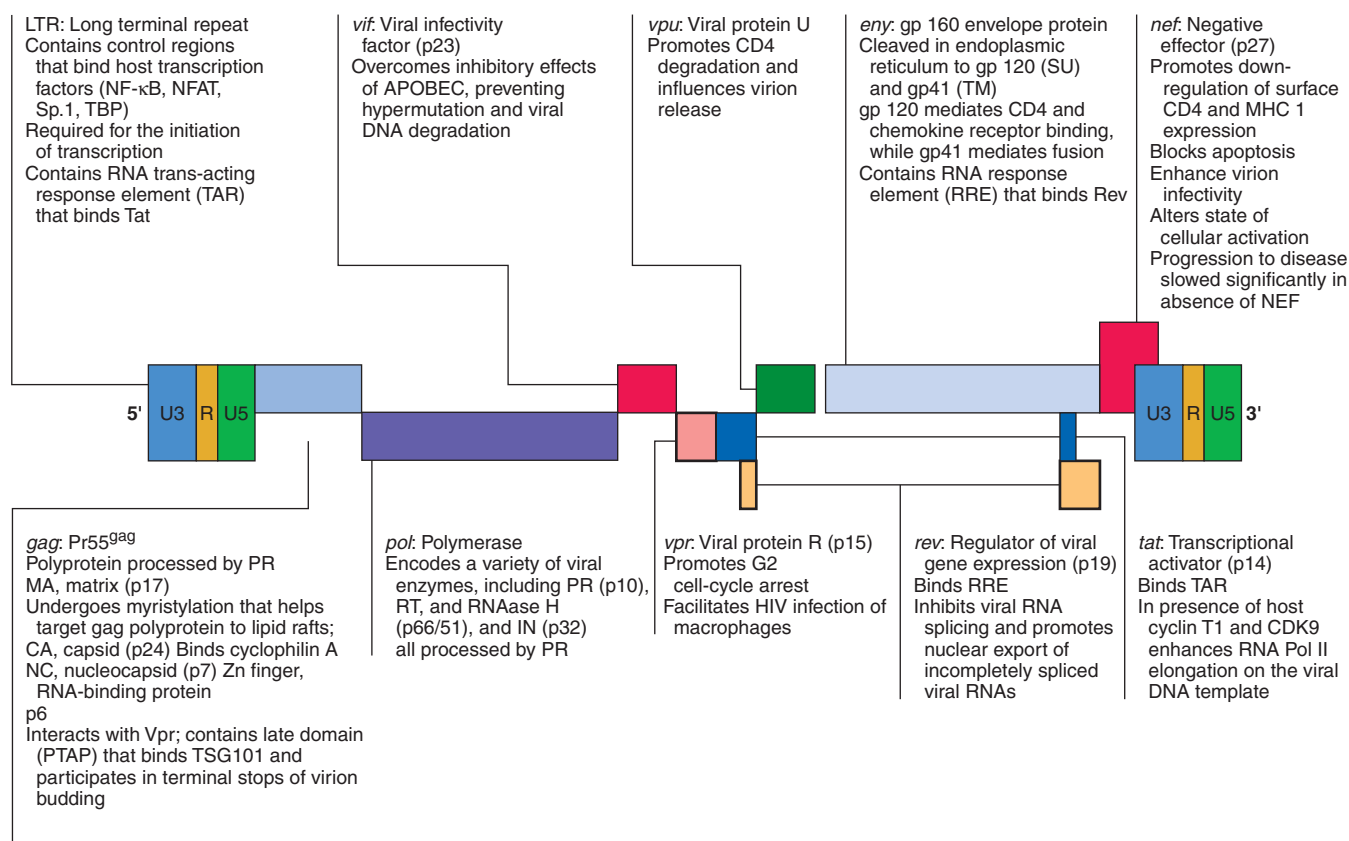

FIGURE 90-5

Organization of the genome of the HIV provirus together with a summary description of its nine genes encoding 15 proteins. (Adapted from Greene and Peterlin.)

the nonprimate group, in that it also contains at least six other genes (*tat*, *rev*, *nef*, *vif*, *vpr*, and *vpu*), which code for proteins involved in the modification of the host cell to enhance virus growth and the regulation of viral gene expression (Chap. 89). Several of these proteins are thought to play a role in the pathogenesis of HIV disease; their various functions are listed in Fig. 90-5. Flanking these genes are the long terminal repeats (LTRs), which contain regulatory elements involved in gene expression (Fig. 90-5). The major difference between the genomes of HIV-1 and HIV-2 is the fact that HIV-2 lacks the *vpu* gene and has a *vpx* gene not contained in HIV-1.

MOLECULAR HETEROGENEITY OF HIV-1

Molecular analyses of HIV isolates reveal varying levels of sequence diversity over all regions of the viral genome. For example, the degree of difference in the coding sequences of the viral envelope protein ranges from a few percent (very close, between isolates from the same infected individual) to 50% (extreme diversity, between isolates from the different groups of HIV-1, M, N, and O; see below). The changes tend to cluster in hypervariable regions. HIV can evolve by several means, including simple base substitution, insertions and deletions, recombination, and gain and loss of glycosylation sites. HIV sequence diversity arises directly from the limited fidelity of the reverse transcriptase. The balance of immune pressure and functional constraints on proteins influences the regional level of variation within proteins. For example, Envelope, which is exposed on the surface of the virion and is under immune selective pressure from both antibodies and cytolytic T lymphocytes, is extremely variable, with clusters of mutations in hypervariable domains. In contrast, Reverse Transcriptase, with important enzymatic functions, is relatively conserved, particularly around the active site. The extraordinary variability of HIV-1 is in marked contrast to the relative stability of HTLV-I and -II.

There are three groups of HIV-1: group M (major), which is responsible for most of the infections in the world; group O (outlier), a relatively rare viral form found originally in Cameroon, Gabon, and France; and group N, first identified in a Cameroonian woman with AIDS; only a few cases of the latter have been identified. Among primate lentiviruses, HIV-1 is most closely related to viruses isolated from chimpanzees and gorillas. The chimpanzee subspecies *Pan troglodytes troglodytes* has been established to be the natural reservoir of the HIV-1 M and N groups. The HIV-1 O group is most closely related to viruses found in Cameroonian gorillas. The M group comprises nine subtypes, or *clades*, designated A, B, C, D, E, G, H, J, and K, as well as a growing number of major and minor circulating recombinant forms (CRFs). CRFs are generated by infection of an individual with two subtypes that then recombine and create a virus with a selective advantage. These CRFs range from highly prevalent forms such as the AE virus, CRF01_AE, which is predominant in southeast Asia and often referred to simply as E, despite the fact that the

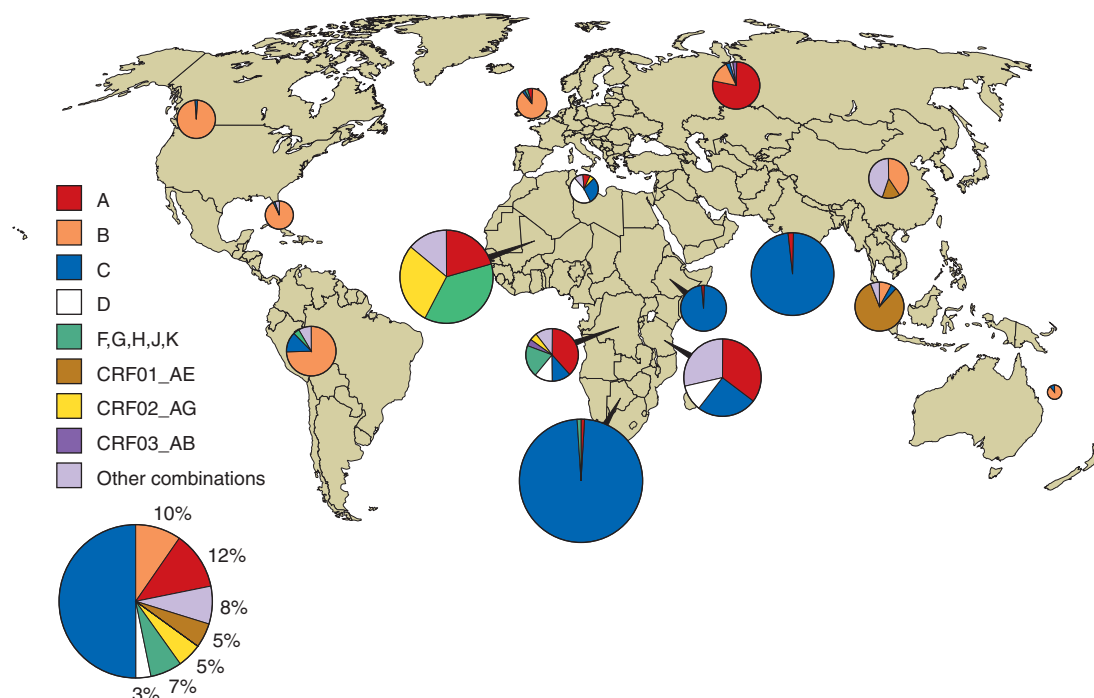

FIGURE 90-6

Phylogenetic tree constructed from representative viral envelope sequences of the subtypes and CRF01 in HIV-1 group M, some isolates from groups N and O (also HIV-1 human), CPZ (chimpanzee), and gorilla (GOR). The scale bar at the bottom indicates the genetic distances between the sequences. A1 and A2, F1 and F2 are subtypes; CRF01_AE is unique in the envelope gene but similar to subtype A in the rest of the genome. (Courtesy of Brian Foley, PhD, Bette Korber, PhD, and Thomas Leitner, PhD, HIV Database, Los Alamos National Laboratory; with permission.)

parental E virus has never been found, and CRF02_AG from west and central Africa, to a large number of CRFs that are relatively rare. The subtypes and CRFs create the major lineages of the M group of HIV-1. The picture has been complicated somewhat when it was found that some subtypes are not equidistant from one another, whereas others contained sequences so diverse that they could not properly be considered to be the same subtype. Thus the term *sub-subtype* was introduced, and subtypes A and F are now subdivided into A1 and A2, F1 and F2. It has also been argued that subtypes B and D are really too close to be separate subtypes and should be considered sub-subtypes; it was decided, however, not to increase the confusion by renaming the clades (Fig. 90-6).

The global patterns of HIV-1 variation likely result from accidents of viral trafficking. Subtype B viruses, which now differ by up to 17% in their *env* coding sequences, are the overwhelmingly predominant viruses seen in the United States, Canada, certain countries in South America, western Europe, and Australia. Other subtypes are also present in these countries to varying degrees. It is thought that, purely by chance, subtype B was seeded into the United States in the late 1970s, thereby establishing an overwhelming founder effect. Subtype C viruses (of the M group) are the most common form worldwide; many countries have co-circulating viral subtypes that are giving rise to new CRFs. Figure 90-7 schematically diagrams the worldwide distribution of HIV-1 subtypes by region. Seven strains account for the majority of HIV infections globally: HIV-1 subtypes A, B, C, D, G and two of the CRFs, CRF01_AE and CRF02_AG. The predominant subtype in Europe, Australia, and the Americas is subtype B. In Sub-Saharan Africa, home to

**FIGURE 90-7**

Geographic distribution of HIV-1 subtypes and recombinants. The prevalence of HIV-1 genetic subtypes varies by geographic region. The proportions of subtypes in different

regions are indicated by pie charts. (From J Hemelaar et al: *AIDS* 20:W13, 2006.)

approximately two-thirds of all individuals living with HIV/AIDS, >50% of infections are caused by subtype C, with smaller proportions of infections caused by subtype A, subtype G, CRF02_AG, and other subtypes and recombinants. In Asia, HIV-1 isolates of the CRF01_AE lineage and subtypes C and B predominate. CRF01_AE accounts for most infections in south and southeast Asia, whereas subtype C is prevalent in India (see “HIV Infection and AIDS Worldwide” later in the chapter). Sequence analyses of HIV-1 isolates from infected individuals indicate that recombination among viruses of different clades likely occurs as a result of infection of an individual with viruses of more than one subtype, particularly in geographic areas where subtypes overlap.

TRANSMISSION

HIV is transmitted by both homosexual and heterosexual contact; by blood and blood products; and by infected mothers to infants either intrapartum, perinatally, or via breast milk. After >25 years of scrutiny, there is no evidence that HIV is transmitted by casual contact or that the virus can be spread by insects, such as by a mosquito bite.

SEXUAL TRANSMISSION

HIV infection is predominantly a sexually transmitted disease (STD) worldwide. In the United States, ~49% of the HIV/AIDS cases diagnosed in 2005 among adults and adolescents were attributed to male-to-male sexual contact. Heterosexual contact accounted for another 32%.

Worldwide, the most common mode of infection, particularly in developing countries, is clearly heterosexual transmission. Furthermore, the yearly incidence of new cases of AIDS attributed to heterosexual transmission of HIV is steadily increasing in the United States, mainly among minorities, particularly women in minority groups (Fig. 90-8).

HIV has been demonstrated in seminal fluid both within infected mononuclear cells and in cell-free material. The virus appears to concentrate in the seminal fluid, particularly in situations where there are increased numbers of lymphocytes and monocytes in the fluid, as in genital inflammatory states such as urethritis and epididymitis, conditions closely associated with other STDs (see below). The virus has also been demonstrated in cervical smears and vaginal fluid. There is a strong association of HIV transmission with receptive anal intercourse, probably because only a thin, fragile rectal mucosal membrane separates the deposited semen from potentially susceptible cells in and beneath the mucosa and trauma may be associated with anal intercourse. Anal douching and sexual practices that traumatize the rectal mucosa also increase the likelihood of infection. It is likely that anal intercourse provides at least two modalities of infection: (1) direct inoculation into blood in cases of traumatic tears in the mucosa; and (2) infection of susceptible target cells, such as Langerhans cells, in the mucosal layer in the absence of trauma (see below). Although the vaginal mucosa is several layers thicker than the rectal mucosa and less likely to be traumatized during intercourse, it is clear that the virus can be transmitted to either partner through vaginal intercourse.

**FIGURE 90-8**

AIDS cases among U.S. adults and adolescents by exposure category and year of diagnosis. The proportion of AIDS cases attributed to heterosexual contact with a person known to have or at high risk for HIV infection (high-risk

heterosexual) increased from 3% in 1985 to 31% in 2005. IDU, injection drug use. [From *The Centers for Disease Control and Prevention (CDC)*.]

Studies in the United States and Europe have found that male-to-female HIV transmission is usually more efficient than female-to-male transmission, but small numbers of HIV-positive female index partners limit conclusive sex-specific estimates of transmission probabilities per sex act. The differences in reported transmission rates between men and women may be due in part to the prolonged exposure to infected seminal fluid of the vaginal and cervical mucosa, as well as the endometrium (when semen enters through the cervical os). By comparison, the penis and urethral orifice are exposed relatively briefly to infected vaginal fluid. Among various cofactors examined in studies of heterosexual HIV transmission, the presence of other sexually transmitted diseases (STDs; see below) has been strongly associated with HIV transmission. In this regard, there is a close association between genital ulcerations and transmission, from the standpoints of both susceptibility to infection and infectivity. Infections with microorganisms such as *Treponema pallidum* (Chap. 70), *Haemophilus ducreyi* (Chap. 47), and herpes simplex virus (HSV; Chap. 80) are important causes of genital ulcerations linked to transmission of HIV. In addition, pathogens responsible for nonulcerative inflammatory STDs such as those caused by *Chlamydia trachomatis* (Chap. 77), *Neisseria gonorrhoeae* (Chap. 45), and *Trichomonas vaginalis* (Chap. 122) are also associated with an increased risk of transmission of HIV infection. Bacterial vaginosis, an infection related to sexual behavior, but not strictly an STD, may also be linked to an increased risk of transmission of HIV infection. Several studies suggest that treating other STDs and genital tract syndromes may help prevent transmission of HIV. This effect is most prominent in populations in which the prevalence of HIV infection is

relatively low. In studies conducted in Uganda, the chief predictor of heterosexual transmission of HIV was the level of plasma viremia. In a cohort of couples in which one partner was HIV-infected and one was initially uninfected, the mean serum HIV RNA level was significantly higher among HIV-infected subjects whose partners seroconverted than among those whose partners did not seroconvert. In fact transmission was rare when the infected partner had a plasma level of <1500 copies of HIV RNA per milliliter. The rate of HIV transmission per coital act was highest during the early stage of HIV infection when plasma HIV RNA levels are highest and in advanced disease as the viral set point increases (Fig. 90-9).

A number of studies have indicated that male *circumcision* is associated with a lower risk of HIV infection among men. This difference may be due to increased susceptibility of uncircumcised men to ulcerative STDs, as well as other factors such as microtrauma to the foreskin and glans penis. In addition, the highly vascularized inner foreskin tissue contains a high density of Langerhans cells as well as increased numbers of CD4+ T cells, macrophages, and other cellular targets for HIV. Finally, the moist environment under the foreskin may promote the presence or persistence of microbial flora that, via inflammatory changes, may lead to even higher concentrations of target cells for HIV in the foreskin. In some studies the use of oral contraceptives was associated with an increase in incidence of HIV infection over and above that which might be expected by not using a condom for birth control. This phenomenon may be due to drug-induced changes in the cervical mucosa, rendering it more vulnerable to penetration by the virus. Adolescent girls might also be more susceptible to

**FIGURE 90-9**

HIV transmission rate per coital act among 235 HIV serodiscordant couples in Uganda, and 95% confidence intervals, by follow-up interval. The risk of HIV transmission was highest during early-stage and late-stage infection. (From Wawer et al.)

infection upon exposure due to the properties of an immature genital tract with increased cervical ectopy or exposed columnar epithelium.

Oral sex is a much less efficient mode of transmission of HIV than is receptive anal intercourse. A number of studies have reported that the incidence of transmission of infection by oral sex among couples discordant for HIV was extremely low. However, there have been reports of documented HIV transmission resulting solely from receptive fellatio and insertive cunnilingus. Therefore, the assumption that receptive oral sex is completely safe is not warranted. The association of alcohol consumption and illicit drug use with unsafe sexual behavior, both homosexual and heterosexual, leads to an increased risk of sexual transmission of HIV. Methamphetamine (“crystal meth,” “tina”) and other so-called club drugs (e.g., ecstasy, ketamine, and gamma hydroxybutyrate), sometimes taken in conjunction with sildenafil (Viagra) or related drugs have been associated with risky sexual practices and increased risk of HIV infection, particularly among men who have sex with men.

TRANSMISSION BY BLOOD AND BLOOD PRODUCTS

HIV can be transmitted to individuals who receive HIV-tainted blood transfusions, blood products, or transplanted tissue as well as to IDUs who are exposed to HIV while sharing injection paraphernalia such as needles, syringes, the water in which drugs are mixed, or the cotton through which drugs are filtered. Parenteral transmission of HIV during injection drug use does not require IV puncture; SC (“skin popping”) or IM (“muscling”) injections can transmit HIV as well, even though these behaviors are sometimes erroneously perceived as low-risk. Among IDUs, the risk of HIV infection increases with the duration of injection drug use; the frequency of needle sharing; the number of partners with whom paraphernalia are shared, particularly in the setting of “shooting galleries” where drugs are sold and large numbers of IDUs may share a limited number of “works”; comorbid psychiatric conditions such as

antisocial personality disorder; the use of cocaine in injectable form or smoked as “crack”; and the use of injection drugs in a geographic location with a high prevalence of HIV infection, such as certain inner-city areas in the United States.

The first transfusion-associated cases of AIDS were reported in 1982, and by the end of 2005, >9300 individuals in the United States who survived the illness for which they received HIV-contaminated blood transfusions, blood components, or transplanted tissue had developed AIDS. Virtually all these cases were due to HIV infection before the spring of 1985, when mandatory testing of donated blood for HIV-1 was initiated. It is estimated that 90–100% of individuals who were exposed to HIV-contaminated products became infected. Transfusions of whole blood, packed red blood cells, platelets, leukocytes, and plasma are all capable of transmitting HIV infection. In contrast, hyperimmune γ globulin, hepatitis B immune globulin, plasma-derived hepatitis B vaccine, and Rh₀ immune globulin have not been associated with transmission of HIV infection. The procedures involved in processing these products either inactivate or remove the virus.

In addition to the above, an estimated 8000–10,000 individuals in the United States with hemophilia or other clotting disorders were infected with HIV by receipt of HIV-contaminated fresh-frozen plasma or concentrates of clotting factors; by the end of 2005, >5400 of these individuals had developed AIDS. Currently, in the United States and in most developed countries, the following measures have made the risk of transmission of HIV infection by transfused blood or blood products extremely small: (1) the screening of all blood for HIV nucleic acid, p24 antigen, and/or anti-HIV antibodies; (2) the self-deferral of donors on the basis of risk behavior; (3) the screening out of HIV-negative individuals with positive surrogate laboratory parameters of HIV infection, such as hepatitis B and C; and (4) serologic testing for syphilis. The chance of infection of a hemophiliac via clotting factor concentrates has essentially been eliminated because of the added layer of safety resulting from heat treatment of the concentrates.

It is currently estimated that the risk of infection with HIV in the United States via transfused screened blood is approximately 1 in 1.5 million donations. Therefore, among the ~15 million donations collected in the United States each year, about 10 infectious donations are available for transfusion. Thus, despite the best efforts of science, one cannot completely eliminate the risk of transfusion-related transmission of HIV since current technology cannot detect HIV RNA for the first 1–2 weeks after infection due to the low levels of viremia. There have been several reports of sporadic breakdowns in routinely available screening procedures in certain countries, where contaminated blood was allowed to be transfused, resulting in small clusters of patients becoming infected. In China, a disturbingly large number of persons have become infected by selling blood in situations where the collectors reused needles that were contaminated and, in some instances, mixed blood products from a number of individuals, separated the plasma, and reinfused red blood cells back into individual donors.

There have been no reported cases of transmission of HIV-2 in the United States via donated blood or tissues, and, currently, donated blood is screened for both HIV-1 and HIV-2 antibodies. Transmission of HIV (both HIV-1 and HIV-2) by blood or blood products is still an ongoing threat in certain developing countries, particularly in Sub-Saharan Africa, where routine screening of blood is not universally practiced.

Before the screening of donors, a small number of cases of transmission of HIV via semen used in artificial insemination and tissues used in organ transplantation were documented. At present, donors of such tissues are prescreened for HIV infection. However, laboratory errors can occur, and in 2007 an incorrect screening report led to the transplantation in Italy of two kidneys and a liver to three recipients from a deceased donor who was later discovered to have been HIV positive. With regard to HIV sero-discordant couples (male, HIV infected; female, HIV-uninfected) who wish to conceive a child, assisted reproductive techniques using sperm-washing to reduce the risk of HIV transmission have been successfully employed, with only one well-documented seroconversion in the uninfected female partner, reported in 1990.

OCCUPATIONAL TRANSMISSION OF HIV: HEALTH CARE WORKERS, LABORATORY WORKERS, AND THE HEALTH CARE SETTING

There is a small, but definite, occupational risk of HIV transmission to health care workers and laboratory personnel and potentially others who work with HIV-containing materials, particularly when sharp objects are used. An estimated 600,000–800,000 health care workers are stuck with needles or other sharp medical instruments in the United States each year.

Exposures that place a health care worker at potential risk of HIV infection are percutaneous injuries (e.g., a needle stick or cut with a sharp object) or contact of

mucous membrane or nonintact skin (e.g., exposed skin that is chapped, abraded, or afflicted with dermatitis) with blood, tissue, or other potentially infectious body fluids. Large, multi-institutional studies have indicated that the risk of HIV transmission after skin puncture from a needle or a sharp object that was contaminated with blood from a person with documented HIV infection is ~0.3% and after a mucous membrane exposure it is 0.09% (see “HIV and the Health Care Worker” later in the chapter). HIV transmission after non-intact skin exposure has been documented, but the average risk for transmission by this route has not been precisely determined; however, it is estimated to be less than the risk for mucous membrane exposure. Transmission of HIV through intact skin has not been documented.

In addition to blood and visibly bloody body fluids, semen and vaginal secretions are also considered potentially infectious but have not been implicated in occupational transmission from patients to health care workers. The following fluids are also considered potentially infectious: cerebrospinal fluid, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid, and amniotic fluid. The risk for transmission after exposure to fluids or tissues other than HIV-infected blood also has not been quantified but is probably considerably lower than for blood exposures. Feces, nasal secretions, saliva, sputum, sweat, tears, urine, and vomitus are not considered potentially infectious unless they are visibly bloody. Rare cases of HIV transmission via human bites have been reported, but not after an occupational exposure.

An increased risk for HIV infection after percutaneous exposures to HIV-infected blood is associated with exposures involving a relatively large quantity of blood, as in the case of a device visibly contaminated with the patient's blood, a procedure that involves a needle placed directly in a vein or artery, or a deep injury. Factors that might be associated with mucocutaneous transmission of HIV include exposure to an unusually large volume of blood, prolonged contact, and a potential portal of entry. In addition, the risk increases for exposures to blood from patients with advanced-stage disease, owing to the higher titer of HIV in the blood as well as to other factors, such as the presence of more virulent strains of virus. The use of antiretroviral drugs as postexposure prophylaxis decreases the risk of infection compared with historic controls in occupationally exposed health care workers (see “HIV and the Health Care Worker” later in the chapter). The risk of hepatitis B virus (HBV) infection after a similar type of exposure is ~6–30% in nonimmune individuals; if a susceptible worker is exposed to HBV, postexposure prophylaxis with hepatitis B immune globulin and initiation of HBV vaccine is >90% effective in preventing HBV infection. The risk of hepatitis C virus (HCV) infection after percutaneous injury is ~1.8% (Chap. 92).

Since the beginning of the HIV epidemic, there have been at least three reported instances in which transmission of infection from a health care worker to patients seemed highly probable. One cluster of infections involved an HIV-infected dentist in Florida who apparently infected as many as six of his patients, most likely

through contaminated instruments. Another case involved an HIV-infected orthopedic surgeon in France who apparently infected a patient during placement of a total hip prosthesis. A third case involved the apparent transmission of HIV from an HIV-infected nurse to a surgical patient in France. Breaches in infection control and the reuse of contaminated syringes have also resulted in the transmission of HIV from patient to patient in hospitals, nursing homes, and outpatient settings. For example, in the only report of HIV transmission from patient to patient during a surgical procedure, four patients in Australia were apparently infected by an HIV-negative general surgeon during routine outpatient surgery. Although the mechanism of transmission was not definitively identified, a failure on the part of the surgeon to sterilize instruments properly after prior surgery on an HIV-infected patient was considered a likely explanation for this outbreak. Three patients (two in hospitals in the United States and one in the Netherlands) undergoing nuclear medicine procedures were reported to have inadvertently received IV injections of blood or other material from patients infected with HIV. Hemodialysis centers have also been implicated in several reported HIV transmission incidents.

The most dramatic reports involved transmission of HIV to 8000–10,000 children in Romanian orphanages in the 1980s. Other large incidents occurred in hospitals in Russia and Libya in the late 1980s and late 1990s, respectively. Each of these incidents received considerable attention and likely was related to reuse of contaminated needles and/or administration of contaminated blood products. Despite the small number of documented cases, the risk of HIV transmission involving health care workers (infected or not) to patients is extremely low in developed countries; in fact, too low to be measured accurately. In this regard, several epidemiologic studies have been performed tracing thousands of patients of HIV-infected dentists, physicians, surgeons, obstetricians, and gynecologists, and no other cases of HIV infection that could be linked to the health care providers were identified. The very rare occurrence of transmission of HIV as well as HBV and HCV to and from health care workers in the workplace underscores the importance of the use of universal precautions when caring for all patients (see below and Chap. 13).

MATERNAL-FETAL/INFANT TRANSMISSION

HIV infection can be transmitted from an infected mother to her fetus during pregnancy, during delivery, or by breast-feeding. This is an extremely important form of transmission of HIV infection in certain developing countries, where the proportion of infected women to infected men is ~1:1. Virologic analysis of aborted fetuses indicate that HIV can be transmitted to the fetus as early as the first and second trimester of pregnancy. However, maternal transmission to the fetus occurs most commonly in the perinatal period. Two studies performed in Rwanda and the former Zaire indicated that the relative proportions of mother-to-child transmissions were 23–30% before birth, 50–65% during birth, and 12–20% via breast-feeding.

In the absence of prophylactic antiretroviral therapy to the mother during pregnancy, labor, and delivery, and to the fetus after birth (see below), the probability of transmission of HIV from mother to infant/fetus ranges from 15–25% in industrialized countries and from 25–35% in developing countries. These differences may relate to the adequacy of prenatal care as well as to the stage of HIV disease and the general health of the mother during pregnancy. Higher rates of transmission have been reported to be associated with many factors, the best documented of which is the presence of high maternal levels of plasma viremia. In one study of 552 singleton pregnancies in the United States, the rate of mother-to-baby transmission was 0% among women with <1000 copies of HIV RNA per milliliter of blood, 16.6% among women with 1000–10,000 copies/mL, 21.3% among women with 10,001–50,000 copies/mL, 30.9% among women with 50,001–100,000 copies/mL, and 40.6% among women with >100,000 copies/mL. However, there may not be a lower “threshold” below which transmission never occurs, since other studies have reported transmission by women with viral RNA levels <50 copies/mL. Low maternal CD4+ T-cell counts have also been associated with higher rates of transmission; however, since low CD4+ T-cell counts are often associated with high levels of plasma viremia, in one study using multivariate analysis including plasma viral load and CD4+ T-cell count, only the level of plasma HIV RNA was significant. Increased mother-to-child transmission is also correlated with closer HLA match between mother and child. A prolonged interval between membrane rupture and delivery is another well-documented risk factor for transmission. Other conditions that are potential risk factors, but which have not been consistently demonstrated, are the presence of chorioamnionitis at delivery; STDs during pregnancy; hard drug use during pregnancy; cigarette smoking; preterm delivery; and obstetrical procedures such as amniocentesis, amniocentesis, fetal scalp electrodes, and episiotomy. In a study conducted in the United States and France, zidovudine treatment of HIV-infected pregnant women from the beginning of the second trimester through delivery and of the infant for 6 weeks after birth dramatically decreased the rate of intrapartum and perinatal transmission of HIV infection from 22.6% in the untreated group to <5%. The rate of mother-to-child transmission is approaching 1% or less in pregnant women who are receiving combination antiretroviral therapy for their HIV infection. Such treatment, combined with cesarean section delivery, has rendered mother-to-child transmission of HIV an unusual event in the United States and other developed nations. In developed countries, current recommendations to reduce perinatal transmission of HIV include universal voluntary HIV testing and counseling of pregnant women, antiretroviral prophylaxis with one or more drugs in cases in which the mother does not require therapy for her HIV infection, combination therapy for women who do require therapy, obstetric management that attempts to minimize exposure of the infant to maternal blood and genital secretions, and avoidance of

**FIGURE 90-10**

Estimated numbers of AIDS cases in children <13 years of age, by year of diagnosis, 1992–2005, 50 states and the District of Columbia. (From CDC.)

breast-feeding. It is recommended that the choice of antiretroviral therapy for pregnant women should be based on the same considerations used for women who are not pregnant, with discussion of the recognized and unknown risks and benefits of such therapy during pregnancy (see later in the chapter under “Treatment”). This approach has led to a remarkable decrease in the number of infants infected with HIV through mother-to-child transmission in the United States, from an estimated peak of 1750 HIV-infected infants born each year during the early to mid-1990s to 280–370 infants in 2000, and a dramatic decrease in reported AIDS cases among children (Fig. 90-10). Certain studies have demonstrated that truncated regimens of zidovudine alone or in combination with lamivudine given to the mother during the last few weeks of pregnancy or even only during labor and delivery, and to the infant for a week or less, significantly reduced transmission to the infant compared with placebo. Short-course prophylactic antiretroviral (ARV) regimens, such as a single dose of nevirapine given to the mother at the onset of labor and a single dose to the infant within 72 h of birth, are of particular relevance to low- to mid-income nations because of the low cost and the fact that in these regions perinatal care is often not available and pregnant women are often seen by a health care provider for the first time at or near the time of delivery. Indeed, short-course ARV regimens have now been used for several years in developing nations for the prevention of mother-to-child transmission. It is estimated that the successful implementation of such regimens has saved as many as 1000 babies per day from becoming infected with HIV, the vast majority of whom are in Sub-Saharan Africa. Given that combination ARV therapy is now increasingly available to individuals in developing countries due to the lower cost of drugs and programs that are making drugs available to these regions of the world, combinations of drugs are being used more frequently, where available, to treat HIV-infected pregnant women who require therapy notwithstanding their pregnancy. This has had the effect of benefitting the women, blocking HIV transmission to the fetus, and protecting against subsequent transmission by breast-feeding (see below).

Breast-feeding is an important modality of transmission of HIV infection in developing countries, particularly where mothers continue to breast-feed for prolonged periods. The risk factors for mother-to-child transmission of HIV via breast-feeding are not fully understood; factors that increase the likelihood of transmission include detectable levels of HIV in breast milk, the presence of mastitis, low maternal CD4+ T-cell counts, and maternal vitamin A deficiency. The risk of HIV infection via breast-feeding is highest in the early months of breast-feeding. In addition, exclusive breast-feeding has been reported to carry a lower risk of HIV transmission than mixed feeding. Certainly in developed countries, breast-feeding by an infected mother should be avoided. However, there is disagreement regarding recommendations for breast-feeding in certain developing countries, where breast milk is the only source of adequate nutrition as well as immunity against potentially serious infections for the infant. The optimal approach to prevent transmission by infected mothers who choose to breast-feed would be to provide continual treatment to the infected mother. This approach has become more feasible as ARV therapy becomes more widely available in developing countries. Despite progress in this regard, ARV therapy is currently available to only ~25% of persons in developing nations who require it. Therefore, alternative approaches to block transmission by breast-feeding are being tested. In this regard, studies are being conducted to determine whether intermittent administration of nevirapine, which has a relatively long half-life, to uninfected babies born of infected mothers decreases the incidence of infection via breast-feeding.

TRANSMISSION BY OTHER BODY FLUIDS

Although HIV can be isolated typically in low titers from saliva of a small proportion of infected individuals, there is no convincing evidence that saliva can transmit HIV infection, either through kissing or through other exposures, such as occupationally to health care workers. Saliva contains endogenous antiviral factors; among these factors, HIV-specific immunoglobulins of IgA, IgG, and IgM isotypes are detected readily in salivary secretions of infected individuals. It has been suggested that large

glycoproteins such as mucins and thrombospondin-1 sequester HIV into aggregates for clearance by the host. In addition, a number of soluble salivary factors inhibit HIV to various degrees in vitro, probably by targeting host cell receptors rather than the virus itself. Perhaps the best-studied of these, secretory leukocyte protease inhibitor (SLPI), blocks HIV infection in several cell culture systems, and it is found in saliva at levels that approximate those required for inhibition of HIV in vitro. In this regard, higher salivary levels of SLPI in breast-fed infants were associated with a decreased risk of HIV transmission through breast milk. It has also been suggested that submandibular saliva reduces HIV infectivity by stripping gp120 from the surface of virions, and that saliva-mediated disruption and lysis of HIV-infected cells occurs because of the hypotonicity of oral secretions. There have been outlier cases of suspected transmission by saliva, but these have probably been blood-to-blood transmissions. Transmission of HIV by a human bite can occur but is a rare event; at least four cases of such transmission have been reported. In addition, a most unusual form of HIV transmission from infected children to mothers in the former Soviet Union has been identified. In those cases, the children (infected through transfusion) were said to have bleeding sores in the mouth, and the mothers were said to have lacerations and abrasions on and around the nipples of the breast resulting from trauma from the children's teeth. Breast-feeding had been continued until the children were older than is usual in other developed countries.

Although virus can be identified, if not isolated, from virtually any body fluid, there is no evidence that HIV transmission can occur as a result of exposure to tears,

sweat, and urine. However, there have been isolated cases of transmission of HIV infection by body fluids that may or may not have been contaminated with blood. Most of these situations occurred in the setting of a close relative providing intensive nursing care for an HIV-infected person without observing universal precautions, underscoring the importance of observing such precautions in the handling of body fluids and wastes from HIV-infected individuals (see below).

EPIDEMIOLOGY

HIV INFECTION AND AIDS WORLDWIDE

HIV infection/AIDS is a global pandemic, with cases reported from virtually every country. At the end of 2007, 33.2 million individuals were living with HIV infection (range: 30.6–36.1 million) according to the Joint United Nations Programme on HIV/AIDS (UNAIDS). More than 95% of people living with HIV/AIDS reside in low- and middle-income countries; ~50% are female, and 2.5 million are children <15 years. The global distribution of these cases is illustrated in [Fig. 90-11](#).

In 2007, there were an estimated 2.5 million new cases of HIV infection worldwide, including 420,000 in children <15 years. In 2007, global AIDS deaths totaled 2.1 million (including 330,000 children <15 years). UNAIDS estimates that global HIV prevalence has been level since 2001. HIV incidence likely peaked in the late 1990s at >3 million new infections per year ([Fig. 90-12](#)). Recent reductions in global HIV incidence likely reflect natural trends in the pandemic as well as the results of prevention programs resulting in behavior change.

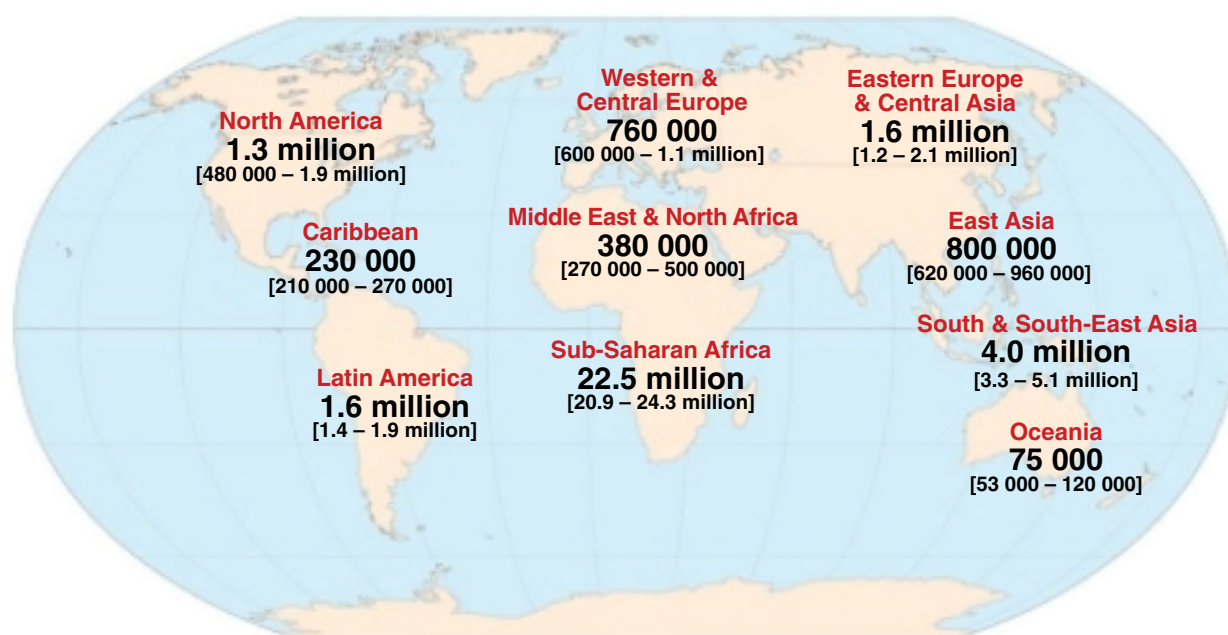

FIGURE 90-11

ESTIMATED NUMBER OF PEOPLE NEWLY INFECTED WITH HIV GLOBALLY, 1990–2007

FIGURE 90-12

Estimated number of people newly infected with HIV globally, 1990–2007. [From United Nations AIDS Program (UNAIDS).]

The HIV epidemic has occurred in “waves” in different regions of the world, each wave having somewhat different characteristics depending on the demographics of the country and region in question and the timing of the introduction of HIV into the population. Although the AIDS epidemic was first recognized in the United States and shortly thereafter in Western Europe, it very likely began in Sub-Saharan Africa (see above), which has been particularly devastated by the epidemic. More than two-thirds of all people with HIV infection (~22.5 million) live in that region, even though Sub-Saharan Africa is home to just 10–11% of the world’s population (Fig. 90-11). Within the region, southern Africa is worst-affected. In eight southern African countries, available seroprevalence data indicate that >15% of the adult population aged 15–49 is HIV-infected. In addition, among high-risk individuals (e.g., commercial sex workers, patients attending STD clinics) who live in urban areas of Sub-Saharan Africa, seroprevalence is now >50% in some countries. According

to projections of the United Nations Population Division, life expectancies in several highly affected countries could drop to <40 years, well below what they would have been without HIV/AIDS and below levels reached in the pre-AIDS era (Fig. 90-13).

In Asia, an estimated 4.9 million people were living with HIV at the end of 2007. National HIV prevalence is highest in southeast Asia, with wide variation in trends between different countries. The epidemic in Asia lagged temporally behind that in Africa; however, the populations of many Asian nations are so large (especially India and China) that even low national HIV prevalence rates result in large numbers of people living with HIV. Encouragingly, HIV prevalence has declined in Myanmar, Cambodia, and Thailand; however, HIV prevalence continues to increase in other countries such as Indonesia and Vietnam.

The epidemic is expanding in Eastern Europe and Central Asia, where ~1.6 million people were living with

FIGURE 90-13

The impact of HIV/AIDS on life expectancy in five Sub-Saharan African countries, 1970–2010. [From United Nations AIDS Program (UNAIDS).]

HIV at the end of 2007. Ninety percent of new HIV infections reported in 2007 occurred in two countries, the Russian Federation and Ukraine. Driven initially by injection drug use and increasingly by heterosexual transmission, the number of new infections in this region has increased dramatically over the past decade.

Approximately 1.8 million people are living with HIV/AIDS in Latin America and the Caribbean. Brazil is home to the largest number of HIV-infected people in the region. However, the epidemic has been slowed in that country due to successful treatment and prevention efforts. The Caribbean region has the highest regional adult seroprevalence rate after Africa, due in large part to the huge case load in Haiti. Approximately 2.1 million people are living with HIV/AIDS in North America and in Western and Central Europe.

The major mode of HIV transmission worldwide is unquestionably heterosexual sex; this is particularly true, and has been so since the beginning of the epidemic, in developing countries, where the numbers of infected men and women are approximately equal. The epidemic in most developed countries was first introduced among men who have sex with men and, to a greater or lesser degree (depending on the individual country), among IDUs. In this regard, the total numbers of AIDS cases in those countries still reflect a high proportion of cases among these high-risk groups. However, in most developed countries, including the United States (see above and below), there has been a gradual shift toward heterosexual transmission (Fig. 90-8).

AIDS IN THE UNITED STATES

AIDS has had—and will continue to have—an extraordinary public health impact in the United States. As of January 1, 2006, an estimated 984,155 cases of AIDS had been diagnosed in the United States and dependent areas, and ~550,394 AIDS-related deaths had occurred. AIDS cases have been reported in all 50 states, the District of Columbia; and in U.S. dependencies, possessions, and associated nations. An estimated 1.1 million individuals in the United States are living with HIV infection, one-quarter of whom are unaware of their infection. The estimated HIV seroprevalence rate among adults aged 15–49 years in the United States is ~0.6%. Prevalence is highest among young adults in their late twenties and thirties and among minorities.

The number of AIDS cases and deaths rose steadily through the 1980s; AIDS cases peaked in 1993 and deaths in 1995 (Fig. 90-14). Since then, the annual numbers of AIDS-related deaths in the United States have fallen ~70%. This trend is due to several factors, including the improved prophylaxis and treatment of opportunistic infections, the growing experience among the health professions in caring for HIV-infected individuals, improved access to health care, and a decrease in new infections due to saturational effects and prevention efforts. However, the most influential factor clearly has been the increased use of potent ARV drugs, generally administered in a combination of three or four agents (see below).

FIGURE 90-14

Estimated number of AIDS cases and AIDS deaths, United States, 1985–2005. (From CDC.)

Approximately 56,000 individuals are newly infected each year in the United States, a figure that has remained stable for at least 10 years. Among adults and adolescents newly diagnosed with HIV infection (regardless of AIDS status) in the United States in 2005, ~74% are men and ~26% are women (Fig. 90-15). Of new HIV/AIDS diagnoses among men, ~67% were due to male-to-male sexual contact, ~15% to heterosexual contact, ~13% to injection drug use, and ~5% to a combination of male-to-male sexual contact and injection drug use. Of new HIV/AIDS diagnoses among women, ~80% were due to heterosexual contact and ~20% to injection drug use.

HIV transmission patterns in the United States have shifted over time. When one looks at the totality of data collected from the beginning of the epidemic, ~46% of all AIDS cases are among men who have had sex with men. However, since the mid-1980s the proportion of newly reported cases of AIDS in this population has declined from ~64% of cases diagnosed in 1985 to ~42% of cases diagnosed in 2005 (Fig. 90-8). Meanwhile, the proportion of new AIDS cases attributed to heterosexual contact has increased dramatically, from 3% in 1985 to 31% in 2005. The share of AIDS diagnoses due to injection drug use was 19% in 1985, peaked at 31% in 1993, and was 21% in 2005. Women are increasingly affected: the proportion of AIDS cases among female adults and adolescents (age >13 years) increased from 7% in 1985 to 27% in 2005.

HIV infection and AIDS have disproportionately affected minority populations in the United States. Among those diagnosed with HIV (regardless of AIDS status) in 2005, 49% percent were African Americans, a group that comprises only 13% of the U.S. population (Fig. 90-16). An estimated 3% of black men and 1% of black women in their thirties are living with HIV infection. HIV/AIDS ranked ninth among all causes of mortality in the United States in 2004 among those aged 35–64 years, but among African Americans it ranked third.

As of January 1, 2006, an estimated 9112 cases of AIDS in children <13 years old had been diagnosed, and ~54% of these children have died. Approximately 93% of

**FIGURE 90-15**

Transmission categories of adults and adolescents with HIV/AIDS diagnosed during 2005 in the United States. Estimates based on data from 33 states with long-term, confidential, name-based HIV infection reporting. Data include persons with a diagnosis of HIV infection regardless of AIDS status at diagnosis. (From CDC.)

these children were born to mothers who were HIV-infected or who were at risk for HIV infection and, in the majority of those cases, the mother was either an IDU or the heterosexual partner of an IDU. The estimated number of AIDS cases diagnosed among children perinatally exposed to HIV peaked in 1992 and has decreased in recent years (Fig. 90-10). The decline of these cases is likely associated with the implementation of guidelines for the universal counseling and voluntary HIV testing of pregnant women and the use of ARV therapy for pregnant women and newborn infants in order to prevent infection. Another contributing factor

is the effective treatment of HIV infection in children who have become infected.

Although the HIV/AIDS epidemic on the whole is plateauing in the United States, it is spreading rapidly among certain populations, stabilizing in others, and decreasing in others. Similar to other STDs, HIV infection will not spread homogeneously throughout the population of the United States. However, it is clear that anyone who practices high-risk behavior is at risk for HIV infection. In addition, recent increases in infections and AIDS cases among young men who have sex with men and among heterosexuals (particularly sexual partners of IDUs, women, and adolescents) as well as the spread in pockets of poverty in both urban and rural regions (particularly among underserved minority populations in the southern United States with inadequate access to health care) testify to the fact that the epidemic of HIV infection in the United States remains a public health problem of major proportions.

PATHOPHYSIOLOGY AND PATHOGENESIS

The hallmark of HIV disease is a profound immunodeficiency resulting primarily from a progressive quantitative and qualitative deficiency of the subset of T lymphocytes referred to as *helper T cells*. This subset of T cells is defined phenotypically by the presence on its surface of the CD4 molecule, which serves as the primary cellular receptor for HIV. A co-receptor must also be present together with CD4 for efficient fusion and entry of HIV-1 into its target cells (Figs. 90-3 and 90-4). HIV uses two major co-receptors for fusion and entry; these co-receptors are also the primary receptors for certain chemoattractive cytokines termed *chemokines* and belong to the seven-transmembrane-domain G protein-coupled family of receptors. CCR5 and CXCR4 are the major

co-receptors used by HIV (see above and below). A number of mechanisms responsible for cellular depletion and/or immune dysfunction of CD4+ T cells have been demonstrated in vitro; these include direct infection and destruction of these cells by HIV and immune clearance of infected cells, as well as indirect effects such as immune exhaustion due to aberrant cellular activation and activation-induced cell death (see below). Patients with CD4+ T-cell levels below certain thresholds (see below) are at high risk of developing a variety of opportunistic diseases, particularly the infections and neoplasms that are AIDS-defining illnesses. Some features of AIDS, such as Kaposi's sarcoma and neurologic abnormalities (see below), cannot be explained completely by the immunodeficiency caused by HIV infection, since these complications may occur before the development of severe immunologic impairment.

The combination of viral pathogenic and immunopathogenic events that occurs during the course of HIV disease from the moment of initial (primary) infection through the development of advanced-stage disease is complex and varied. It is important to appreciate that the pathogenic mechanisms of HIV disease are multifactorial and multiphasic and are different at different stages of the disease. Therefore, it is essential to consider the typical clinical course of an untreated HIV-infected individual in order to more fully appreciate these pathogenic events (Fig. 90-17).

PRIMARY HIV INFECTION, INITIAL VIREMIA, AND DISSEMINATION OF VIRUS

The events associated with primary HIV infection are likely critical determinants of the subsequent course of

HIV disease. In particular, the early dissemination of virus to lymphoid organs, particularly the gut-associated lymphoid tissue (GALT), is a major factor in the establishment of a chronic and persistent infection (see below). The initial infection of susceptible cells may vary somewhat with the route of infection. Virus that enters directly into the bloodstream via infected blood or blood products (i.e., transfusions, use of contaminated needles for injecting drugs, sharp-object injuries, maternal-to-fetal transmission either intrapartum or perinatally, or sexual intercourse where there is enough trauma to cause bleeding) is likely cleared from the circulation to the spleen and other lymphoid organs, where primary focal infections begin, followed by wider dissemination throughout other lymphoid tissues, particularly the GALT, leading to a burst of viremia. Dendritic cells play an important role in the initiation of HIV infection. These cells express a diversity of C-type lectin receptors on their surface, one of which is called *DC-SIGN* (see above). *DC-SIGN* binds with high affinity to the HIV envelope gp120 and can retain infectious particles for days in vitro. In this regard, dendritic cells can trap HIV and mediate the efficient transinfection of CD4+ T cells. In addition, *DC-SIGN* may also facilitate CD4-mediated infection of dendritic cells. These mechanisms likely operate in humans when HIV enters "locally" (as opposed to directly into the blood) and encounters mucosal dendritic cells via the vagina, rectum, or urethra during intercourse or via the upper gastrointestinal tract from swallowed infected breast milk or rarely semen or vaginal fluid. In primary HIV infection, virus replication in CD4+ T cells intensifies before the initiation of an HIV-specific immune response (see below, Fig. 90-17), with a

FIGURE 90-17

Typical course of an untreated HIV-infected individual. See text for detailed description. [From G Pantaleo et al: *N*

Engl J Med 328(5):327, 1993. Copyright 1993 Massachusetts Medical Society. All rights reserved.]

burst of viremia resulting from the rapid replication of virus in susceptible cells in lymphoid organs (particularly the GALT), with subsequent dissemination of virus to the brain and other tissues. Of note, animal studies have demonstrated that a significant percentage of CD4⁺ T cells (particularly memory cells) in the GALT is depleted early after SIV infection, via either direct infection of cells or bystander cell killing. The repopulation of such cells may be extremely problematic, even after initiation of ARV therapy. Individuals who experience the “acute HIV syndrome,” which occurs to varying degrees in ~50% of individuals with primary infection, have high levels of viremia measured in millions of copies of HIV RNA per milliliter that last for several weeks (see below). Acute mononucleosis-like symptoms are well correlated with the presence of viremia. Virtually all patients develop some degree of viremia during primary infection, which contributes to virus dissemination throughout the lymphoid tissue (see above), even though they may remain asymptomatic or not recall experiencing symptoms. It appears that the initial level of plasma viremia in primary HIV infection does not necessarily determine the rate of disease progression; however, the set point of the level of steady-state plasma viremia after ~1 year does seem to correlate with the slope of disease progression (see below).

ESTABLISHMENT OF CHRONIC AND PERSISTENT INFECTION

Persistent Virus Replication

HIV infection is unique among human viral infections. Despite the robust cellular and humoral immune responses that are mounted after primary infection (see below), once infection has been established, the virus succeeds in escaping immune-mediated clearance (see below), paradoxically seems to thrive on immune activation, and is never eliminated completely from the body. Rather, a chronic infection develops that persists with varying degrees of continual virus replication in the untreated patient for a median of ~10 years before the patient becomes clinically ill (see below). It is this establishment of a chronic, persistent infection that is the hallmark of HIV disease. Throughout the often protracted course of chronic infection, virus replication can invariably be detected in untreated patients, both by highly sensitive assays for plasma viremia as well as by demonstration of cell-associated HIV RNA in immunocompetent cells (predominantly CD4⁺ T cells and macrophages) in the circulation and in lymphoid tissue. Recent studies using highly sensitive molecular techniques have demonstrated that even in patients in whom plasma viremia is suppressed to below 50 copies of HIV RNA/mL by ARV therapy, there is a continual low level of virus replication (see below). In other human viral infections, with very few exceptions, if the host survives, the virus is completely cleared from the body and a state of immunity against subsequent infection develops. HIV infection very rarely kills the host during primary infection. Certain viruses, such as HSV (Chap. 80), are not completely cleared from the body after infection but instead enter a

latent state; in these cases, clinical latency is accompanied by microbiologic latency. This is not the case with HIV infection as described above. Chronicity associated with persistent virus replication can also be seen in certain cases of HBV and HCV infections (Chap. 93); however, in these infections, the immune system is not a target of the virus.

Evasion of Immune System Control

Inherent to the establishment of chronicity of HIV infection is the ability of the virus to evade elimination and control by the immune system. There are a number of mechanisms whereby the virus accomplishes this evasion. Paramount among these is the establishment of a sustained level of replication associated with the generation of viral diversity via mutation and recombination, thus providing a means to evade control and elimination by the immune system. The selection of mutants that escape control by CD8⁺ cytolytic T lymphocytes (CTLs) is critical to the propagation and progression of HIV infection. The high rate of virus replication and the continual mutation of virus also contribute to the inability of neutralizing antibody to contain the virus quasispecies present in an individual at any given time. Molecular analysis of clonotypes has demonstrated that clones of CD8⁺ CTLs that expand greatly during primary HIV infection, and likely represent the high-affinity clones that would be expected to be most efficient in eliminating virus-infected cells, are no longer detectable after their initial burst of expansion. It is thought that the initially expanded clones may have been deleted or rendered dysfunctional owing to the overwhelming immune activation resulting from exposure to viral antigens during the initial burst of viremia, similar to the exhaustion of CD8⁺ CTLs that has been reported in the murine model of lymphocytic choriomeningitis virus (LCMV) infection. Recent studies have indicated that exhaustion of effector cells during prolonged immune activation is associated with expression of the programmed death (PD)-1 molecule (of the B7-CD28 family of molecules) on activated cells and its interaction with its ligands (L) PD-L1 and PD-L2 on antigen-presenting cells. This interaction results in a partially reversible signal for cell death and/or dysfunction. Another mechanism contributing to the evasion by HIV of immune system control is the downregulation of HLA class I molecules on the surface of HIV-infected cells by the Nef protein of HIV, resulting in the lack of ability of the CD8⁺ CTL to recognize and kill the infected target cell. Although this downregulation of HLA class I molecules would favor elimination of HIV-infected cells by natural killer (NK) cells, this latter mechanism does not seem to remove HIV-infected cells effectively (see below). The principal targets of neutralizing antibodies against HIV are the envelope proteins gp120 and gp41. HIV employs three mechanisms to evade neutralizing responses: hypervariability in the primary sequence of the envelope, extensive glycosylation of the envelope, and conformational masking of neutralizing epitopes.

CD4⁺ T-cell help is essential for the integrity of antigen-specific immune responses, both humoral and cell-mediated. HIV preferentially infects activated CD4⁺ T cells including HIV-specific CD4⁺ T cells, and so this loss of viral-specific helper T-cell responses has profound negative consequences for the immunologic control of HIV replication. Furthermore, this loss occurs early in the course of infection, and animal studies indicate that 40–70% of all memory CD4⁺ T cells in the GALT are eliminated during acute infection. Another means of escape of HIV-infected cells from elimination by CD8⁺ CTLs is the sequestration of infected cells in immunologically privileged sites such as the central nervous system (CNS).

Finally, the escape of HIV from elimination during primary infection allows the formation of a pool of latently infected cells that cannot be eliminated by virus-specific CTLs (see below). Thus, despite a potent immune response and the marked downregulation of virus replication after primary HIV infection, HIV succeeds in establishing a state of chronic infection with a variable degree of persistent virus replication. In most cases, during this period, patients make the clinical transition from acute primary infection to variable periods of clinical latency or smoldering disease activity (see below).

Reservoirs of HIV-Infected Cells: Obstacle to the Eradication of Virus

There exists in virtually all HIV-infected individuals a pool of latently infected, resting CD4⁺ T cells that serves as at least one component of the persistent reservoir of virus. Such cells manifest postintegration latency in that the HIV provirus integrates into the genome of the cell and can remain in this state until an activation signal drives the expression of HIV transcripts and ultimately replication-competent virus. This form of latency is to be distinguished from preintegration latency, in which HIV enters a resting CD4⁺ T cell and, in the absence of an activation signal, only a limited degree of reverse transcription of the HIV genome occurs. This period of preintegration latency may last hours to days, and if no activation signal is delivered to the cell, the proviral DNA loses its capacity to initiate a productive infection. If these cells do become activated, reverse transcription proceeds to completion and the virus continues along its replication cycle (see above and Fig. 90-18). The pool of cells that are in the postintegration state of latency is established early during the course of primary HIV infection. Despite the suppression of plasma viremia to <50 copies of HIV RNA per milliliter by potent combinations of several ARV drugs administered over several years, this pool of latently infected cells persists and can give rise to replication-competent virus. Modeling studies built on projections of decay curves (see below) have estimated that in such a setting of prolonged suppression, it would require from 7–70 years for the pool of latently infected cells to be completely eliminated. Furthermore, the reservoir of latently infected cells is replenished during minor detectable rebounds of virus replication that may occur intermittently, during the low levels of persistent virus

FIGURE 90-18

replication that goes undetectable (see below) (Fig. 90-18), even in patients who for the most part are treated successfully, and certainly during major rebounds of viremia in patients whose therapy is interrupted for a period of weeks or longer. Over the past several years, attempts have been made to eliminate HIV in the latent viral reservoir using agents that stimulate resting CD4⁺ T cells during the course of antiretroviral therapy; however, such attempts have been unsuccessful. As more sophisticated techniques become available for measuring extremely low levels of virus replication, it is becoming clear that virus replication continually occurs at very low levels in a substantial proportion of individuals whose viral load is “undetectable” by the standard assays of plasma viremia (see above and below). Thus, although a small pool of truly resting, latently infected cells exists at any given point in time, this pool is continually being activated and replenished by ongoing low levels of virus replication. Reservoirs of HIV infected cells, latent or otherwise, can exist in a number of compartments including the lymphoid tissue, peripheral blood, and the CNS (likely in cells of the monocyte/macrophage lineage), as well as in other unidentified locations. Thus this persistent reservoir of infected cells at various stages of latency and/or low

**FIGURE 90-19**

Dynamics of HIV infection in vivo. See text for detailed description. (From AS Perelson et al: *Science* 271:1582, 1996.)

levels of persistent virus replication are major obstacles to any goal of eradication of virus from infected individuals, despite the favorable clinical outcomes that have resulted from ARV therapy (see below).

Viral Dynamics

The dynamics of viral production and turnover have been quantified using mathematical modeling in the setting of the administration of reverse transcriptase and protease inhibitors to HIV-infected individuals in clinical studies. Treatment with these drugs resulted in a precipitous decline in the level of plasma viremia, which typically fell by well over 90% within 2 weeks. The number of CD4+ T cells in the blood increased concurrently, which suggested that the killing of CD4+ T cells was linked directly to the levels of replicating virus. However, a significant component of the early rise in CD4+ T cell numbers after the initiation of therapy may be due to the redistribution of cells into the peripheral blood from other body compartments as a consequence of therapy-related diminution in viremia-associated immune system activation. It was determined on the basis of modeling the kinetics of viral decline and the emergence of resistant mutants during therapy that 93–99% of the circulating virus originated from recently infected, rapidly turning over CD4+ T cells and that ~1–7% of circulating virus originated from longer-lived cells, likely monocytes/macrophages. A negligible amount of circulating virus originated from the pool of latently infected cells (see above) (Fig. 90-19). It was also determined that the half-life of a circulating virion was ~30–60 min and that of productively infected cells was 1 day. Given the relatively steady level of plasma viremia and of infected cells, it appears that extremely large amounts of virus ($\sim 10^{10}$ – 10^{11} virions) are produced and cleared from the circulation each day. In addition, data suggest that the minimal duration of the HIV-1 replication cycle in vivo is ~2 days. Other studies have demonstrated that the decrease in plasma viremia that results from ARV therapy correlates closely with a decrease in virus replication in lymph nodes, further confirming that lymphoid tissue is the main site of HIV replication and the main source of plasma viremia.

The level of steady-state viremia, called the viral *set point*, at ~1 year has important prognostic implications for the progression of HIV disease. It has been demonstrated that as a group HIV-infected individuals who have a low set point at 6 months to 1 year progress to AIDS much more slowly than individuals whose set point is very high at that time (Fig. 90-20). Levels of viremia generally increase as disease progresses. Measurement of the level of viremia is critical in guiding therapeutic decisions in HIV-infected individuals (see below).

Clinical Latency Versus Microbiologic Latency

With the exception of long-term nonprogressors (see below), the level of CD4+ T cells in the blood decreases progressively in HIV-infected individuals. The decline in CD4+ T cells may be gradual or abrupt, the latter usually reflecting a significant spike in the level of plasma viremia. Most patients are relatively asymptomatic while this progressive decline is taking place (see below) and are often described as being in a state of *clinical latency*. However, this term is misleading; it does not mean disease latency, since progression, although slow in many cases, is generally relentless during this period. Furthermore, clinical latency should not be confused with microbiologic latency, since some level of virus replication invariably occurs during this period of clinical latency. Even in those rare patients who have <50 copies of HIV RNA per milliliter in the absence of therapy, there is virtually always some degree of ongoing virus replication.

ADVANCED HIV DISEASE

In untreated patients or in patients in whom therapy has not adequately controlled virus replication (see below), after a variable period, usually measured in years, the CD4+ T-cell count falls below a critical level (<200/ μ L) and the patient becomes highly susceptible to opportunistic disease (Fig. 90-17). For this reason, the CDC case definition of AIDS includes all HIV-infected individuals with CD4+ T-cell counts below this level (Table 90-1). Patients may experience constitutional signs and symptoms or may develop an opportunistic disease abruptly

**FIGURE 90-20**

Relationship between levels of virus and rates of disease progression. Kaplan-Meier curves for AIDS-free survival stratified by baseline HIV-1 RNA categories (copies per milliliter). (From Mellors et al.)

without any prior symptoms, although the latter scenario is unusual. The depletion of CD4⁺ T cells continues to be progressive and unrelenting in this phase. It is not uncommon for CD4⁺ T-cell counts in the untreated patient to drop as low as 10/ μ L or even to zero. In countries where ARV therapy and prophylaxis and treatment for opportunistic infections are readily accessible to such patients, survival is increased dramatically even with this level of advanced disease. In contrast, untreated patients who progress to this severest form of immunodeficiency usually succumb to opportunistic infections or neoplasms (see below).

LONG-TERM SURVIVORS AND LONG-TERM NONPROGRESSORS

The prognosis for HIV-infected individuals who have access to health care and ARV therapy has improved greatly since the beginning of the epidemic. The median time from primary HIV infection to the development of AIDS in untreated individuals in the developed world is ~10 years. This period has been markedly extended by the wide availability of combinations of ARV drugs in the developed world, and increasingly in low- to mid-income countries; the full extent of this benefit is yet to be realized (see below). It is important to distinguish between the terms *long-term survivor* and *long-term nonprogressor*. Long-term nonprogressors are by definition long-term survivors; however, the reverse is not always true. The definitions of these categories are empirical and continue to change as more data are collected from prospective cohort studies. Predictions from one study that antedated the availability of effective ARV therapy estimated that ~13% of homosexual/bisexual men who were infected at an early age may remain free of clinical AIDS for >20 years. Originally, individuals were considered to be long-term survivors if they remained alive for 10–15 years after initial infection. Currently, individuals are considered to be long-term survivors if they remain alive for ≥ 20 years after initial infection. In most such individuals the disease has progressed, in that they have significant immunodeficiency, and many have experienced opportunistic diseases.

Some of these individuals have CD4⁺ T-cell counts that have decreased to $\leq 200/\mu$ L but have remained stable at that level for years. The mechanisms of this stabilization are not entirely clear but may relate to the beneficial effects of ARV therapy and prophylaxis against opportunistic infections. In addition, a number of viral and/or host determinants likely contribute to the long-term survival of these individuals. Quantitative and qualitative aspects of the HIV-specific immune response, as well as recognized and unrecognized genetic factors (see below), may also contribute to the long-term survival of these individuals.

Definitions of long-term nonprogressors have varied considerably over the years, and so such individuals constitute a heterogeneous group. Originally, individuals considered to be long-term nonprogressors were those who had been infected with HIV for a long period (≥ 10 years), whose CD4⁺ T-cell counts were in the normal range and remained stable over years, and who had not received ARV therapy. Such patients had relatively low, but usually detectable, levels of plasma viremia, generally normal immune function according to commonly measured parameters (skin tests, in vitro lymphocyte responses to various mitogens and antigens), and normal-appearing lymphoid tissue architecture as determined on lymph node biopsy. In general, long-term nonprogressors manifested robust HIV-specific immune responses, both humoral (neutralizing antibodies) and cell-mediated (HIV-specific CTLs). However, this may also be true of some individuals early in the course of disease who ultimately progress to advanced disease. No qualitative abnormalities in the virus were detected in most of these patients. However, a small subset of patients did have defective virus; in particular, in one cohort of five long-term nonprogressors, the virus had a defect in the *nef* gene. In another report, a blood donor in Australia who was HIV-infected and a group of seven individuals who were infected by blood or blood products from that donor remained free of HIV-related disease and maintained normal and stable CD4⁺ T-cell counts for several years after infection. Sequence analysis of viruses isolated from the donor and recipients revealed similar

deletions in the *nef* gene and the region of overlap of *nef* and the U3 region of the HIV LTR (Fig. 90-5). The vast majority of these originally reported long-term nonprogressors have now gone on to progressive disease. More recently, cohorts of rare long-term nonprogressors have been described who have been infected for 20 years with normal CD4+ T-cell counts and who typically maintain plasma viral RNA <50 copies per milliliter without ARV therapy. When these more stringent definitions based predominantly on levels of plasma viremia are applied, very strong associations with HLA B*5701 or HLA B*2705 alleles have been found. In addition, the HIV-specific CD8+ T-cell response in these patients is highly focused on B5701-restricted peptides, suggesting that the B5701 molecule plays a direct role in restriction of virus replication in these individuals, although the precise mechanisms of this effect remain unclear.

A number of other host genetic factors exert more modest effects on restriction of HIV replication, yet they also may be associated with slower progression of disease (see “Genetic Factors in HIV Pathogenesis” later in the chapter). The precise role of host factors in long-term nonprogression remains unclear. There is no single genetic determinant for nonprogression. However, several genetic variants and mutations have been demonstrated to result in a delay in the progression of HIV disease. These include heterozygosity for the *CCR5*-Δ32 deletion, heterozygosity for the *CCR2*-64I mutation, homozygosity for the *SDF1*-3'A mutation, and heterozygosity for the *RANTES*-28G mutation (see “Genetic Factors in HIV Pathogenesis” later in the chapter). Since *CCR5* is the major co-receptor for R5 or macrophage-tropic strains of HIV and since individuals who are homozygous for the *CCR5*-Δ32 deletion are, with rare exceptions, protected against HIV infection, the potential mechanism for slow progression in heterozygotes is clear. In addition, certain single nucleotide polymorphisms in the *CCR5* promoter have been shown to be associated with slower progression of disease. The reason for the slowing of progression of HIV disease in individuals who are heterozygous for the *CCR2*-64I mutation is less clear; however, it has been demonstrated that CXCR4 can dimerize with the *CCR2*-64I mutant but not with wild-type *CCR2*. This dimerization may reduce the amount of CXCR4 on the cell surface and as a result inhibit infection with X4 viruses. Homozygosity for the *SDF1*-3' A mutation may upregulate the *SDF1* gene enabling SDF-1, which is the natural ligand for CXCR4, to compete more effectively with X4 virus for the CXCR4 co-receptor. The *RANTES*-28G mutation increases *RANTES* (*CCL5*) expression, which is the natural ligand for *CCR5* and may thus inhibit infection with R5 viruses. The gene *CCL3L1* codes for MIP1αP and has an influence on both susceptibility to infection and disease progression based upon the gene copy number in the individual. Finally, maximal HLA heterozygosity of class I loci (A, B, and C) has been shown to be associated with delayed progression of HIV disease. Although most long-term nonprogressors have robust HIV-specific immune responses as well as competent CD8+ T-cell suppressors of HIV

replication, it is unclear whether these factors are directly responsible for the state of nonprogression. A substantial proportion of HIV-infected individuals manifest comparable immune responses early in the course of their disease and still experience disease progression. As noted above, long-term nonprogressors likely represent a heterogeneous group. It has recently been reported in some cohorts that individuals co-infected with HIV and *GB virus C* (GBV-C) have lower mortality than HIV-infected individuals without GBV-C infection. The precise mechanisms of this apparent beneficial effect are unclear at present.

LYMPHOID ORGANS AND HIV PATHOGENESIS

Regardless of the portal of entry of HIV, lymphoid tissues are the major anatomic sites for the establishment and propagation of HIV infection (see above). Despite the use of measurements of plasma viremia to determine the level of disease activity, virus replication occurs mainly in lymphoid tissue and not in blood; indeed, the level of plasma viremia directly reflects virus production in lymphoid tissue.

Some patients experience progressive generalized lymphadenopathy (see below) early in the course of the infection; others experience varying degrees of transient lymphadenopathy. Lymphadenopathy reflects the cellular activation and immune response to the virus in the lymphoid tissue, which is generally characterized by follicular or germinal center hyperplasia. Lymphoid tissue involvement is a common denominator of virtually all patients with HIV infection, even those without easily detectable lymphadenopathy.

Simultaneous examinations of lymph tissue and peripheral blood in patients and monkeys during various stages of HIV and SIV infection, respectively, have led to substantial insight into the pathogenesis of HIV disease. In most of the original human studies, peripheral lymph nodes have been used predominantly as the source of lymphoid tissue. More recent studies in monkeys and humans have focused on the GALT, where the earliest burst of virus replication occurs associated with marked depletion of CD4+ T cells (see below). In detailed studies in peripheral lymph node tissue, using a combination of polymerase chain reaction (PCR) techniques for HIV DNA and HIV RNA in tissue and HIV RNA in plasma, in situ hybridization for HIV RNA, and light and electron microscopy, the following picture has emerged. During acute HIV infection, high levels of plasma viremia at first originating from virus replication in the GALT occurs with dissemination of virus to peripheral lymphoid tissue where extensive viral replication in individual cells is demonstrated. A profound degree of cellular activation occurs (see below) and is reflected in follicular or germinal center hyperplasia. At this time copious amounts of extracellular virions (both infectious and defective) are trapped on the processes of the follicular dendritic cells (FDCs) in the germinal centers of the lymph nodes. Virions that have bound complement components on their surfaces attach to the surface of FDCs via interactions with complement

FIGURE 90-21

HIV in the lymph node of an HIV-infected individual. An individual cell infected with HIV shown expressing HIV RNA by in situ hybridization using a radiolabeled molecular probe. Original $\times 500$. (Adapted from G Pantaleo et al: *Nature* 362:355, 1993.)

receptors and likely via Fc receptors that bind to antibodies that are attached to the virions. In situ hybridization reveals expression of virus in individual cells of the paracortical area and, to a lesser extent, the germinal center (Fig. 90-21). The persistence of trapped virus after the transition from acute to chronic infection likely reflects a steady state whereby trapped virus turns over and is replaced by fresh virions, which are continually produced to a greater or lesser degree in individual patients. The trapped virus, either as whole virion or shed envelope, serves as a continual activator of CD4+ T cells, thus driving further virus replication.

During early-stage HIV disease, the architecture of the germinal centers is generally preserved and may even be hyperplastic owing to in situ proliferation of cells (mostly B lymphocytes) and recruitment to the lymph nodes of a number of cell types (B cells, CD4+ and CD8+ T cells). Electron-microscopic studies have demonstrated a fine network of FDCs with many long, fingerlike processes that envelop virtually every lymphocyte in the germinal center. Extracellular virions can be seen attached to the processes, yet the FDCs appear to be relatively healthy. The trapping of antigen is a physiologically normal function for the FDCs, which present antigen to B cells and contribute to the generation of B-cell memory. However, in the case of HIV, the trapped virions serve as a persistent source of cellular activation, resulting in the secretion of proinflammatory cytokines such as interleukin (IL)-1 β , tumor necrosis factor (TNF)- α , and IL-6, which can upregulate virus replication in infected cells (see below). Furthermore, although trapped virus is coated by neutralizing antibodies, it has been demonstrated that certain of these virions remain infectious for CD4+ T cells while attached to the processes of the FDCs. CD4+ T cells that migrate into the germinal center to provide help to B cells in the generation of an HIV-specific immune response are susceptible to infection by these trapped

virions. Thus, in HIV infection, a normal physiologic function of the immune system, which contributes to the clearance of virus as well as to the generation of a specific immune response, can also have deleterious consequences.

As the disease progresses, the architecture of the germinal centers begins to show disruption, and the trapping efficiency of the lymphoid tissue diminishes. Electron microscopy reveals swollen organelles, and the FDCs begin to undergo cell death. The mechanisms of FDC death remain unclear; there is no indication by electron microscopy of copious virus replication or budding of virions off the cell in great quantities. This process of FDC death is accompanied by the deposition of collagen, leading to irreparable damage to the germinal centers. As the disease progresses to an advanced stage, there is complete disruption of the architecture of the germinal centers, accompanied by dissolution of the FDC network and massive dropout of FDCs. At this point, the lymph nodes are “burnt out.” This destruction of lymphoid tissue compounds the immunodeficiency of HIV disease and contributes both to the inability to control HIV replication (leading usually to high levels of plasma viremia in the untreated or inadequately treated patient) and to the inability to mount adequate immune responses against opportunistic pathogens. The events from primary infection to the ultimate destruction of the immune system are illustrated in Fig. 90-22. Recently, nonhuman primate studies and some human studies have examined GALT at various stages of HIV disease. It is noteworthy that before infection approximately half of all CD4+ T cells in the jejunum express the HIV cellular co-receptor CCR5, rendering them highly susceptible to infection. Within the GALT, the basal level of activation combined with virus-mediated cellular activation results in the infection and elimination of an estimated 50–90% of CD4+ T cells in the gut. The extent of this early damage to GALT, which comprises a major component of lymphoid tissue in the body, plays a role in determining the potential for immunologic recovery of the memory cell subset.

CELLULAR ACTIVATION AND HIV PATHOGENESIS

Activation of the immune system is an essential component of an appropriate immune response to a foreign antigen. The immune system is normally in a state of homeostasis, awaiting perturbation by foreign antigenic stimuli. Once the immune response deals with and clears the antigen, the system returns to relative quiescence. In HIV infection, however, the immune system is chronically activated, providing the cell substrates necessary for persistent virus replication throughout the course of HIV disease, particularly in the untreated patient (see above) and to variable degrees even in certain patients receiving ARV therapy whose level of plasma viremia is suppressed to below the level of detection by standard assays (see below). Aberrant immune activation is the hallmark of HIV infection and is a critical component of the pathogenesis of HIV disease. This

**FIGURE 90-22**

Events that transpire from primary HIV infection through the establishment of chronic persistent infection to the ultimate destruction of the immune system. See text for details.

CTLs, cytolytic T lymphocytes; GALT, gut-associated lymphoid tissue.

activated state is reflected by hyperactivation of B cells leading to hypergammaglobulinemia; spontaneous lymphocyte proliferation; activation of monocytes; expression of activation markers on CD4+ and CD8+ T cells; increased activation-associated cellular apoptosis; lymph node hyperplasia, particularly early in the course of disease (see above); increased secretion of proinflammatory cytokines (see below); elevated levels of neopterin, β_2 -microglobulin, acid-labile interferon, and soluble IL-2 receptors; and autoimmune phenomena (see below). Even in the absence of direct infection of a target cell, HIV envelope proteins can interact with cellular receptors (CD4 molecules and chemokine receptors) to deliver potent activation signals resulting in calcium flux, the phosphorylation of certain proteins involved in signal transduction, co-localization of cytoplasmic proteins including those involved in cell trafficking, immune dysfunction, and, under certain circumstances, apoptosis (see below). The secretion of certain proinflammatory and immunoregulatory cytokines is both a consequence of the aberrant immune activation associated with HIV infection and a mechanism of propagation of the process of aberrant cellular activation (see below).

In addition to endogenous factors such as cytokines, a number of exogenous factors such as other microbes that are associated with heightened cellular activation can enhance HIV replication and thus may have important effects on HIV pathogenesis. Co-infection *in vivo* or *in vitro* with a range of viruses, such as HSV types 1 and 2, cytomegalovirus (CMV), human herpesvirus (HHV) 6, Epstein-Barr virus (EBV), HBV, adenovirus, and HTLV-I have been shown to upregulate HIV expression. Other microbes, such as *Mycoplasma*, have been reported to contribute to the induction of HIV expression. In addition, infestation with nematodes has

been shown to be associated with a heightened state of immune activation that facilitates HIV replication; in certain studies, deworming of the infected host has resulted in a decrease in plasma viremia. Two diseases of extraordinary global health significance, malaria and tuberculosis (TB), have been shown to increase HIV viral load in dually infected individuals. Globally, *Mycobacterium tuberculosis* is probably the most common opportunistic infection in HIV-infected individuals (see below and Chap. 66). In addition to the fact that HIV-infected individuals are more likely to develop active TB after exposure, it has been demonstrated that active TB can accelerate the course of HIV infection. It has also been shown that levels of plasma viremia are greatly elevated in HIV-infected individuals with active TB, compared with pre-TB levels and levels of viremia after successful treatment of the active TB. *In vitro* studies demonstrated that virus replication was markedly enhanced in lymphocytes of HIV-infected individuals who were skin test-positive for purified protein derivative (PPD) when PPD antigen was added to culture, resulting in cellular activation. Confirmatory evidence that antigen-induced activation was a major contributor to the accelerated viremia in HIV-infected individuals with active TB was provided by studies in which HIV-infected individuals were immunized with common recall antigens such as tetanus toxoid, influenza, or pneumococcal polysaccharide. Under these circumstances, a transient elevation of plasma viremia accompanied the cellular activation induced by the immunization. A greater degree of induction of virus was seen in those individuals with early-stage as opposed to advanced stage HIV disease (i.e., in those with more competent immune systems), and the degree of virus induction correlated with the level of immune system activation.

The situation is similar in the interaction between HIV and malaria parasites (Chap. 116). Acute infection of HIV-infected individuals with *Plasmodium falciparum* increases HIV viral load, and the increased viral load is reversed by effective malaria treatment.

Persistent immune activation may have several deleterious consequences. From a virologic standpoint, although quiescent CD4⁺ T cells can be infected with HIV, reverse transcription, integration, and virus spread are much more efficient in activated cells. Furthermore, cellular activation induces expression of virus in cells latently infected with HIV (see above). From an immunologic standpoint, chronic exposure of the immune system to a particular antigen over an extended period may ultimately lead to an inability to sustain an adequate immune response to the antigen in question. In many chronic viral infections, including HIV infection, persistent viremia is associated with “functional exhaustion” and apoptosis of virus-specific T cells. It has been demonstrated that this phenomenon may be mediated, at least in part, by the engagement of PD-1, which is highly expressed on the majority of HIV-specific T cells, with its ligands (PD-L1 and PD-L2) on antigen-presenting cells and epithelial cells, resulting in either T-cell death or anergy (see above). Furthermore, the ability of the immune system to respond to a broad spectrum of antigens may be compromised if immunocompetent cells are maintained in a state of chronic activation. In addition, activation of the immune system may favor the elimination of cells via programmed cell death (apoptosis) (see below) as well as the secretion of certain cytokines that can induce HIV expression (see below).

The deleterious effects of chronic immune activation on the progression of HIV disease are well established. As in most conditions of persistent antigen exposure, the host must maintain sufficient activation of antigen (HIV)-specific responses but must also prevent excessive activation and potential immune-mediated damage to tissues. Certain studies suggest that normal immunosuppressive mechanisms that act to keep hyperimmune activation in check, particularly CD4⁺, FoxP3⁺, CD25⁺ regulatory T cells (T-regs), may be dysfunctional or depleted in the context of advanced HIV disease.

Apoptosis

Apoptosis is a form of programmed cell death that is a normal mechanism for the elimination of effete cells in organogenesis as well as in the cellular proliferation that occurs during a normal immune response. Apoptosis is strictly dependent on cellular activation, and the aberrant cellular activation associated with HIV disease (see above) is correlated with a heightened state of apoptosis. It has been hypothesized that, in HIV infection, sequential activation signals delivered to CD4⁺ T cells induce apoptosis. Cross-linking of the CD4 molecule by gp120 or gp120/anti-gp120 complexes delivers the first of two signals required for apoptosis. The second signal supposedly leading to cell death is delivered via the T-cell receptor by antigen. According to this hypothesis, direct infection of CD4⁺ T cells is not required for apoptosis

to occur, although it has been demonstrated that alterations in tyrosine kinase activity of HIV-infected cells may induce the cell to undergo apoptosis. HIV can trigger both Fas-dependent and Fas-independent pathways of apoptosis. Mechanisms involved in this process include upregulation of Fas and Fas ligand, upregulation of caspase-1 and caspase-6, downregulation of the anti-apoptotic Bcl-2 protein, and activation of cyclin-dependent kinases. Certain viral gene products have been associated with enhanced susceptibility to apoptosis including Env, Tat, and Vpr. In contrast, Nef has been shown to possess antiapoptotic properties. A number of studies, including those examining lymphoid tissue, have demonstrated that the rate of apoptosis is elevated in HIV infection and that apoptosis is seen in “bystander” cells such as CD8⁺ T cells and B cells as well as in CD4⁺ T cells. The intensity of apoptosis correlates with the general state of activation of the immune system and not with the stage of disease or with viral burden. It is likely that apoptosis of immunocompetent cells contributes to the immune abnormalities in HIV disease; however, this is probably a nonspecific mechanism that merely reflects the aberrant state of immune activation.

Autoimmune Phenomena

The autoimmune phenomena that are common in HIV-infected individuals reflect, at least in part, chronic immune system activation as well as molecular mimicry by viral components. Although these phenomena usually occur in the absence of autoimmune disease, a wide spectrum of clinical manifestations that may be associated with autoimmunity have been described (see below). Autoimmune phenomena include antibodies to lymphocytes and, less commonly, to platelets and neutrophils. Antiplatelet antibodies have some clinical relevance, in that they may contribute to the thrombocytopenia of HIV disease (see below). Antibodies to nuclear and cytoplasmic components of cells have been reported, as have antibodies to cardiolipin; CD4 molecules; CD43 molecules, C1q-A; variable regions of the T-cell receptor α , β , and γ chains; Fas; denatured collagen; and IL-2. In addition, autoantibodies to a range of serum proteins, including albumin, immunoglobulin, and thyroglobulin, have been reported. There is antigenic cross-reactivity between HIV viral proteins (gp120 and gp41) and MHC class II determinants, and anti-MHC class II antibodies have been reported in HIV infection. These antibodies could potentially lead to the elimination of MHC class II-bearing cells via antibody-dependent cellular cytotoxicity (ADCC), although this has not been clearly demonstrated to occur. In addition, regions of homology exist between HIV envelope glycoproteins and IL-2 as well as MHC class I molecules. With the widespread use of effective antiretroviral therapy, an *immune reconstitution inflammatory syndrome* (IRIS) has become increasingly more common. IRIS is an autoimmune-like phenomenon characterized by a paradoxical deterioration of clinical condition, which is usually compartmentalized to a particular organ system, in individuals in whom ARV therapy has recently been initiated. It is associated with a

decrease in viral load and at least partial recovery of immune competence, usually associated with increases in CD4+ T-cell counts. The immunopathogenesis is felt to be related to an increase in immune response against the presence of residual antigens that are usually microbial and is commonly seen with underlying *Mycobacterium tuberculosis* and cryptococcosis. This syndrome is discussed in more detail below.

THE CYTOKINE NETWORK IN HIV PATHOGENESIS

The immune system is homeostatically regulated by a complex network of immunoregulatory cytokines, which are pleiotropic and redundant and operate in an autocrine and paracrine manner. They are expressed continuously, even during periods of apparent quiescence of the immune system. On perturbation of the immune system by antigenic challenge, the expression of cytokines increases to varying degrees. Cytokines that are important components of this immunoregulatory network have been demonstrated to play a major role in the regulation of HIV expression in vitro. Potent modulation of HIV expression has been demonstrated either by manipulating endogenous cytokines or by adding exogenous cytokines to culture. Cytokines that induce HIV expression in one or more of these systems include IL-1, IL-2, IL-3, IL-6, IL-12, TNF- α , TNF- β , macrophage colony-stimulating factor (M-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF). Among these cytokines, the most consistent and potent inducers of HIV expression are the *proinflammatory cytokines* TNF- α , IL-1 β , and IL-6. Interferon (IFN)- α and - β suppress HIV replication, whereas transforming growth factor (TGF) β , IL-4, IL-10, and IFN- γ can either induce or suppress HIV expression, depending on the system involved. The *CC-chemokines* RANTES (CCL5), macrophage inflammatory protein (MIP)-1 α (CCL3), and MIP-1 β (CCL4) inhibit infection by and spread of R5 HIV-1 strains, whereas *stromal cell-derived factor* (SDF) 1 inhibits infection by and spread of X4 strains (see below). The alpha defensin family of cytokines has been shown to inhibit both R5 and X4 viruses, and other soluble factors that have not yet been fully characterized have also been shown to suppress HIV replication.

The molecular mechanisms of HIV regulation are best understood for TNF- α , which activates NF- κ B proteins that function as transcriptional activators of HIV expression. The HIV-inducing effect of IL-1 β is thought to occur at the level of viral transcription in an NF- κ B-independent manner. IL-6, GM-CSF, and IFN- γ regulate HIV expression mainly by posttranscriptional mechanisms. Elevated levels of TNF- α and IL-6 have been demonstrated in plasma and cerebrospinal fluid (CSF), and increased expression of TNF- α , IL-1 β , IFN- γ , and IL-6 has been demonstrated in the lymph nodes of HIV-infected individuals. The mechanisms whereby the CC-chemokines RANTES (CCL5), MIP-1 α (CCL3), and MIP-1 β (CCL4) inhibit infection of R5 strains of HIV or SDF-1 blocks X4 strains of HIV involve blocking of the binding of the virus to its co-receptors, the

CC-chemokine receptor CCR5 and the CXC-chemokine receptor CXCR4, respectively (see above and below). However, several CC-chemokines, including but not limited to CCL3, -4, and -5, induce intracellular signals that actually enhance infection by X4 strains of virus at both the entry and postentry levels. The mechanisms whereby other less well-characterized factors (see above) inhibit HIV replication are not completely understood.

Blocking of endogenous HIV-inducing cytokines or addition of inhibitors of HIV-suppressor cytokines in cultures of peripheral blood and lymph node mononuclear cells from HIV-infected individuals has demonstrated that HIV replication is controlled tightly by endogenous cytokines that act synergistically and in an autocrine and paracrine manner, similar to their physiologic function in the regulation of the immune system. Indeed, the net level of virus replication in an HIV-infected individual reflects at least in part a balance between inductive and suppressive host factors, mediated mainly by cytokines.

LYMPHOCYTE TURNOVER IN HIV INFECTION

The immune systems of patients with HIV infection are characterized by a profound increase in lymphocyte turnover that is immediately reduced with effective ARV therapy. Studies utilizing in vivo or in vitro labeling of lymphocytes in the S-phase of the cell cycle have demonstrated a tight correlation between the degree of lymphocyte turnover and plasma levels of HIV RNA. This increase in turnover is seen in CD4+ and CD8+ T lymphocytes as well as B lymphocytes and can be observed in peripheral blood and lymphoid tissue. Mathematical models derived from these data suggest that one can view the lymphoid pool as consisting of dynamically distinct subpopulations of cells that are differentially affected by HIV infection. A major consequence of HIV infection appears to be a shift in cells from a more quiescent pool to a pool with a higher turnover rate. It is likely that a consequence of a higher rate of turnover is a higher rate of cell death. The role of the thymus in adult human T-cell homeostasis and HIV pathogenesis is an area of controversy. Although some data point to an important role for the thymus in maintaining T-cell numbers and suggest that impairment of thymic function may be responsible for the declines in CD4+ T cells seen in the setting of HIV infection, other studies have concluded that the thymus plays a minor role in HIV pathogenesis. Among the data supporting an important role for the thymus are those that demonstrate an increase in the levels of T-cell receptor excision circles (TRECs) after initiation of ARV therapy. TRECs are a byproduct of T-cell development and represent episomal fragments of DNA that are excised during T-cell receptor gene rearrangement. Levels of TRECs will be the net result of changes in thymic output together with changes in T-cell turnover. An increase in thymic output and/or a decrease in T-cell turnover will lead to an increase in levels of TRECs. Although it is clear that levels of TRECs increase after initiation of

ARV therapy, it is not clear whether this is a consequence of increased thymic output or decreased T-cell turnover.

THE ROLE OF CO-RECEPTORS IN HIV PATHOGENESIS

As mentioned above, HIV-1 utilizes two major co-receptors along with CD4 to bind to, fuse with, and enter target cells; these co-receptors are CCR5 and CXCR4, which are also receptors for certain endogenous chemokines. Strains of HIV that utilize CCR5 as a co-receptor are referred to as *R5 viruses*. Strains of HIV that utilize CXCR4 are referred to as *X4 viruses*. Many virus strains are *dual tropic* in that they utilize both CCR5 and CXCR4; these are referred to as *R5X4 viruses*.

The natural chemokine ligands for the major HIV co-receptors can readily block entry of HIV. For example, the CC-chemokines RANTES (CCL5), MIP-1 α (CCL3), and MIP-1 β (CCL4), which are the natural ligands for CCR5, block entry of R5 viruses, whereas SDF-1, the natural ligand for CXCR4, blocks entry of X4 viruses. The mechanism of inhibition of viral entry is a steric inhibition of binding that is not dependent on signal transduction (Fig. 90-23).

The transmitting virus is almost invariably an R5 virus that predominates during the early stages of HIV disease. In ~40% of HIV-infected individuals, there is a transition to a predominantly X4 virus that is associated with a relatively rapid progression of disease. However, at least 60% of infected individuals progress in their disease while maintaining predominance of an R5 virus. It should be pointed out that clade C viruses, unlike other subgroups, almost never switch from CCR5 tropism to CXCR4 tropism; the reason for this difference is unclear. Other chemokine receptor family members may function as co-receptors for HIV and SIV entry, but to a much lesser extent than do CCR5 and CXCR4; these include CCR3, BOB/GPR15, CXCR6 (Bonzo/STRL33/TYMSTR), CCR2, CCR8, CX₃CR1(V28), and GPR1.

The basis for the tropism of different envelope glycoproteins for either CCR5 or CXCR4 relates to the ability of the HIV envelope, including the third variable region (V3 loop) of gp120, to interact with these co-receptors. In this regard, binding of gp120 to CD4 induces a conformational change in gp120 that increases its affinity for CCR5 (see above). Finally, R5 viruses are more efficient in infecting monocytes/macrophages and microglial cells of the brain (see “Neuropathogenesis” later in the chapter).

CELLULAR TARGETS OF HIV

Although the CD4+ T lymphocytes and CD4+ cells of monocyte lineage are the principal targets of HIV, virtually any cell that expresses the CD4 molecule together with co-receptor molecules (see above and below) can potentially be infected with HIV. Circulating dendritic cells have been reported to express low levels of CD4 and, depending on their stage of maturation, these cells can be infected with HIV (see below). Epidermal Langerhans cells express CD4 and have been infected by

FIGURE 90-23

Model for the role of co-receptors CXCR4 and CCR5 in the efficient binding and entry of X4 (A) and R5 (B) strains of HIV-1, respectively, into CD4+ target cells. Blocking of this initial event in the virus life cycle can be accomplished by inhibition of binding to the co-receptor by the normal ligand for the receptor in question. The ligand for CXCR4 is stromal cell-derived factor (SDF-1); the ligands for CCR5 are RANTES, MIP-1 α , and MIP-1 β .

HIV in vivo. In vitro, HIV has been reported also to infect a wide range of cells and cell lines that express low levels of CD4, no detectable CD4, or only CD4 mRNA; among these are FDCs, megakaryocytes, eosinophils, astrocytes, oligodendrocytes, microglial cells, CD8+ T cells, B cells, and NK cells as well as a variety of organ-specific cells. Since the only cells that have been shown unequivocally to be infected with HIV and to support replication of the virus are CD4+ T lymphocytes and cells of monocyte/macrophage lineage, the relevance of the in vitro infection of these other cell types is questionable.

Of potentially important clinical relevance is the demonstration that thymic precursor cells, which were assumed to be negative for CD3, CD4, and CD8 molecules, actually do express low levels of CD4 and can be infected with HIV in vitro. In addition, human thymic epithelial cells transplanted into an immunodeficient

mouse can be infected with HIV by direct inoculation of virus into the thymus. Since these cells may play a role in the normal regeneration of CD4+ T cells, it is possible that their infection and depletion contribute, at least in part, to the impaired ability of the CD4+ T-cell pool to completely reconstitute itself in certain infected individuals in whom ARV therapy has suppressed viral replication to <50 copies of HIV RNA per milliliter (see below). In addition, CD34+ monocyte precursor cells have been shown to be infected *in vivo* in patients with advanced HIV disease. It is likely that these cells express low levels of CD4, and therefore it is not essential to invoke CD4-independent mechanisms to explain the infection.

ABNORMALITIES OF MONONUCLEAR CELLS

CD4+ T Cells

The range of T-cell abnormalities in advanced HIV infection is broad. The defects are both quantitative and qualitative and affect virtually every limb of the immune system (see below), indicating the critical dependence of the integrity of the immune system on the inducer/helper function of CD4+ T cells. In advanced HIV disease, most of the observed immune defects can ultimately be explained by the quantitative depletion of CD4+ T cells. However, T-cell dysfunction (see below) can be demonstrated in patients early in the course of infection, even when the CD4+ T-cell count is in the low-normal range. The degree and spectrum of dysfunctions increase as the disease progresses. One of the first abnormalities to be detected is a defect in response to remote recall antigens, such as tetanus toxoid and influenza, at a time when mononuclear cells can still respond normally to mitogenic stimulation. Indeed, defects of central memory cells are a critical component of HIV immunopathogenesis. The progressive loss of antigen-specific CD4+ T cells has important implications for the control of HIV infection. In this regard, there is a correlation between the maintenance of HIV-specific CD4+ T-cell proliferative responses and improved control of infection. Essentially every T-cell function has been reported to be abnormal at some stage of HIV infection. These abnormalities include defective T-cell cloning and colony-forming efficiencies, impaired expression of IL-2 receptors, defective IL-2 production, reduced expression of the IL-7 receptor (CD127), and decreased IFN- γ production in response to antigens. The proportion of CD4+ T cells that express CD28, which is a major co-stimulatory molecule necessary for the normal activation of T cells, is reduced during HIV infection. Cells lacking expression of CD28 do not respond normally to activation signals and may express markers of terminal activation including HLA-DR, CD38, and CD45RO. CD4+ T cells from HIV-infected individuals express abnormally low levels of CD40 ligand, which may contribute to the dysregulation of B-cell function observed in HIV disease. As mentioned above (see “Cellular Activation and HIV Pathogenesis”), a subset of CD4+ T cells referred to as *T regulatory cells*, or T-regs, may be

TABLE 90-3

MECHANISMS OF CD4+ T-CELL DYSFUNCTION AND DEPLETION

| DIRECT MECHANISMS | INDIRECT MECHANISMS |
|--|--|
| Loss of plasma membrane integrity due to viral budding | Aberrant intracellular signaling events |
| Accumulation of unintegrated viral DNA | Autoimmunity |
| Interference with cellular RNA processing | Innocent bystander killing of viral antigen-coated cells |
| Intracellular gp120-CD4 autolysis events | Apoptosis |
| Syncytia formation | Inhibition of lymphopoiesis |
| | Activation-induced cell death |
| | Elimination of HIV-infected cells by virus-specific immune responses |

involved in dampening aberrant immune activation that propagates HIV replication. The presence of these T-reg cells correlates with lower viral loads and higher CD4+/CD8+ T-cell ratios. A loss of this T-reg capability with advanced disease may be detrimental to the control of virus replication.

It is difficult to explain completely the profound immunodeficiency noted in HIV-infected individuals solely on the basis of direct infection and quantitative depletion of CD4+ T cells. This is particularly apparent during the early stages of HIV disease, when CD4+ T-cell numbers may be only marginally decreased.

In this regard, it is likely that CD4+ T-cell dysfunction results from a combination of depletion of cells due to direct infection of the cell and a number of virus-related but indirect effects on the cell (Table 90-3). Indeed, it has been demonstrated that patients with high levels of plasma viremia have a variety of subtle abnormalities of CD4+ T-cell function, particularly involving aberrancies in signal transduction pathways. These abnormalities could be due either to aberrant activation induced by the cascade of cytokines that are expressed in viremic patients or by the direct effect of virus on the cell. In this regard, certain of these abnormalities can be reproduced by exposing CD4+ T cells of normal individuals to oligomeric HIV envelope proteins *in vitro* (see below).

Single-cell killing and the formation of syncytia between infected and uninfected cells have been demonstrated clearly *in vitro*, although there is little evidence that this process occurs *in vivo*. Cytopathicity in an infected cell *in vitro* may result from a number of mechanisms, including copious budding of virions from the cell surface with resulting disruption of the integrity of the cell membrane; interference with cellular RNA processing or the accumulation of high levels of heterodisperse RNA molecules; disruption of cellular protein synthesis owing to high levels of viral RNA; accumulation of high levels of unintegrated viral DNA in the cell cytoplasm; induction of aberrant patterns of

protein tyrosine phosphorylation; and the interaction between HIV gp120 and CD4 intracellularly. Strain differences in single-cell killing are determined largely by gp120 sequences, which supports the importance of the viral envelope in this process. Humoral and cellular immune responses to HIV may contribute to protective immunity by eliminating virus and virus-infected cells (see below). However, since the main targets of HIV infection are immunocompetent cells, these responses may contribute to immune cell depletion and immunologic dysfunction by eliminating both infected cells and “innocent bystander” cells. Soluble viral proteins, particularly gp120, can bind with high affinity to the CD4 molecules on uninfected T cells and monocytes; in addition, virus and/or viral proteins can bind to dendritic cells or FDCs. HIV-specific antibody can recognize these bound molecules and potentially collaborate in the elimination of the cells by ADCC.

Nonpolymorphic determinants of MHC class I products share a degree of homology with gp120 and gp41 proteins of HIV. Such similarities may lead to the generation of autoantibodies to self-MHC determinants. Anti-HLA-DR antibodies have been demonstrated in the sera of HIV-infected individuals (see “Autoimmune Phenomena” earlier in the chapter). These antibodies could contribute to the elimination of HLA-DR-expressing cells by ADCC; in addition, it has been suggested that these antibodies may inhibit certain T-cell functions that involve HLA-DR molecules.

HIV envelope glycoproteins gp120 and gp160 manifest high-affinity binding to CD4 as well as to various chemokine receptors (see above). Intracellular signals transduced by gp120 through both CD4 and CCR5/CXCR4 have been associated with a number of immunopathogenic processes including anergy, apoptosis, and abnormalities of cell trafficking. The molecular mechanisms responsible for these abnormalities include dysregulation of the T-cell receptor–phosphoinositide pathway, p56lck activation, phosphorylation of focal adhesion kinase, activation of the MAP kinase and ras signaling pathways, and downregulation of the co-stimulatory molecules CD40 ligand and CD80.

Finally, the inexorable decline in CD4+ T-cell counts that occurs in most HIV-infected individuals may result in part from the inability of the immune system to regenerate the rapidly turning over CD4+ T-cell pool efficiently enough to compensate for both HIV-mediated and naturally occurring attrition of cells. At least two major mechanisms may contribute to the failure of the CD4+ T-cell pool to reconstitute itself adequately over the course of HIV infection. The first is the destruction of lymphoid precursor cells, including thymic and bone marrow progenitor cells (see above); the other is the gradual disruption of the lymphoid tissue microenvironment, which is essential for efficient regeneration of immunocompetent cells (see above).

CD8+ T Cells

A relative CD8+ T lymphocytosis is generally associated with high levels of HIV plasma viremia and may in part

reflect the expansion of clones of HIV-specific CD8+ CTLs. During the late stages of HIV infection, there may be a significant reduction in the numbers of CD8+ T cells despite the presence of high levels of viremia. HIV-specific CD8+ CTLs have been demonstrated in HIV-infected individuals early in the course of disease (see below). The emergence of HIV escape mutants may ultimately evade these HIV-specific CD8+ T cells. However, as the disease progresses, the functional capability of these cells may decrease and may be lost entirely. The cause of this loss of cytolytic activity is unclear. However, it has been demonstrated that, as disease progresses, CD8+ T cells assume an abnormal phenotype characterized by expression of activation markers such as HLA-DR and CD38 with an absence of expression of the IL-2 receptor (CD25), a loss of clonogenic potential, and a reduced expression of the IL-7 receptor (CD127). In this regard, it has been reported that nonprogressors can be distinguished from progressors by the maintenance in the former of a high proliferative capacity of their HIV-specific CD8+ T cells coupled to increases in perforin expression. It has been reported that the phenotype of CD8+ T cells in HIV-infected individuals may be of prognostic significance. Those individuals whose CD8+ T cells developed a phenotype of HLA-DR+/CD38– after seroconversion had stabilization of their CD4+ T-cell counts, whereas those whose CD8+ T cells developed a phenotype of HLA-DR+/CD38+ had a more aggressive course and a poorer prognosis. In addition to the defects in HIV-specific CTLs, functional defects in other MHC-restricted CTLs, such as those directed against influenza and CMV, have been demonstrated. CD8+ T cells secrete a variety of soluble factors that inhibit HIV replication including the CC-chemokines RANTES (CCL5), MIP-1 α (CCL3), and MIP-1 β (CCL4) as well as one or more as yet poorly identified factors (see above). The presence of high levels of HIV viremia in vivo as well as exposure of CD8+ T cells in vitro to HIV envelope, both of which are associated with aberrant immune activation, has been shown to be associated with a variety of cellular functional abnormalities. Furthermore, since the integrity of CD8+ T-cell function depends in part on adequate inductive signals from CD4+ T cells, the defect in CD8+ CTLs is likely compounded by the quantitative loss and qualitative dysfunction of CD4+ T cells. Finally, as mentioned above, certain cell surface negative regulatory molecules such as CTLA-4 and PD-1 are upregulated on activated T cells, and engagement of these molecules with their ligands may play a role in the exhaustion and death of CD8+, HIV-specific T cells.

B Cells

The predominant defect in B cells from HIV-infected individuals is one of aberrant cellular activation, which is reflected by spontaneous proliferation and immunoglobulin secretion and by increased spontaneous secretion of TNF- α and IL-6. In addition, B cells from HIV viremic patients manifest a decreased capacity to mount a proliferative response to ligation of the B-cell antigen receptor (surface IgM) at the same time as they are capable of robust differentiation in response to a variety of stimuli. B cells from

HIV-infected individuals manifest enhanced spontaneous *in vitro* transformation with EBV, a process that is likely due to defective T-cell immune surveillance. The *in vivo* counterpart of this phenomenon is an increase in the incidence of EBV-related B-cell lymphomas in HIV-infected individuals. Untransformed B cells cannot be infected with HIV. However, HIV or its products can activate B cells directly; portions of the HIV gp41 envelope protein have been reported to induce polyclonal B cell activation. In addition, it has been reported that products of the VH_3 genes on the surface of B cells can serve as a receptor for HIV. B cells from patients with high levels of viremia bind virions to their surface via the CD21 complement receptor. It is likely that *in vivo* activation of B cells by replication-competent or -defective virus as well as viral products during the viremic state account at least in part for the spontaneous activation of these cells noted *ex vivo*. B-cell subpopulations from HIV-infected individuals undergo a number of changes over the course of HIV disease, including the attrition of memory B cells; the appearance of mature, activated B cells defined by reduced expression of CD21, increased expression of activation markers, increased secretion of immunoglobulins, and increased susceptibility to Fas-mediated apoptosis; and the appearance of immature B cells associated with CD4+ T-cell lymphopenia. Cognate B cell-CD4+ T-cell interactions are abnormal in viremic HIV-infected individuals in that B cells respond poorly to CD4+ T-cell help and CD4+ T cells receive inadequate co-stimulatory signals from activated B cells. *In vivo*, the aberrant activated state of B cells manifests itself by hypergammaglobulinemia and by the presence of circulating immune complexes and autoantibodies (see above). HIV-infected individuals respond poorly to primary and secondary immunizations with protein and polysaccharide antigens. Using immunization with influenza vaccine, it has been demonstrated that there is a memory B-cell defect in HIV-infected individuals, particularly those with high levels of HIV viremia. Taken together, these B-cell defects are likely responsible in part for the increase in certain bacterial infections seen in advanced HIV disease in adults, as well as for the important role of bacterial infections in the morbidity and mortality of HIV-infected children, who cannot mount an adequate humoral response to common bacterial pathogens. The absolute number of circulating B cells may be depressed in HIV infection; this phenomenon likely reflects increased activation-induced apoptosis as well as a redistribution of cells out of the circulation and into the lymphoid tissue—phenomena that are associated with ongoing viral replication.

Monocytes/Macrophages

Circulating monocytes are generally normal in number in HIV-infected individuals. Monocytes express the CD4 molecule and several co-receptors for HIV on their surface, including CCR5, CXCR4, and CCR3, and thus are targets of HIV infection. The degree of cytopathicity of HIV for cells of the monocyte lineage is low, and HIV can replicate extensively in cells of the monocyte lineage with relatively little cytopathic effect.

Hence monocyte-lineage cells may play a role in the dissemination of HIV in the body and can serve as reservoirs of HIV infection, thus representing an obstacle to the eradication of HIV by ARV drugs. *In vivo* infection of circulating monocytes is difficult to demonstrate; however, infection of tissue macrophages and macrophage-lineage cells in the brain (infiltrating macrophages or resident microglial cells) and lung (pulmonary alveolar macrophages) can be demonstrated easily. Tissue macrophages are an important source of HIV during the inflammatory response associated with opportunistic infections. Infection of monocyte precursors in the bone marrow may directly or indirectly be responsible for certain of the hematologic abnormalities in HIV-infected individuals. A number of abnormalities of circulating monocytes have been reported in HIV-infected individuals, including decreased secretion of IL-1 and IL-12; increased secretion of IL-10; defects in antigen presentation and induction of T-cell responses due to decreased MHC class II expression; and abnormalities of Fc receptor function, C3 receptor-mediated clearance, oxidative burst responses, and certain cytotoxic functions such as ADCC, possibly related to low levels of expression of Fc and complement receptors. Exposure of monocytes to viral proteins such as gp120 and Tat, as well as to certain cytokines, can cause abnormal activation, and this may play a role in cellular dysfunction (see above).

Dendritic and Langerhans Cells

Dendritic cells may play an important role in the initiation of HIV infection by virtue of the ability of HIV to bind to cell surface C-type lectin receptors, particularly DC-SIGN (see above). This allows efficient presentation of virus to CD4+ T-cell targets that become infected; complexes of infected CD4+ T cells and dendritic cells provide an optimal microenvironment for virus replication. There has been considerable disagreement regarding the HIV infectibility and hence the depletion as well as the dysfunction of dendritic cells themselves. Depending on their state of maturation, dendritic cells express varying levels of CD4 as well as several chemokine receptors. In this regard, it appears that the ability of a dendritic cell to become infected depends in part on its state of maturation. Mature dendritic cells have been demonstrated to be infectable by both R5 and X4 isolates of HIV-1. Immature tissue dendritic cells have been less well studied in their native state. Even in those dendritic cells in which infection occurs, the efficiency of infection and level of productivity of infection is quite low compared with CD4+ T cells.

Natural Killer Cells

The role of NK cells is to provide immunosurveillance against virus-infected cells, certain tumor cells, and allogeneic cells. Functional abnormalities in NK cells have been observed throughout the course of HIV disease, and the severity of these abnormalities increases as disease progresses. HIV infection of target cells downregulates HLA-A and -B, but not HLA-C and -D molecules;

this may explain in part the relative inability of NK cells to kill HIV-infected target cells. Most studies report that NK cells are normal in number; however, patients with high levels of virus replication manifest an abnormal representation of a functionally defective CD56⁺/CD16⁺ NK cell subset. This abnormal subset of NK cells manifests an increased expression of inhibitory NK cell receptors (iNKR) and a substantial decrease in expression of natural cytotoxicity receptors (NCR) and shows a markedly impaired lytic activity. The overrepresentation of this abnormal subset of NK cells may explain in part the observed defects in NK cell function in HIV-infected individuals. NK cells also serve as important sources of HIV-inhibitory CC-chemokines. NK cells isolated from HIV-infected individuals constitutively produce high levels of MIP-1 α (CCL3), MIP-1 β (CCL4), and RANTES (CCL5). In addition, high levels of these chemokines are seen when NK cells are stimulated with IL-2 or IL-15 or when CD16 is cross-linked or during the process of lytic killing of target cells. HIV-infected patients with high levels of plasma viremia manifest a decreased ability, compared with HIV-infected individuals who are aviremic, of their NK cells to block HIV replication in vitro in assays of both cell contact and supernatant-mediated suppression of virus. Finally, NK cell–dendritic cell interactions are important for normal immune function. NK cells and dendritic cells reciprocally modulate each other's activation and maturation. These interactions are markedly impaired in HIV-infected individuals with high levels of plasma viremia.

GENETIC FACTORS IN HIV PATHOGENESIS

MHC Genes

Several reports have described MHC alleles and other host factors that may influence the pathogenesis and course of HIV disease. These include associations with transmission and with the type of clinical course, such as slow or rapid rates of progression to AIDS (Table 90-4). For example, researchers recently employed a whole-genome association strategy to identify two independently acting groups of polymorphisms associated with HLA loci B and C, which explained 15% of the variation in viral load among individuals during the asymptomatic period of infection. A number of mechanisms have been proposed whereby MHC-encoded molecules might predispose an individual either to rapid progression or to nonprogression to AIDS. These proposed mechanisms include the ability to present certain immunodominant HIV T helper or CTL epitopes, leading to a relatively protective immune response against HIV and hence to a slower rate of disease progression. In contrast, certain MHC class I or class II alleles might predispose an individual to an immunopathogenic response against viral epitopes in certain tissues, such as the CNS or lungs, or against certain HIV-infected cell types, such as macrophages or dendritic cells/Langerhans cells. In addition, certain rare MHC class I and class II alleles might facilitate rapid recognition of HIV-infected cells from the infecting partner in primary HIV infection and promote rejection of these cells by alloreactive responses. Similarly, common MHC alleles could lead to less effective removal

of HIV-infected allogeneic cells. In this regard, it has been demonstrated that allele sharing at HLA-B loci is associated with increased risk of transmission of HIV infection between heterosexual Zambian couples discordant for HIV. It has been clearly demonstrated that maximal *HLA* heterozygosity for class I loci (A, B, and C) is associated with a delayed onset of AIDS among HIV-infected individuals, whereas homozygosity for these loci was associated with a more rapid progression to AIDS and death. This observation is likely due to the fact that individuals who are heterozygous at *HLA* loci are able to present a greater variety of antigenic peptides to cytotoxic T lymphocytes than are homozygotes, resulting in a more effective immune response against a number of pathogens, including HIV. Of particular note is the fact that the *HLA* class I alleles B*35 and Cw*04 were consistently associated with rapid development of AIDS. Other data have indicated that transporter associated with antigen-processing (TAP) genes play a role in determining the outcome of HIV infection. *HLA* profiles that reflect certain combinations of MHC-encoded TAP and class I and class II genes are strongly associated with different rates of progression to AIDS. A recent finding of genetic association with HIV disease progression has highlighted the role for NK cells in HIV disease. A single nucleotide polymorphism (SNP) in the killer immunoglobulin-like receptor (KIR) gene was shown to be strongly associated with rapid progression to AIDS. However, when the KIR3 DS1 SNP was present with *HLA*-B Bw4-80I, the resultant phenotype was delayed progression to AIDS, even though this *HLA*-B allele alone has no effect on HIV disease progression. Furthermore, the KIR3 DS1/*HLA*-B Bw4-80I-carrying individuals had a significantly reduced viral load, beginning early in the course of infection, and protection against opportunistic infections during the later stages of the disease. This observation points to the potential role of NK cells in the maintenance of the viral set point, and strongly suggests that *HLA*-B Bw4-80I serves as the ligand activating the KIR, resulting in the death of the target cell. These gene-gene interactions between KIR and MHC genes are illustrated in Table 90-4.

Chemokine Receptors

The most dramatic example of a genetic factor influencing HIV infection and/or pathogenesis relates to the gene that codes for the HIV cellular co-receptor CCR5. Rare individuals have been reported who had repetitive sexual exposure to HIV in high-risk situations but remained uninfected. The peripheral blood mononuclear cells of two such individuals were found to be highly resistant to infection in vitro with R5 strains of HIV-1 but were readily infected with X4 strains. Genetic analysis revealed that these two individuals inherited a homozygous defect in the gene that codes for CCR5, the cellular co-receptor for R5 strains of HIV-1. The defective *CCR5* allele contained a 32-bp deletion corresponding to the second extracellular loop of the receptor ($\Delta 32$ allele). The encoded protein was severely truncated and the receptor was nonfunctional, explaining the refractoriness to infection with R5 strains

TABLE 90-4

HOST GENETIC FACTORS THAT INFLUENCE RISK OF TRANSMISSION AND RATES OF DISEASE PROGRESSION TO AIDS

| MHC GENES | | |
|--|---|------------------------------------|
| | HLA CLASS I ^a | HLA CLASS II ^a |
| Disease Progression | | |
| Rapid | A23, A24, A26, A28, A29, A31, B7 supertype, B*08, B14, B21, B22, B25, B35, B37, B38, B53, B44, B49, C4, C7, C8, C16, homozygosity for class I alleles | DRB1*01, DRB1*03, DRB1*05, DRB1*11 |
| Slow | A10, A19, A*30, A32, B14, B16, B17, B18, B27, B*39, B51, B57, B58, C8, heterozygosity for class I alleles | DRB1*03, DRB1*13 |
| Transmission | | |
| Increased risk | A2, B21, B35, Cw4, allele sharing between HIV donor and recipient | DRB1*05, DRB1*06, DRB1*13 |
| Reduced risk | A2/A6802 supertype, A11, B18, B52, B57, B58, C2 | |
| FACTOR | ASSOCIATION | |
| Chemokine and Chemokine Receptor Genes | | |
| CCR5 | Homozygous defect involving a 32-bp deletion corresponding to the second extracellular loop of the receptor results in loss of surface expression and, consequently, resistance to infection; heterozygous defect appears to result in partial protection against transmission and disease progression. Several single nucleotide polymorphisms (SNPs) in the CCR5 promoter have been identified that along with the CCR2-64I polymorphism define nine human haplogroups (HHA to HHE, HHF*1, HHF*2, HHG*1 and HHG*2). Homozygosity for the HHE haplotype is associated with an increased risk of transmission and an accelerated rate of disease progression. | |
| CCR2 | Heterozygosity for the CCR2-64I polymorphism is associated with a slower rate of disease progression, and in one study this effect was found to be more prominent in African Americans. | |
| CX3CR1 | Mutations 249I and 280M are associated with a rapid rate of disease progression to AIDS in a French-Caucasian cohort. Inconsistent effects were detected in other cohorts. | |
| CCL3L1 (MIP-1αP) | The copy number of CCL3L1 varies within and among populations (range 0–10 copies per diploid genome). A copy number lower than the average gene dose found in a population is associated with an increased risk of acquiring HIV and a more rapid rate of disease progression to AIDS. | |
| CCL5 (RANTES) | SNPs in the promoter, intron, and 3'-untranslated region can influence transcription and protein production and, consequently, affect risk of acquiring HIV and rates of disease progression. For example, a haplotype defined by two promoter SNPs (-471A/-96C) is associated with a faster rate of disease progression in European Americans. However, the -471A/-96G haplotype is found mostly in populations from East Asia, and this haplotype was associated with a slow rate of disease progression in a Japanese cohort. | |
| CCL2 (MCP-1) | The MCP-1 -2578G allele results in increased transcription, protein production, and monocyte recruitment. Homozygosity for the MCP-1 -2578G allele is associated with an enhanced risk of developing HIV-1-associated dementia and a rapid disease course. | |
| CXCL12 (SDF-1) | The SDF-1 3'A SNP in the 3' untranslated region was initially reported to be associated with a slower disease rate of progression in a large U.S.-based cohort, but the results in other cohorts suggest an opposite effect. | |
| Cytokine Genes | | |
| IL-10 | Individuals carrying the IL-10 -592A promoter allele were at increased risk for HIV infection and, once infected, progressed more rapidly than did homozygotes for the alternative IL-10-5'-592 C/C genotype. | |
| IL-4 | The IL-4-589T results in higher levels of IL-4 production in vivo, resulting in downregulation of CCR5. However, the effects of this polymorphism on disease progression are inconsistent. | |
| IL-6 | A single report showed that possession of the IL-6 promoter polymorphism (-174G) is associated with an increased risk of developing Kaposi's sarcoma in HIV-1-positive individuals. | |
| TNF-α | A single report showed that the SNP TNF-α-238A, but not the -308A allele, correlates with a higher frequency of lipodystrophy. | |
| Other Genes | | |
| APOBEC3G | The 186R allele is associated with a decline in CD4 T cells and an accelerated rate of progression to AIDS in African Americans. | |
| VDR | Homozygosity for the vitamin D receptor gene polymorphism B (VDR-BB) correlates with a rapid progression to AIDS. | |
| MBL2 | Conflicting effects have been reported for MBL variants. | |

(Continued)

TABLE 90-4 (CONTINUED)

HOST GENETIC FACTORS THAT INFLUENCE RISK OF TRANSMISSION AND RATES OF DISEASE PROGRESSION TO AIDS

| FACTOR | ASSOCIATION |
|-----------------------------------|--|
| Gene-Gene Interactions | |
| <i>KIR</i> gene with <i>HLA-B</i> | In the absence of <i>HLA-B</i> Bw4-80I, <i>KIR3DS1</i> is strongly associated with rapid progression to AIDS. This effect is reversed by the presence of <i>HLA-B</i> Bw4-80I. Individuals carrying both genes have a delayed progression to AIDS; in the absence of <i>KIR3DS1</i> , <i>HLA-B</i> Bw4-80I has no effect on disease progression. |
| <i>CCL3L1</i> and <i>CCR5</i> | Based on possession of a low or high copy number of <i>CCL3L1</i> (<i>CCL3L1</i> ^{low} or <i>CCL3L1</i> ^{high}) and a detrimental or nondetrimental (<i>CCR5</i> ^{det} or <i>CCR5</i> ^{nondet}) <i>CCR5</i> genotype, variations in these two genes segregate into four genetic risk groups (GRGs). In HIV-infected adults followed in a U.S.-based cohort, an association for a low, moderate, and high risk of acquiring HIV or progressing rapidly to AIDS and death was detected in those possessing a <i>CCL3L1</i> ^{high} / <i>CCR5</i> ^{nondet} , <i>CCL3L1</i> ^{high} / <i>CCR5</i> ^{det} or <i>CCL3L1</i> ^{low} / <i>CCR5</i> ^{nondet} , and <i>CCL3L1</i> ^{low} / <i>CCR5</i> ^{det} GRG, respectively. |

^aFor MHC genes, bold denotes alleles that in multiple reports have been shown to have consistent effects in different cohorts, whereas italic denotes alleles that have been shown to have effects in a few cohorts. HH, human haplogroup.

of HIV-1. Population studies revealed that ~1% of the Caucasian population of western European ancestry possessed the homozygous defect. Up to 20% of individuals of European descent were found to be heterozygous for the *CCR5*-Δ32 allele. Of note, cohort studies of hundreds of DNA samples originating from western and central Africa and Far East Asia indicate that the *CCR5*-Δ32 allele is either absent or extremely rare in these populations. A number of studies found that the frequency of *CCR5*-Δ32 allele was enriched in exposed, uninfected individuals. Furthermore, in a cohort of 1400 HIV-1-infected Caucasian individuals, no subject homozygous for the mutation was found, strongly supporting the concept that the homozygous defect confers protection against infection. This finding is particularly compelling in light of the fact that transmitting viruses are strongly biased toward R5 strains of HIV-1 (see above). Of note, several individuals have been identified who were homozygous for the *CCR5*-Δ32 defect who in fact did become infected with HIV. These individuals were found to have an X4 strain of HIV that was associated in some cases with an accelerated course of disease. In some studies, HIV-infected individuals who are heterozygous for the *CCR5*-Δ32 allele had a slower rate of disease progression. Slow progression of HIV disease is also seen in individuals who are heterozygous for the *CCR2*-64I polymorphism. This *CCR2*-64I allele-associated effect could be due to its linkage with SNPs in the *CCR5* promoter that are known to influence disease progression rates and/or due to dimerization of CXCR4 with the mutated *CCR2*-64I resulting in a decreased expression of CXCR4 on the cell surface.

A number of SNPs in the *CCR5* promoter have been associated with varied rates of disease progression. The promoter SNPs along the *CCR5*-Δ32 and *CCR2*-V64I alleles define nine *CCR5* human haplogroups (HH) designated as HHA through HHE, and HHG*1,

HHG*2, HHE*1 and HHE*2 (Table 90-4). Studies have shown that homozygosity for the HHE haplotype is associated with an increased risk of acquiring HIV and progressing rapidly to AIDS. Pairing of the HHC and the *CCR5*-Δ32-containing HHG*2 haplotype is associated with a slower rate of disease progression and reduced risk of acquiring HIV.

Chemokines

The varied distribution of the copy number of *CCL3L1* and *RANTES* polymorphisms provides some striking examples of the effect of chemokine genes on HIV pathogenesis. The *CCL3L1* gene encodes MIP-1αP, the most potent agonist of CCR5 and HIV-suppressive chemokine for R5 strains of HIV-1. This gene is present in a range of copy numbers in and among different racial groups. Individuals with fewer than average copy numbers for their racial group showed both an increased susceptibility to infection with HIV and a faster rate of progression to AIDS. When the interaction of this gene with the different *CCR5* alleles was examined, individuals with a low *CCL3L1* gene dose and certain *CCR5* alleles, which have a detrimental effect on disease progression, were shown to have a significantly greater risk of transmission and faster disease progression rates. SNPs have been identified in the gene that encodes for CCL5 (*RANTES*), another potent agonist of CCR5 and an R5 HIV-suppressive chemokine. Some of these SNPs correlate with either an increased or decreased *CCL5* gene transcription and this is thought to underlie the disease associations detected. For example, the *CCL5* -96G SNP upregulates *CCL5* gene transcription and is associated with delayed progression to AIDS in a Japanese cohort; the prevalence of this allele is very low in other populations. The opposite effects are observed for an intronic *CCL5* SNP designated as In1.1C. This SNP is

associated with decreased *CCL5* gene transcription and correlates strongly with a rapid progression rate to AIDS. Other SNPs that decrease *CCL5* gene transcription are associated with a higher rate of HIV infection. The results of these genotype-phenotype studies with *CCL3L1* and *CCL5* genes reinforce the central role for R5 viruses in the establishment of HIV infection.

Additional associations for other chemokines have been noted. *CCL2* is a one of the most potent chemokines that attracts and activates mononuclear phagocytes (MP). In a U.S. population-based study, homozygosity for the *CCL2* (*MCP-1*) -2578G allele was associated with a 50% reduction in the risk of acquiring HIV-1. However, once HIV-1 infection was established, this same *CCL2* genotype was associated with accelerated disease progression and a 4.5-fold increased risk of HIV-associated dementia. Possession of the *CCL2* -2578G allele is associated with increased *CCL2* serum levels and recruitment of MPs to inflamed tissues. Since recruitment of MPs to the CNS and the activation status of MPs in the CNS is thought to be a key determinant of HIV-associated dementia, these association studies implicate a central role for *CCL2* in the pathogenesis of HIV-related CNS disease.

Cytokines

In addition to the chemokine receptors and chemokines, polymorphisms in cytokine genes have also been found to influence intersubject differences in susceptibility to HIV/AIDS. Individuals who carry a certain allele (-592A) of the IL-10 promoter are at increased risk of infection and, once infected, progress more rapidly than homozygotes for the alternative genotype. The mechanism of this effect is felt to be a downregulation of the inhibitory cytokine IL-10 resulting in facilitation of HIV replication. The SNP, IL-4 -589T, increases IL-4 production. This allele associates with a slower progression to AIDS, presumably through the downregulation of *CCR5* by higher and more sustained levels of IL-4. However, the effects of this IL-4 polymorphism on disease progression are inconsistent in different studies.

Other Genes

Additional genes such as those involved in innate immunity, lipid metabolism, and cell cycle have also been found to be associated with altered HIV/AIDS susceptibility. For example, a histidine-arginine change at position 186 in the gene that encodes APOBEC3G is found at a higher frequency in individuals of African descent and is associated with more rapid disease progression rates. Homozygosity for the vitamin D receptor form B correlates with rapid progression to AIDS. The mechanism is thought to relate to the known effects of vitamin D on immune modulation.

The effects of some genes [e.g., *CX3CR1*, *CXCL12* (*SDF-1*), *IL-4*, *IL-6*, *TNF- α* , and *MBL2*] on HIV pathogenesis are either from a single cohort or the findings are inconsistent in different cohorts. Nevertheless, there is growing appreciation that the evolutionary histories

of human populations have had a significant impact on the distribution of variation of some genes that are thought to play a key role in HIV-1/AIDS pathogenesis, and that this might be responsible, in part, for the heterogeneous nature of the epidemiology of the HIV-1 pandemic.

NEUROPATHOGENESIS

Although there has been a remarkable decrease in the incidence of HIV encephalopathy among those with access to treatment in the era of effective ARV therapy, HIV-infected individuals can still experience a variety of neurologic abnormalities due either to opportunistic infections and neoplasms or to direct effects of HIV or its products (see below). With regard to the latter, HIV has been demonstrated in the brain and CSF of infected individuals with and without neuropsychiatric abnormalities. The main cell types that are infected in the brain in vivo are the perivascular macrophages and the microglial cells; monocytes that have already been infected in the blood can migrate into the brain, where they then reside as macrophages, or macrophages can be directly infected within the brain. The precise mechanisms whereby HIV enters the brain are unclear; however, they are thought to relate, at least in part, to the ability of virus-infected and immune-activated macrophages to induce adhesion molecules such as E-selectin and vascular cell adhesion molecule-1 (VCAM-1) on brain endothelium. Other studies have demonstrated that HIV gp120 enhances the expression of intercellular adhesion molecule-1 (ICAM-1) in glial cells; this effect may facilitate entry of HIV-infected cells into the CNS and may promote syncytia formation. Virus isolates from the brain are preferentially R5 strains as opposed to X4 strains (see above); in this regard, HIV-infected individuals who are heterozygous for *CCR5- Δ 32* appear to be relatively protected against the development of HIV encephalopathy compared with wild-type individuals. Distinct HIV envelope sequences are associated with the clinical expression of the AIDS dementia complex (see below). There is no convincing evidence that brain cells other than those of monocyte/macrophage lineage can be productively infected in vivo. Astrocytes have been reported to be susceptible to HIV infection in vitro despite the fact that they do not express detectable levels of cell-surface CD4 or the main HIV co-receptors. Nonetheless, they do not support active virus replication. There is no convincing evidence that oligodendrocytes or neurons can be infected with HIV (see below).

HIV-infected individuals may manifest white matter lesions as well as neuronal loss. Given the absence of evidence of HIV infection of neurons either in vivo or in vitro, it is highly unlikely that direct infection of these cells accounts for their loss. Rather, the HIV-mediated effects on neurons and oligodendrocytes are thought to involve indirect pathways whereby viral proteins, particularly gp120 and Tat, trigger the release of endogenous neurotoxins from macrophages and to a lesser extent from astrocytes. In addition, it has been demonstrated

that both HIV-1 Nef and Tat can induce chemotaxis of leukocytes, including monocytes, into the CNS. Neurotoxins can be released from monocytes as a consequence of infection and/or immune activation. Monocyte-derived neurotoxic factors have been reported to kill neurons via the *N*-methyl-D-aspartate (NMDA) receptor. In addition, HIV gp120 shed by virus-infected monocytes could cause neurotoxicity by antagonizing the function of vasoactive intestinal peptide (VIP), by elevating intracellular calcium levels, and by decreasing nerve growth factor levels in the cerebral cortex. A variety of monocyte-derived cytokines can contribute directly or indirectly to the neurotoxic effects in HIV infection; these include TNF- α , IL-1, IL-6, TGF- β , IFN- γ , platelet-activating factor, and endothelin. Furthermore, among the CC-chemokines, elevated levels of monocyte chemotactic protein (MCP)1 in the brain and CSF have been shown to correlate best with the presence and degree of HIV encephalopathy. In addition, infection and/or activation of monocyte-lineage cells can result in increased production of eicosanoids, nitric oxide, and quinolinic acid, which may contribute to neurotoxicity. Astrocytes may play diverse roles in HIV neuropathogenesis. Reactive gliosis or astrogliosis has been demonstrated in the brains of HIV-infected individuals, and TNF- α and IL-6 have been shown to induce astrocyte proliferation. In addition, astrocyte-derived IL-6 can induce HIV expression in infected cells in vitro. Furthermore, it has been suggested that astrocytes may downregulate macrophage-produced neurotoxins. It has been reported that HIV-infected individuals with the E4 allele for apolipoprotein E (apo E) are at increased risk for AIDS encephalopathy and peripheral neuropathy. The likelihood that HIV or its products are involved in neuropathogenesis is supported by the observation that neuropsychiatric abnormalities may undergo remarkable and rapid improvement upon the initiation of ARV therapy.

It has also been suggested that the CNS may serve as a relatively sequestered site for a reservoir of latently infected cells and for the slow, continual replication of HIV that might be a barrier for the eradication of virus by ARV therapy (see “Reservoirs of HIV-Infected Cells: Obstacle to the Eradication of Virus” earlier in the chapter).

PATHOGENESIS OF KAPOSI'S SARCOMA

There are at least four distinct epidemiologic forms of KS: (1) the classic form that occurs in older men of predominantly Mediterranean or eastern European Jewish backgrounds with no recognized contributing factors; (2) the equatorial African form that occurs in all ages, also without any recognized precipitating factors; (3) the form associated with organ transplantation and its attendant iatrogenic immunosuppressed state; and (4) the form associated with HIV-1 infection. In the latter two forms, KS is an opportunistic disease; in HIV-infected individuals, unlike typical opportunistic infections, its occurrence is not strictly related to the level of depression of CD4⁺ T-cell counts (see below). The pathogenesis of KS is complex; fundamentally, it is an angioproliferative

disease that is not a true neoplastic sarcoma, at least not in its early stages. It is a manifestation of excessive proliferation of spindle cells that are believed to be of vascular origin and have features in common with endothelial and smooth-muscle cells. In HIV disease, the development of KS is dependent on the interplay of a variety of factors including HIV-1 itself, human herpes virus 8 (HHV-8), immune activation, and cytokine secretion. A number of epidemiologic and virologic studies have clearly linked HHV-8, which is also referred to as *Kaposi's sarcoma-associated herpesvirus* (KSHV), to KS not only in HIV-infected individuals, but also in individuals with the other forms of KS. HHV-8 is a γ -herpesvirus related to EBV and herpesvirus saimiri. It encodes a homologue to human IL-6 and in addition to KS has been implicated in the pathogenesis of body cavity lymphoma, multiple myeloma, and monoclonal gammopathy of undetermined significance. Sequences of HHV-8 are found universally in the lesions of KS, and patients with KS are virtually all seropositive for HHV-8. HHV-8 DNA sequences can be found in the B cells of 30–50% of patients with KS and 7% of patients with AIDS without clinically apparent KS.

Between 1 and 2% of eligible blood donors are positive for antibodies to HHV-8, whereas the prevalence of HHV-8 seropositivity in HIV-infected men is 30–35%. The prevalence in HIV-infected women is ~4%. This finding is reflective of the lower incidence of KS in women. It has been debated whether HHV-8 is actually the transforming agent in KS; the bulk of the cells in the tumor lesions of KS are not neoplastic cells. However, it has been demonstrated that endothelial cells can be transformed in vitro by HHV-8. In this regard, HHV-8 possesses a number of genes including homologues of the IL-8 receptor, Bcl-2, and cyclin D, which can potentially transform the host cell. Despite the complexity of the pathogenic events associated with the development of KS in HIV-infected individuals, HHV-8 is the etiologic agent of this disease. The initiation and/or propagation of KS requires an activated state and is mediated, at least in part, by cytokines. A number of factors, including TNF- α , IL-1 β , IL-6, GM-CSF, basic fibroblast growth factor, and oncostatin M, function in an autocrine and paracrine manner to sustain the growth and chemotaxis of the KS spindle cells. In this regard, KSHV-derived IL-6 has been demonstrated to induce proliferation of lymphoma cells and to inhibit the cytostatic effects of INF- α on KSHV-infected lymphoma cells.

IMMUNE RESPONSE TO HIV

As detailed above and below, after the initial burst of viremia during primary infection, HIV-infected individuals mount robust immune responses that in most cases substantially curtail the levels of plasma viremia and likely contribute to delaying the ultimate development of clinically apparent disease for a median of 10 years in untreated individuals. This immune response contains elements of both humoral and cell-mediated immunity involving both innate and adaptive immune responses

TABLE 90-5**ELEMENTS OF THE IMMUNE RESPONSE TO HIV**

| |
|---|
| Humoral immunity |

| ADCC |
| Natural killer cells |

(Table 90-5; Fig. 90-24). It is directed against multiple antigenic determinants of the HIV virion as well as against viral proteins expressed on the surface of infected cells. Ironically, those CD4+ T cells with T-cell receptors specific for HIV are theoretically those CD4+ T cells most likely to be activated and thus to serve as early targets for productive HIV infection and the cell death or dysfunction associated with infection. Thus an early consequence of HIV infection is interference with and decrease of the helper cell population needed to generate an effective immune response.

Although a great deal of investigation has been directed toward delineating and better understanding the components of this immune response, it remains unclear which immunologic effector mechanisms are most important in delaying progression of infection and which, if any, play a role in the pathogenesis of HIV disease. This lack of knowledge has also hampered the ability to develop an effective vaccine for HIV disease.

HUMORAL IMMUNE RESPONSE

Antibodies to HIV usually appear within 6 weeks and almost invariably within 12 weeks of primary infection (Fig. 90-25); rare exceptions are individuals who have defects in the ability to produce HIV-specific antibodies. Detection of these antibodies forms the basis of most diagnostic screening tests for HIV infection. The appearance of HIV-binding antibodies detected by ELISA and Western blot assays occurs before the appearance of neutralizing antibodies; the latter generally appear after the initial decreases in plasma viremia, which is more closely related to the appearance of HIV-specific CD8+ T lymphocytes. The first antibodies detected are those directed against the structural or gag proteins of HIV, p24 and p17, and the gag precursor p55. The development of antibodies to p24 is associated with a decrease in the serum levels of free p24 antigen. Antibodies to the gag proteins are followed by the appearance of antibodies to the envelope proteins (gp160,

**FIGURE 90-24**

Schematic representation of the different immunologic effector mechanisms thought to be active in the setting of HIV infection. Detailed descriptions are given in the text. TCR, T-cell receptor; ADCC, antibody-dependent cellular cytotoxicity; MHC, major histocompatibility complex.

gp120, p88, and gp41) and to the products of the *pol* gene (p31, p51, and p66). In addition, one may see antibodies to the low-molecular-weight regulatory proteins encoded by the HIV genes *vpr*, *vpu*, *vif*, *rev*, *tat*, and *nef*. On rare occasion, levels of HIV-specific antibodies may decline during treatment of acute HIV infection.

Although antibodies to multiple antigens of HIV are produced, the precise functional significance of these different antibodies is unclear. The only viral proteins that elicit neutralizing antibodies are the envelope proteins gp120 and gp41. As noted above, the envelope of HIV consists of an outer envelope glycoprotein with a molecular mass of 120 kDa and a transmembrane glycoprotein with a molecular mass of 41 kDa. These are initially synthesized as a 160-kDa precursor that is cleaved by cellular proteases. Most of the anti-envelope antibodies are directed either toward an epitope in the gp41 region

**FIGURE 90-25**

Relationship between antigenemia and the development of antibodies to HIV. Antibodies to HIV proteins are generally seen 6–12 weeks after infection and 3–6 weeks after the development of plasma viremia. Late in the course of illness, antibody levels to p24 decline, generally in association with a rising titer of p24 antigen.

comprising amino acids 579–613 or toward a hypervariable region in the gp120 molecule, known as the *V3 loop region*, comprising amino acids 303–338. This V3 region is a major site for the development of mutations that lead to variants of HIV that are not well recognized by the immune system.

Antibodies directed toward the envelope proteins of HIV have been characterized both as being protective and as possibly contributing to the pathogenesis of HIV disease. Among the protective antibodies are those that function to neutralize HIV directly and prevent the spread of infection to additional cells, as well as those that participate in ADCC. Within the first 6 months of infection neutralizing antibodies appear; however, the virus quickly escapes these neutralizing antibodies. One of the principal mechanisms of immune escape is the addition of N-linked glycosylation sites. The added carbohydrate moieties interfere with envelope recognition by these initial antibodies. The hyperglycosylation of the envelope protein has been termed the *glycan shield*. Neutralizing antibodies appear to be of two forms, type-specific and group-specific. *Type-specific neutralizing antibodies* are generally directed to the V3 loop region. These antibodies neutralize only viruses of a given strain and are present in low titer in most infected individuals. *Group-specific neutralizing antibodies* are capable of neutralizing a wide variety of HIV isolates. At least two forms of group-specific antibodies have been identified: those binding to amino acids 423–437 of gp120, which lie close to the CD4 binding site, and those binding to amino acids 728–745 of gp41, which lie proximal to the viral membrane. The other major class of protective antibodies are those that participate in ADCC, which is actually a form of cell-mediated immunity in which NK cells that bear Fc receptors are armed with specific anti-HIV antibodies that bind to the NK cells via their Fc portion. These armed NK cells then bind to and destroy cells expressing HIV antigens. Antibodies to both gp120 and gp41 have been shown to participate in ADCC-mediated killing of HIV-infected cells. The levels of anti-envelope antibodies capable of mediating ADCC are highest in the earlier stages of HIV infection. In vitro, IL-2 can augment ADCC-mediated killing.

In addition to playing a role in host defense, HIV-specific antibodies have also been implicated in disease pathogenesis. Antibodies directed to gp41, when present in low titer, have been shown in vitro to be capable of facilitating infection of cells through an Fc receptor-mediated mechanism known as *antibody enhancement*. Thus the same regions of the envelope protein of HIV that give rise to antibodies capable of mediating ADCC also elicit the production of antibodies that can facilitate infection of cells in vitro. In addition, it has been postulated that anti-gp120 antibodies that participate in the ADCC killing of HIV-infected cells might also kill uninfected CD4⁺ T cells if the uninfected cells had bound free gp120, a phenomenon referred to as *bystander killing*. One of the most primitive components of the humoral immune system is the complement system. This element of innate immunity consists of ~30 proteins that are found circulating in blood or associated with cell membranes. Although HIV alone is capable of directly activating the complement cascade, the resulting lysis is weak due to the presence of host cell regulatory proteins captured in the virion envelope during budding. It is possible that complement-opsonized HIV virions have increased infectivity in a manner analogous to antibody-mediated enhancement.

CELLULAR IMMUNE RESPONSE

Given the fact that T-cell-mediated immunity is known to play a major role in host defense against most viral infections, it is generally thought to be an important component of the host immune response to HIV. T-cell immunity can be divided into two major categories, mediated respectively by the *helper/inducer CD4⁺ T cells* and the *cytotoxic/immunoregulatory CD8⁺ T cells*.

HIV-specific CD4⁺ T cells can be detected in the majority of HIV-infected patients through the use of flow cytometry to measure intracellular cytokine production in response to MHC class II tetramers pulsed with HIV peptides or through lymphocyte proliferation assays utilizing HIV antigens such as p24. HIV-specific CD4⁺ T cells may be preferential targets of HIV infection by HIV-infected antigen-presenting cells during the generation of an immune response to HIV (see above). However, they also

are likely to undergo clonal expansions in response to HIV antigens and thus survive as a population of cells. No clear correlations exist between levels of HIV-specific CD4+ T lymphocytes and plasma HIV RNA levels; however, in the setting of high viral loads, CD4+ T-cell responses to HIV antigens appear to shift from one of proliferation and IL-2 production to one of IFN- γ production. Thus, although a reverse correlation exists between the level of p24-specific proliferation and levels of plasma HIV viremia, the nature of the causal relationship between these parameters is unclear.

MHC class I-restricted, HIV-specific CD8+ T cells have been identified in the peripheral blood of patients with HIV-1 infection. These cells include CTLs that produce perforins and T cells that can be induced by HIV antigens to express an array of cytokines such as IFN- γ . CTLs have been identified in the peripheral blood of patients within weeks of HIV infection. These CD8+ T lymphocytes, through their HIV-specific antigen receptors, bind to and cause the lytic destruction of target cells bearing autologous MHC class I molecules associated with HIV antigens. Two types of CTL activity can be demonstrated in the peripheral blood or lymph node mononuclear cells of HIV-infected individuals. The first type directly lyses appropriate target cells in culture without before vitro stimulation (*spontaneous CTL activity*). The other type of CTL activity reflects the *precursor frequency of CTLs* (CTLp); this type of CTL activity can be demonstrated by stimulation of CD8+ T cells in vitro with a mitogen such as phytohemagglutinin or anti-CD3 antibody.

In addition to CTLs, CD8+ T cells capable of being induced by HIV antigens to express cytokines such as IFN- γ also appear in the setting of HIV-1 infection. It is not clear whether these are the same or different effector pools compared with those cells mediating cytotoxicity; in addition, the relative roles of each in host defense against HIV are not fully understood. It does appear that these CD8+ T cells are driven to in vivo expansion by HIV antigen. There is a direct correlation between levels of CD8+ T cells capable of producing IFN- γ in response to HIV antigens and plasma levels of HIV-1 RNA. Thus, although these cells are clearly induced by HIV-1 infection, their overall ability to control infection remains unclear. Multiple HIV antigens, including Gag, Env, Pol, Tat, Rev, and Nef, can elicit CD8+ T-cell responses. Among patients who control viral replication in the absence of ARV drugs are a subset of patients whose peripheral blood contains a population of CD8+ T cells that undergo substantial proliferation and perforin expression in response to HIV antigens. It is possible that these cells play an important role in HIV-specific host defense.

At least three other forms of cell-mediated immunity to HIV have been described: CD8+ T-cell-mediated suppression of HIV replication, ADCC, and NK cell activity. *CD8+ T-cell-mediated suppression of HIV replication* refers to the ability of CD8+ T cells from an HIV-infected patient to inhibit the replication of HIV in tissue culture in a noncytolytic manner. There is no requirement for HLA compatibility between the CD8+

T cells and the HIV-infected cells. This effector mechanism is thus nonspecific and appears to be mediated by soluble factor(s) including the CC-chemokines RANTES (CCL5), MIP-1 α (CCL3), and MIP-1 β (CCL4) (see above). These CC-chemokines are potent suppressors of HIV replication and operate at least in part via blockade of the HIV co-receptor (CCR5) for R5 (macrophage-tropic) strains of HIV-1 (see above). ADCC, as described above in relation to humoral immunity, involves the killing of HIV-expressing cells by NK cells armed with specific antibodies directed against HIV antigens. Finally, NK cells alone have been shown to be capable of killing HIV-infected target cells in tissue culture. This primitive cytotoxic mechanism of host defense is directed toward nonspecific surveillance for neoplastic transformation and viral infection through recognition of altered class I MHC molecules.

DIAGNOSIS AND LABORATORY MONITORING OF HIV INFECTION

The establishment of HIV as the causative agent of AIDS and related syndromes early in 1984 was followed by the rapid development of sensitive screening tests for HIV infection. By March 1985, blood donors in the United States were routinely screened for antibodies to HIV. In June 1996, blood banks in the United States added the p24 antigen capture assay to the screening process to help identify the rare infected individuals who were donating blood in the time (up to 3 months) between infection and the development of antibodies. In 2002 the ability to detect early infection with HIV was further enhanced by the licensure of nucleic acid testing (NAT) as a routine part of blood donor screening. These refinements decreased the interval between infection and detection (window period) from 22 days for antibody testing to 16 days with p24 antigen testing and subsequently to 12 days with nucleic acid testing. The development of sensitive assays for monitoring levels of plasma viremia ushered in a new era of being able to monitor the progression of HIV disease more closely. Utilization of these tests, coupled with the measurement of levels of CD4+ T lymphocytes in peripheral blood, is essential in the management of patients with HIV infection.

DIAGNOSIS OF HIV INFECTION

The CDC has recommended that screening for HIV infection be performed as a matter of routine health care. The diagnosis of HIV infection depends upon the demonstration of antibodies to HIV and/or the direct detection of HIV or one of its components. As noted above, antibodies to HIV generally appear in the circulation 2–12 weeks after infection.

The standard blood screening test for HIV infection is the ELISA, also referred to as an *enzyme immunoassay* (EIA). This solid-phase assay is an extremely good screening test with a sensitivity of >99.5%. Most diagnostic laboratories use a commercial EIA kit that contains antigens from both HIV-1 and HIV-2 and thus are

able to detect either. These kits use both natural and recombinant antigens and are continuously updated to increase their sensitivity to newly discovered species, such as group O viruses (Fig. 90-6). The fourth generation EIA tests combine detection of antibodies to HIV with detection of the p24 antigen of HIV. EIA tests are generally scored as positive (highly reactive), negative (nonreactive), or indeterminate (partially reactive). Although the EIA is an extremely sensitive test, it is not optimal with regard to specificity. This is particularly true in studies of low-risk individuals, such as volunteer blood donors. In this latter population, only 10% of EIA-positive individuals are subsequently confirmed to have HIV infection. Among the factors associated with false-positive EIA tests are antibodies to class II antigens, autoantibodies, hepatic disease, recent influenza vaccination, and acute viral infections. For these reasons, anyone suspected of having HIV infection based upon a positive or inconclusive EIA result must have the result confirmed with a more specific assay such as the Western blot. One can estimate whether or not an individual has a recent infection with HIV-1 by comparing the results on a standard assay that will score positive for all infected individuals to the results on an assay modified to be less sensitive ("detuned assay") that will score positive only for individuals with established HIV infection. In rare instances, an HIV-infected individual treated

early in the course of infection may revert to a negative EIA. This does *not* indicate clearing of infection; rather, it signifies levels of ongoing exposure to virus insufficient to maintain a measurable antibody response. When these individuals have discontinued therapy, viruses and antibodies have reappeared.

The most commonly used confirmatory test is the Western blot (Fig. 90-26). This assay takes advantage of the fact that multiple HIV antigens of different, well-characterized molecular weights elicit the production of specific antibodies. These antigens can be separated on the basis of molecular weight, and antibodies to each component can be detected as discrete bands on the Western blot. A negative Western blot is one in which no bands are present at molecular weights corresponding to HIV gene products. In a patient with a positive or indeterminate EIA and a negative Western blot, one can conclude with certainty that the EIA reactivity was a false positive. On the other hand, a Western blot demonstrating antibodies to products of all three of the major genes of HIV (*gag*, *pol*, and *env*) is conclusive evidence of infection with HIV. Criteria established by the U.S. Food & Drug Administration (FDA) in 1993 for a positive Western blot state that a result is considered positive if antibodies exist to two of the three HIV proteins: p24, gp41, and gp120/160. Using these criteria, ~10% of all blood donors deemed positive for HIV-1 infection

FIGURE 90-26

Western blot assay for detection of antibodies to HIV.

A. Schematic representation of how a Western blot is performed. **B.** Examples of patterns of Western blot reactivity. In each instance, the Western blot strip contains antigens to HIV-1. The serum from the patient immunized to the HIV-1

envelope contains only antibodies to the HIV-1 envelope proteins. The serum from the patient with HIV-2 infection cross-reacts with both *reverse transcriptase* and *gag* gene products of HIV-1.

lacked an antibody band to the *pol* gene product p31. Some 50% of these blood donors were subsequently found to be false positives. Thus the absence of the p31 band should increase the suspicion that one may be dealing with a false-positive test result. In this setting it is prudent to obtain additional confirmation with an RNA-based test and/or a follow-up Western blot. By definition, Western blot patterns of reactivity that do not fall into the positive or negative categories are considered “indeterminate.” There are two possible explanations for an indeterminate Western blot result. The most likely explanation in a low-risk individual is that the patient being tested has antibodies that cross-react with one of the proteins of HIV. The most common patterns of cross-reactivity are antibodies that react with p24 and/or p55. The least likely explanation in this setting is that the individual is infected with HIV and is in the process of mounting a classic antibody response. In either instance, the Western blot should be repeated in 1 month to determine whether or not the indeterminate pattern is a pattern in evolution. In addition, one may attempt to confirm a diagnosis of HIV infection with the p24 antigen capture assay or one of the tests for HIV RNA (discussed below). Although the Western blot is an excellent confirmatory test for HIV infection in patients with a positive or indeterminate EIA, it is a poor screening test. Among individuals with a negative EIA and PCR for HIV, 20–30% may show one or more bands on Western blot. Although these bands are usually faint and represent cross-reactivity, their presence creates a situation in which other diagnostic modalities (such as DNA PCR, RNA PCR, the bDNA assay, or p24 antigen capture) must be employed to ensure that the bands do not indicate early HIV infection.

A guideline for the use of these serologic tests in attempting to make a diagnosis of HIV infection is depicted in [Fig. 90-27](#). In patients in whom HIV infection is suspected, the appropriate initial test is the

EIA. If the result is negative, unless there is strong reason to suspect early HIV infection (as in a patient exposed within the previous 3 months), the diagnosis is ruled out and retesting should be performed only as clinically indicated. If the EIA is indeterminate or positive, the test should be repeated. If the repeat is negative on two occasions, one can assume that the initial positive reading was due to a technical error in the performance of the assay and that the patient is negative. If the repeat is indeterminate or positive, one should proceed to the HIV-1 Western blot. If the Western blot is positive, the diagnosis is HIV-1 infection. If the Western blot is negative, the EIA can be assumed to have been a false positive for HIV-1 and the diagnosis of HIV-1 infection is ruled out. It would be prudent at this point to perform specific serologic testing for HIV-2 following the same type of algorithm. If the Western blot for HIV-1 is indeterminate, it should be repeated in 4–6 weeks; in addition, one may proceed to a p24 antigen capture assay, HIV-1 RNA assay, or HIV-1 DNA PCR and specific serologic testing for HIV-2. If the p24 and HIV RNA assays are negative and there is no progression in the Western blot, a diagnosis of HIV-1 is ruled out. If either the p24 or HIV-1 RNA assay is positive and/or the HIV-1 Western blot shows progression, a tentative diagnosis of HIV-1 infection can be made and later confirmed with a follow-up Western blot demonstrating a positive pattern. In addition to these standard laboratory-based assays for detecting antibodies to HIV, a series of point-of-care tests are also available. Among the most popular of these is the OraQuick Rapid HIV-1 antibody test that can be run on blood, plasma, or saliva. The sensitivity and specificity of this test are each ~99%. Although negative results from this test are adequate to rule out a diagnosis of HIV infection, a positive finding should be considered preliminary and confirmed with standard serologic testing, as described above.

As mentioned above, a variety of laboratory tests are available for the direct detection of HIV or its components ([Table 90-6](#); [Fig. 90-28](#)). These tests may be of considerable help in making a diagnosis of HIV infection when the Western blot results are indeterminate. In addition, the tests detecting levels of HIV RNA can be used to determine prognosis and to assess the response to ARV therapies. The simplest of the direct detection tests is the *p24 antigen capture assay*. This is an EIA-type assay in which the solid phase consists of antibodies to the p24 antigen of HIV. It detects the viral protein p24 in the blood of HIV-infected individuals where it exists either as free antigen or complexed to anti-p24 antibodies. Overall, ~30% of individuals with untreated HIV infection have detectable levels of free p24 antigen. This increases to ~50% when samples are treated with a weak acid to dissociate antigen-antibody complexes. Throughout the course of HIV infection, an equilibrium exists between p24 antigen and anti-p24 antibodies. During the first few weeks of infection, before an immune response develops, there is a brisk rise in p24 antigen levels ([Fig. 90-25](#)). After the development of anti-p24 antibodies, these levels decline. Late in the course of infection, when circulating levels of virus are high, p24

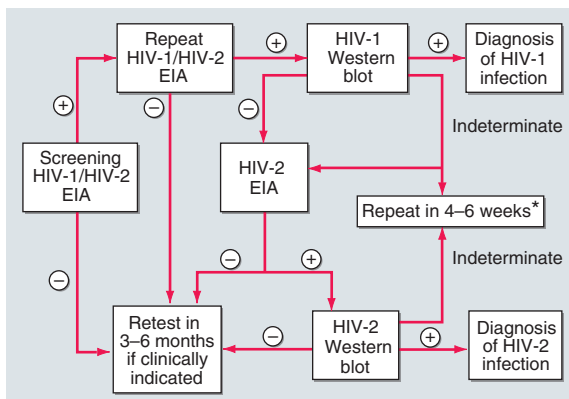

FIGURE 90-27

Algorithm for the use of serologic tests in the diagnosis of HIV-1 or HIV-2 infection. *Stable indeterminate Western blot 4–6 weeks later makes HIV infection unlikely. However, it should be repeated twice at 3-month intervals to rule out HIV infection. Alternatively, one may test for HIV-1 p24 antigen or HIV RNA. EIA, enzyme immunoassay.

TABLE 90-6

CHARACTERISTICS OF TESTS FOR DIRECT DETECTION OF HIV

| TEST | TECHNIQUE | SENSITIVITY ^a | COST/TEST ^b |
|--|--|--|------------------------|
| Immune complex–dissociated p24 antigen capture assay | Measurement of levels of HIV-1 core protein in an EIA-based format following dissociation of antigen-antibody complexes by weak acid treatment | Positive in 50% of patients; detects down to 15 pg/mL of p24 protein | \$1–2 |
| HIV RNA by PCR | PCR amplification of cDNA generated from viral RNA (target amplification) | Reliable to 40 copies/mL of HIV RNA | \$75–150 |
| HIV RNA by bDNA | Measurement of levels of particle-associated HIV RNA in a nucleic acid capture assay employing signal amplification | Reliable to 50 copies/mL of HIV RNA | \$75–150 |
| HIV RNA by NucliSens | Isothermic nucleic acid amplification with internal controls | Reliable to 80 copies/mL of HIV RNA | \$75–150 |

^aSensitivity figures refer to those approved by the U.S. FDA.

^bPrices may be lower in large volume settings.

Note: EIA, enzyme immunoassay; PCR, polymerase chain reaction.

antigen levels also increase, particularly when detected by techniques involving dissociation of antigen-antibody complexes. The p24 antigen capture assay has its greatest use as a screening test for HIV infection in patients suspected of having the acute HIV syndrome, as high levels of p24 antigen are present before the development of antibodies. Its use for routine blood donor screening for HIV infection has been replaced by use of nucleic acid testing. The ability to measure and monitor levels of HIV RNA in the plasma of patients with HIV infection has been of extraordinary value in furthering our understanding of the pathogenesis of HIV infection and in providing a diagnostic tool in settings where measurements of anti-HIV antibodies may be misleading, such as in acute infection and neonatal infection. Three assays are predominantly used for this purpose. They are

reverse transcriptase PCR (RT-PCR; Amplicor); branched DNA (bDNA; VERSANT); and nucleic acid sequence-based amplification (NASBA; NucliSens). These tests are of value in making a diagnosis of HIV infection, in establishing initial prognosis, in determining the need for therapy, and for monitoring the effects of therapy. In addition to these three commercially available tests, the DNA PCR is also employed by research laboratories for making a diagnosis of HIV infection by amplifying HIV proviral DNA from peripheral blood mononuclear cells. The commercially available RNA detection tests have a sensitivity of 40–80 copies of HIV RNA per milliliter of plasma. Research laboratory-based RNA assays can detect as few as one HIV RNA copy per milliliter, although the DNA PCR tests can detect proviral DNA at a frequency of one copy per

FIGURE 90-28

Comparison of RT-PCR and bDNA assays. **A.** Schematic representation of reverse transcriptase–polymerase chain reaction (RT-PCR) and bDNA assays. See text for detailed description. **B.** Scatter plot of \log_{10} v3-bDNA versus \log_{10} RT-PCR with the line of equity (solid) and the fitted regression

line (hatched). The equation for the fitted regression line is given in the lower-right-hand corner. There is good agreement between the two assays. v3, version 3 of the bDNA assay. (Adapted from HC Highbarger et al: *J Clin Microbiol* 37:3612, 1999.)

10,000–100,000 cells. Thus these tests are extremely sensitive. One frequent consequence of a high degree of sensitivity is some loss of specificity, and false-positive results have been reported with each of these techniques. For this reason, a positive EIA with a confirmatory Western blot remains the “gold standard” for a diagnosis of HIV infection, and the interpretation of other test results must be done with this in mind.

In the RT-PCR technique, after DNase treatment, a cDNA copy is made of all RNA species present in plasma. Insofar as HIV is an RNA virus, this will result in the production of DNA copies of the HIV genome in amounts proportional to the amount of HIV RNA present in plasma. This cDNA is then amplified and characterized using standard PCR techniques, employing primer pairs that can distinguish genomic cDNA from messenger cDNA. The bDNA assay involves the use of a solid-phase nucleic acid capture system and signal amplification through successive nucleic acid hybridizations to detect small quantities of HIV RNA. Both tests can achieve a tenfold increase in sensitivity to 40–50 copies of HIV RNA per milliliter with a preconcentration step in which plasma undergoes ultracentrifugation to pellet the viral particles. The NASBA technique involves the isothermal amplification of a sequence within the gag region of HIV in the presence of internal standards and employs the production of multiple RNA copies through the action of T7-RNA polymerase. The resulting RNA species are quantitated through hybridization with a molecular beacon DNA probe that is quenched in the absence of hybridization. The lower limit of detection for the NucliSens assay is 80 copies/mL.

In addition to being a diagnostic and prognostic tool, RT-PCR is also useful for amplifying defined areas of the HIV genome for sequence analysis and has become an important technique for studies of sequence diversity and microbial resistance to ARV agents. In patients with a positive or indeterminate EIA test and an indeterminate Western blot, and in patients in whom serologic testing may be unreliable (such as patients with hypogammaglobulinemia or advanced HIV disease), these tests for quantitating HIV RNA in plasma provide valuable tools for making a diagnosis of HIV infection; however, they should be used for diagnosis only when standard serologic testing has failed to provide a definitive result.

LABORATORY MONITORING OF PATIENTS WITH HIV INFECTION

The epidemic of HIV infection and AIDS has provided the clinician with new challenges for integrating clinical and laboratory data to effect optimal patient management. The close relationship between clinical manifestations of HIV infection and CD4+ T-cell count has made measurement of the latter a routine part of the evaluation of HIV-infected individuals. Determinations of CD4+ T-cell counts and measurements of the levels of HIV RNA in serum or plasma provide a powerful set of tools for determining prognosis and monitoring response to therapy.

CD4+ T-Cell Counts

The CD4+ T-cell count is the laboratory test generally accepted as the best indicator of the immediate state of immunologic competence of the patient with HIV infection. This measurement, which can be made directly or calculated as the product of the percent of CD4+ T cells (determined by flow cytometry) and the total lymphocyte count [determined by the white blood cell count (WBC) and the differential percent], has been shown to correlate very well with the level of immunologic competence. Patients with CD4+ T-cell counts $<200/\mu\text{L}$ are at high risk of disease from *P. jiroveci*, whereas patients with CD4+ T-cell counts $<50/\mu\text{L}$ are at high risk of disease from CMV, mycobacteria of the *M. avium* complex (MAC), and/or *T. gondii* (Fig. 90-29). Patients with HIV infection should have CD4+ T-cell measurements performed at the time of diagnosis and every 3–6 months thereafter. More frequent measurements should be made if a declining trend is noted. According to most guidelines, a CD4 T-cell count $<350/\mu\text{L}$ is an indication for consideration of initiating ARV therapy, and a decline in CD4+ T-cell count of $>25\%$ is an indication for considering a change in therapy. Once the CD4+ T-cell count is $<200/\mu\text{L}$, patients should be placed on a regimen for *P. jiroveci* prophylaxis, and once the count is $<50/\mu\text{L}$, primary prophylaxis for MAC infection is indicated. As with any laboratory measurement, one may wish to obtain two determinations before any significant changes in patient management based upon CD4+ T-cell count alone. In patients with hypersplenism or who have undergone splenectomy, the CD4+ T-cell percentage may be a more reliable indication of immune function than the CD4+ T-cell count. A CD4+ T-cell percent of 15 is comparable to a CD4+ T-cell count of $200/\mu\text{L}$.

HIV RNA Determinations

Facilitated by highly sensitive techniques for the precise quantitation of small amounts of nucleic acids, the measurement of serum or plasma levels of HIV RNA has become an essential component in the monitoring of patients with HIV infection. As discussed under diagnosis of HIV infection, the two most commonly used techniques are the RT-PCR assay and the bDNA assay. Both assays generate data in the form of number of copies of HIV RNA per milliliter of serum or plasma. Standard assays can detect as few as 40–50 copies of HIV RNA per milliliter of plasma, whereas research-based assays can detect down to one copy per milliliter. Although earlier versions of the bDNA assay generated values that were ~50% of those of the RT-PCR assay, the more recent versions (version 3 or higher) provide numbers essentially identical to those of the RT-PCR test (Fig. 90-28). Although it is common practice to describe levels of HIV RNA below these cut-offs as “undetectable,” this is a term that should be avoided, as it is imprecise and leaves the false impression that the level of virus is 0. By utilizing more sensitive, nested PCR techniques and by studying tissue levels of virus as well as plasma levels, HIV RNA can be detected in virtually every patient with HIV infection. Measurements of changes in

**FIGURE 90-29**

Relationship between CD4+ T-cell counts and the development of opportunistic diseases. Boxplot of the median (line inside the box), first quartile (bottom of the box), third quartile (top of the box), and mean (asterisk) CD4+ lymphocyte count at the time of the development of opportunistic disease. HIV RNA levels over time have been of great value in delineating the relationship between levels of virus and rates of disease progression (Fig. 90-20), the rates of viral turnover, the relationship between immune system activation and viral replication, and the time to development of drug resistance. HIV RNA measurements are greatly influenced by the state of activation of the immune system and may fluctuate greatly in the setting of secondary infections or immunization. For these reasons, decisions based upon HIV RNA levels should never be made on a single determination. Measurements of plasma HIV RNA levels should be made at the time of HIV diagnosis and every 3–6 months thereafter in the untreated patient. In general, most guidelines suggest that therapy be considered in patients with >100,000 copies of HIV RNA per milliliter (see below). After the initiation of therapy or any change in therapy, plasma HIV RNA levels should be monitored approximately every 4 weeks until the effectiveness of the therapeutic regimen is determined by the development of a new steady-state level of HIV RNA. In most instances of effective therapy this will be <50 copies per milliliter. This level of virus is generally achieved within 6 months of the initiation of effective treatment. During therapy, levels of HIV RNA should be monitored every 3–4 months to evaluate the continuing effectiveness of therapy.

HIV Resistance Testing

The availability of multiple ARV drugs as treatment options has generated a great deal of interest in the potential for measuring the sensitivity of an individual's HIV virus(es) to different ARV agents. HIV resistance testing can be done through either genotypic or phenotypic measurements. In the genotypic assays, sequence analyses of the HIV

infection; HZos, herpes zoster; KS, Kaposi's sarcoma; MAC, *Mycobacterium avium* complex bacteremia; NHL, non-Hodgkin's lymphoma; PCP, primary *Pneumocystis jiroveci* pneumonia; PCP2, secondary *P. jiroveci* pneumonia; PML, progressive multifocal leukoencephalopathy; Tox, *Toxoplasma gondii* encephalitis; WS, wasting syndrome. (From RD Moore, RE Chaisson: *Ann Intern Med* 124:633, 1996.)

genomes obtained from patients are compared with sequences of viruses with known ARV resistance profiles. In the phenotypic assays, the in vivo growth of viral isolates obtained from the patient are compared with the growth of reference strains of the virus in the presence or absence of different ARV drugs. A modification of this phenotypic approach utilizes a comparison of the enzymatic activities of the reverse transcriptase or protease genes obtained by molecular cloning of patients' isolates to the enzymatic activities of genes obtained from reference strains of HIV in the presence or absence of different drugs targeted to these genes. These tests are quite good in identifying those ARV agents that have been utilized in the past and suggesting agents that may be of future value in a given patient. Drug resistance testing in the setting of virologic failure should be performed while the patient is still on the failing regimen because of the propensity for the pool of HIV quasi-species to rapidly revert to wild-type in the absence of the selective pressure of ARV therapy. In the hands of experts, resistance testing enhances the short-term ability to decrease viral load by ~0.5 log compared with changing drugs merely on the basis of drug history. In addition to the use of resistance testing to help in the selection of new drugs in patients with virologic failure, it may also be of value in selecting an initial regimen for treatment of therapy-naïve individuals. This is particularly true in geographic areas with a high level of background resistance.

Co-Receptor Tropism Assays

After the licensure of maraviroc as the first CCR5 antagonist for the treatment of HIV infection (see below), it became necessary to be able to determine whether or not a patient's virus was likely to respond to this treatment. Patients tend to have CCR5-tropic virus

(see above) early in the course of infection, with a trend toward CXCR4 viruses later in disease. Maraviroc is only effective against CCR5-tropic viruses. Due to the fact that the genotypic determinants of cellular tropism are poorly defined, a phenotypic assay is necessary to determine this property of HIV. Two commercial assays; the Trofile assay (Monogram Biosciences) and the Phenoscript assay (VIRalliance), are available to make this determination. These assays clone the envelope regions of the patient's virus into an indicator virus that is then used to infect target cells expressing either CCR5 or CXCR4 as their co-receptor. These assays take weeks to perform and are expensive.

Other Tests

A variety of other laboratory tests have been studied as potential markers of HIV disease activity. Among these are quantitative culture of replication-competent HIV from plasma, peripheral blood mononuclear cells, or resting CD4+ T cells; circulating levels of β_2 -microglobulin, soluble IL-2 receptor, IgA, acid-labile endogenous interferon, or TNF- α ; and the presence or absence of activation markers such as CD38, HLA-DR, or PD-1 on CD8+ T cells. Although these measurements have value as markers of disease activity and help to increase our understanding of the pathogenesis of HIV disease, they do not currently play a major role in the monitoring of patients with HIV infection.

CLINICAL MANIFESTATIONS

The clinical consequences of HIV infection encompass a spectrum ranging from an acute syndrome associated with primary infection to a prolonged asymptomatic state to advanced disease. It is best to regard HIV disease as beginning at the time of primary infection and progressing through various stages. As mentioned above, active virus replication and progressive immunologic impairment occur throughout the course of HIV infection in most patients. With the exception of the rare true long-term nonprogressors (see above), HIV disease in untreated patients inexorably progresses even during the clinically latent stage. However, ARV therapy has had a major impact on blocking or slowing the progression of disease over extended periods of time in a substantial proportion of adequately treated patients (see below).

THE ACUTE HIV SYNDROME

It is estimated that 50–70% of individuals with HIV infection experience an acute clinical syndrome ~3–6 weeks after primary infection (Fig. 90-30). Varying degrees of clinical severity have been reported, and although it has been suggested that symptomatic seroconversion leading to the seeking of medical attention indicates an increased risk for an accelerated course of disease, there does not appear to be a correlation between the level of the initial burst of viremia in acute HIV infection and the subsequent course of disease. The typical clinical findings in the acute HIV syndrome are listed in Table 90-7; they

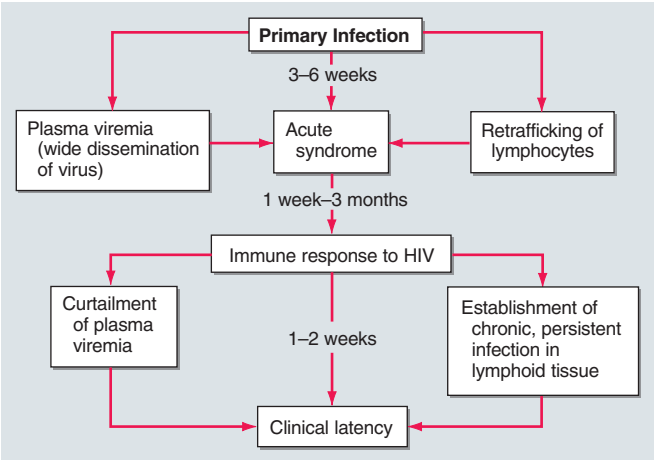

FIGURE 90-30
The acute HIV syndrome. See text for detailed description. (Adapted from G Pantaleo et al: *N Engl J Med* 328:327, 1993. Copyright 1993 Massachusetts Medical Society. All rights reserved.)

occur along with a burst of plasma viremia. It has been reported that several symptoms of the acute HIV syndrome (fever, skin rash, pharyngitis, and myalgia) occur less frequently in those infected by injection drug use versus those infected by sexual contact. The syndrome is typical of an acute viral syndrome and has been likened to acute infectious mononucleosis. Symptoms usually persist for one to several weeks and gradually subside as an immune response to HIV develops and the levels of plasma viremia decrease. Opportunistic infections have been reported during this stage of infection, reflecting the immunodeficiency that results from reduced numbers of CD4+ T cells and likely also from the dysfunction of CD4+ T cells owing to viral protein and endogenous cytokine-induced perturbations of cells (see Table 90-3) associated with the extremely high levels of plasma viremia. A number of immunologic abnormalities accompany the acute HIV syndrome, including multiphasic perturbations of the numbers of circulating lymphocyte subsets. The number of total lymphocytes and T-cell

subsets (CD4+ and CD8+) are initially reduced. An inversion of the CD4+/CD8+ T-cell ratio occurs later because of a rise in the number of CD8+ T cells. In fact, there may be a selective and transient expansion of CD8+ T-cell subsets, as determined by T-cell receptor analysis (see above). The total circulating CD8+ T-cell count may remain elevated or return to normal; however, CD4+ T-cell levels usually remain somewhat depressed, although there may be a slight rebound toward normal. Lymphadenopathy occurs in ~70% of individuals with primary HIV infection. Most patients recover spontaneously from this syndrome and many are left with only a mildly depressed CD4+ T-cell count that remains stable for a variable period before beginning its progressive decline (see below); in some individuals, the CD4+ T-cell count returns to the normal range. Approximately 10% of patients manifest a fulminant course of immunologic and clinical deterioration after primary infection, even after the disappearance of initial symptoms. In most patients, primary infection with or without the acute syndrome is followed by a prolonged period of clinical latency or smoldering low disease activity. A small percentage of HIV-infected individuals treated with ARV drugs during acute infection may revert to a negative EIA test during the time they remain on therapy. They rapidly re-seroconvert with the discontinuation of treatment.

THE ASYMPTOMATIC STAGE—CLINICAL LATENCY

Although the length of time from initial infection to the development of clinical disease varies greatly, the median time for untreated patients is ~10 years. As emphasized above, HIV disease with active virus replication is ongoing and progressive during this asymptomatic period. The rate of disease progression is directly correlated with HIV RNA levels. Patients with high levels of HIV RNA in plasma progress to symptomatic disease faster than do patients with low levels of HIV RNA (Fig. 90-20). Some patients referred to as *long-term nonprogressors* show little if any decline in CD4+ T-cell counts over extended periods of time. These patients generally have extremely low levels of HIV RNA, with a subset, referred to as *elite nonprogressors*, exhibiting HIV RNA levels <50 copies per milliliter. Certain other patients remain entirely asymptomatic despite the fact that their CD4+ T-cell counts show a steady progressive decline to extremely low levels. In these patients, the appearance of an opportunistic disease may be the first manifestation of HIV infection. During the asymptomatic period of HIV infection, the average rate of CD4+ T-cell decline is ~50/μL per year. When the CD4+ T-cell count falls to <200/μL, the resulting state of immunodeficiency is severe enough to place the patient at high risk for opportunistic infection and neoplasms and hence for clinically apparent disease.

SYMPTOMATIC DISEASE

Symptoms of HIV disease can appear at any time during the course of HIV infection. Generally speaking, the spectrum of illnesses that one observes changes as

the CD4+ T-cell count declines. The more severe and life-threatening complications of HIV infection occur in patients with CD4+ T-cell counts <200/μL. A diagnosis of AIDS is made in anyone with HIV infection and a CD4+ T-cell count <200/μL and in anyone with HIV infection who develops one of the HIV-associated diseases considered to be indicative of a severe defect in cell-mediated immunity (category C, Table 90-2). Although the causative agents of the secondary infections are characteristically opportunistic organisms such as *P. jiroveci*, atypical mycobacteria, CMV, and other organisms that do not ordinarily cause disease in the absence of a compromised immune system, they also include common bacterial and mycobacterial pathogens. Fewer than 50% of deaths among AIDS patients are as a direct result of an AIDS-defining illness, and the average CD4+ T-cell count of an HIV-infected patient at the time of death is just over 300 cells/μL. Similarly, after the widespread use of combination ARV therapy and implementation of guidelines for the prevention of opportunistic infections (Table 90-8), the incidence of secondary infections has decreased dramatically (Fig. 90-31). Overall, the clinical

NIH/CDC/IDSA 2008 GUIDELINES FOR THE PREVENTION OF OPPORTUNISTIC INFECTIONS IN PERSONS INFECTED WITH HIV

SECTION V

Viral Infections

| PATHOGEN | INDICATIONS | FIRST CHOICE(S) | ALTERNATIVES |
|--|---|---|---|
| Recommended as Standard of Care for Primary and Secondary Prophylaxis | | | |
| <i>Pneumocystis jiroveci</i> | CD4+ T-cell count <200/ μ L or Oropharyngeal candidiasis or Prior bout of PCP | Trimethoprim/sulfamethoxazole (TMP/SMZ), 1 DS tablet qd PO | Dapsone 50 mg bid PO or 100 mg/d PO Dapsone 50 mg/d PO + Pyrimethamine 50 mg/wk PO + Leucovorin 25 mg/wk PO Dapsone 200 mg PO + Pyrimethamine 75 mg PO + Leucovorin 25 mg PO weekly Aerosolized pentamidine, 300 mg qm via Respirgard II nebulizer Atovaquone 1500 mg/d PO TMP/SMZ 1 DS tablet PO 3 \times /wk |
| | May stop prophylaxis if CD4+ T-cell count >200/ μ L for \geq 3 mo | TMP/SMZ, 1 SS tablet qd PO | |
| <i>Mycobacterium tuberculosis</i> | | | |
| Isoniazid sensitive | Skin test >5 mm or Prior positive test without treatment or Close contact with case of active pulmonary TB | Isoniazid 300 mg PO + Pyridoxine 50 mg PO qd \times 9 mo Isoniazid 900 mg PO + Pyridoxine 100 mg PO 2 \times /wk \times 9 mo | Isoniazid 900 mg PO + pyridoxine 50 mg PO 2 \times /wk \times 9 mo Isoniazid 300 mg + rifampin 600 mg (or rifabutin 300 mg) + pyridoxine 50 mg/d \times 4 mo |
| Isoniazid resistant | Same with high probability of exposure to isoniazid-resistant TB | Rifabutin 300 mg or Rifampin 600 mg PO qd \times 4 mo | |
| Multidrug resistant | Same with high probability of exposure to multidrug resistant TB | Consult local public health authorities | |
| <i>Mycobacterium-avium</i> complex | CD4+ T-cell count <50/ μ L | Azithromycin 1200 mg weekly PO or Clarithromycin 500 mg bid PO | Rifabutin 300 mg/d PO Azithromycin 1200 mg weekly PO + Rifabutin 300 mg/d PO Azithromycin 500 mg/d PO + |
| | Prior documented disseminated disease | Clarithromycin 500 mg bid PO + | |
| | May stop prophylaxis if CD4+ T-cell count >100/ μ L for \geq 3 mo | Ethambutol 15 (mg/kg)/d PO +/- Rifabutin 300 mg/d PO | Ethambutol 15 (mg/kg)/d PO +/- Rifabutin 300 mg/d PO |
| <i>Toxoplasma gondii</i> | TOXO IgG antibody and CD4+ T-cell count <100/ μ L | TMP/SMZ 1 DS tablet PO qd | TMP/SMZ 1 DS 3 \times weekly Dapsone 50 mg/d PO + Pyrimethamine 50 mg weekly PO + Leucovorin 25 mg weekly PO Dapsone 200 mg PO + Pyrimethamine 75 mg PO + Leucovorin 25 mg PO weekly Atovaquone 1500 mg PO +/- Pyrimethamine 25 mg PO + Leucovorin 10 mg PO daily Clindamycin 600 mg q8h PO + Pyrimethamine 25–50 mg/d PO + Leucovorin 10–25 mg/d PO Atovaquone 750 mg PO q6–12 h +/- Pyrimethamine 25 mg/d + Leucovorin 10 mg/d PO |
| | Prior toxoplasmic encephalitis and CD4+ T-cell count <200 | Sulfadiazine 500–1000 mg qid PO + pyrimethamine 25–50 mg/d PO + leucovorin 10–25 mg/d PO | |
| | May stop prophylaxis if CD4+ T-cell count >200/ μ L for \geq 3 months | | |
| Varicella-zoster virus | Significant exposure to chickenpox or shingles in a patient with no history of immunization or prior exposure to either | Varicella zoster immune globulin 6.25 mL, IM, within 96 h of exposure | |
| <i>Cryptococcus neoformans</i> | Prior documented disease May stop prophylaxis if CD4+ T-cell count >200 for 6 mo and no evidence of active infection | Fluconazole 200 mg/d PO | Itraconazole 200 mg/d PO |

(Continued)

TABLE 90-8 (CONTINUED)

NIH/CDC/IDSA 2008 GUIDELINES FOR THE PREVENTION OF OPPORTUNISTIC INFECTIONS IN PERSONS INFECTED WITH HIV

| PATHOGEN | INDICATIONS | FIRST CHOICE(S) | ALTERNATIVES |
|---|--|--|---|
| <i>Histoplasma capsulatum</i> | Prior documented disease May stop prophylaxis after 1 year if CD4+ T-cell count >150 and patient on ARV therapy for ≥6 mo | Itraconazole 200 mg bid PO | Fluconazole 800 mg/d PO |
| <i>Coccidioides immitis</i> | Prior documented disease or Positive serology and CD4+ T-cell count <250 [for this indication, prophylaxis can be stopped if CD4+ T-cell count ≥250 for 6 mo] | Fluconazole 400 mg/d PO | Itraconazole 200 mg bid PO |
| <i>Penicillium marneffei</i> | Prior documented disease May stop secondary prophylaxis in patients on ARVs with CD4+ T-cell count >100 for ≥6 mo | Itraconazole 200 mg/d PO | |
| <i>Salmonella</i> species | Prior bacteremia | Ciprofloxacin 500 mg bid PO for 6 mo or more | |
| <i>Bartonella</i> | Prior infection May stop if CD4+ T-cell count >200 for >3 mo | Doxycycline 200 mg/d Azithromycin 1200 mg weekly PO Clarithromycin 500 mg bid PO | |
| Cytomegalovirus | Prior end-organ disease May stop prophylaxis if CD4+ T-cell count >100/μL for 6 mo and no evidence of active CMV disease Restart if prior retinitis and CD4+ T cells <100/μL | Ganciclovir, 5–6 mg/kg 5–7 d/wk IV Valganciclovir 900 mg bid PO Foscarnet 90–120 (mg/kg)/d IV Ganciclovir sustained-release implant q6–9 mo + Valganciclovir 900 mg bid PO | Cidofovir 5 mg/kg every other week IV + Probenecid Formivirsen 330 μg intravitreal q2–4 wk Valganciclovir 900 mg PO daily Formivirsen, 1 vial injected into the vitreous q2–4 wk |
| Immunizations Generally Recommended | | | |
| Hepatitis B virus | All susceptible (anti-HBc and anti-HBs negative) patients | Hepatitis B vaccine: 3 doses | |
| Hepatitis A virus | All susceptible (anti-HAV negative) patients | Hepatitis A vaccine: 2 doses | |
| Influenza virus | All patients annually | Inactivated trivalent influenza virus vaccine 1 dose yearly | Oseltamivir 75 mg PO qd Rimantadine or amantadine 100 mg PO bid (influenza A only) |
| <i>Streptococcus pneumoniae</i> | All patients, preferably before CD4+ T-cell count ≥200/μL | Pneumoccal vaccine 0.5 mL IM ×1 if CD4+ T-cell count >200/μL Reimmunize patients initially immunized at a CD4+ T-cell count <100/μL whose CD4+ T-cell count then increases to >200/μL | |
| Human papilloma-virus | Girls and women 9–26 years of age | HPV vaccine; 3 doses | |
| Recommended for Prevention of Severe or Frequent Recurrences | | | |
| Herpes simplex | Frequent/severe recurrences | Acyclovir 200 mg tid PO Acyclovir 400 mg bid PO Famciclovir 250 mg bid PO | Valacyclovir 500 mg PO bid |
| <i>Candida</i> | Frequent/severe recurrences | Fluconazole 100–200 mg/d PO | Itraconazole solution 200 mg/d PO |

Note: DS, double strength; SS, single strength; PCP, *Pneumocystis carinii* pneumonia; TB, tuberculosis.

spectrum of HIV disease is constantly changing as patients live longer and new and better approaches to treatment and prophylaxis are developed. In addition to the classic AIDS-defining illnesses, patients with HIV infection also have an increase in serious non-AIDS illnesses, including cardiovascular, renal, and hepatic disease. The physician providing care to a patient with HIV infection must be well versed in general internal medicine as well as HIV-related infectious diseases and new clinical syndromes related to chronic illness and long-term ARV therapy. In general, it should be stressed that a key element of treatment of symptomatic complications of HIV disease, whether they are primary or secondary, is achieving good control of HIV replication through the use of combination ARV therapy and instituting primary and secondary prophylaxis for opportunistic infections as indicated.

Disease of the Respiratory System

Acute bronchitis and sinusitis are prevalent during all stages of HIV infection. The most severe cases tend to occur in patients with lower CD4+ T-cell counts. Sinusitis presents as fever, nasal congestion, and headache. The diagnosis is made by CT or MRI. The maxillary sinuses are most commonly involved; however, disease is also frequently seen in the ethmoid, sphenoid, and frontal sinuses. Although some patients may improve without antibiotic therapy, radiographic improvement is quicker and more pronounced in patients who have received antimicrobial therapy. It is postulated that this high incidence of sinusitis results from an increased frequency of infection with encapsulated organisms such as *H. influenzae* and *Streptococcus pneumoniae*. In patients with low CD4+ T-cell counts, one may see mucormycosis infections of the sinuses. In contrast to the course of this infection in other patient populations, mucormycosis of the sinuses in patients with HIV infection may progress more slowly. In this setting, aggressive, frequent local debridement in addition to local and systemic amphotericin B may be needed for effective treatment.

Pulmonary disease is one of the most frequent complications of HIV infection. The most common manifestation of pulmonary disease is pneumonia. The two most common causes of pneumonia are bacterial infections and the unicellular fungus *P. jiroveci* infection. Other major causes of pulmonary infiltrates include mycobacterial infections, other fungal infections, non-specific interstitial pneumonitis, KS, and lymphoma.

Pneumonia is seen with an increased frequency in patients with HIV infection; they appear to be particularly prone to infections with encapsulated organisms. *S. pneumoniae* (Chap. 34) and *H. influenzae* (Chap. 47) are responsible for most cases of bacterial pneumonia in patients with AIDS. This may be a consequence of altered B-cell function and/or defects in neutrophil function that may be secondary to HIV disease (see above). *S. pneumoniae* (pneumococcal) infection may be the earliest serious infection to occur in patients with HIV disease. This can present as pneumonia, sinusitis, and/or bacteremia. Patients with untreated HIV infection have a sixfold increase in the incidence of pneumococcal pneumonia and a 100-fold increase in the incidence of pneumococcal

bacteremia. Pneumococcal disease may be seen in patients with relatively intact immune systems. In one study, the baseline CD4+ T-cell count at the time of a first episode of pneumococcal pneumonia was $\sim 300/\mu\text{L}$. Of interest is the fact that the inflammatory response to pneumococcal infection appears proportional to the CD4+ T-cell count. Due to this high risk of pneumococcal disease, immunization with pneumococcal polysaccharide is one of the generally recommended prophylactic measures for patients with HIV infection. This is likely most effective if given while the CD4+ T-cell count is $>200/\mu\text{L}$. It is less clear whether this intervention is effective when given to patients with more advanced disease and high viral loads.

Pneumocystis pneumonia (PCP), once the hallmark of AIDS, has dramatically declined in incidence after the development of effective prophylactic regimens and the widespread use of combination ARV therapy. It is, however, the single most common cause of pneumonia in patients with HIV infection in the United States and can be identified as a likely etiologic agent in 25% of cases of pneumonia in patients with HIV infection. Approximately 25% of cases of HIV-associated PCP occur in patients who are unaware of their HIV status. The risk of PCP is greatest among those who have experienced a previous bout of PCP and those who have CD4+ T-cell counts of $<200/\mu\text{L}$. Overall, 79% of patients with PCP have CD4+ T-cell counts $<100/\mu\text{L}$ and 95% of patients have CD4+ T-cell counts $<200/\mu\text{L}$. Recurrent fever, night sweats, thrush, and unexplained weight loss are also associated with an increased incidence of PCP. For these reasons, it is strongly recommended that all patients with CD4+ T-cell counts $<200/\mu\text{L}$ (or a CD4 percentage <15) receive some form of PCP prophylaxis. The incidence of PCP is approaching zero in patients with known HIV infection receiving appropriate ARV therapy and prophylaxis. In the United States, primary PCP is now occurring at a median CD4+ T-cell count of $36/\mu\text{L}$, whereas secondary PCP is occurring at a median CD4+ T-cell count of $10/\mu\text{L}$. Patients with PCP generally present with fever and a cough that is usually nonproductive or productive of only scant amounts of white sputum. They may complain of a characteristic retrosternal chest pain that is worse on inspiration and is described as sharp or burning. HIV-associated PCP may have an indolent course characterized by weeks of vague symptoms and should be included in the differential diagnosis of fever, pulmonary complaints, or unexplained weight loss in any patient with HIV infection and <200 CD4+ T-cells/ μL . The most common finding on chest x-ray is either a normal film, if the disease is suspected early, or a faint bilateral interstitial infiltrate. The classic finding of a dense perihilar infiltrate is unusual in patients with AIDS. In patients with PCP who have been receiving aerosolized pentamidine for prophylaxis, one may see an x-ray picture of upper lobe cavitory disease, reminiscent of TB. Other less common findings on chest x-ray include lobar infiltrates and pleural effusions. Routine laboratory evaluation is usually of little help in the differential diagnosis of PCP. A mild leukocytosis is common,

although this may not be obvious in patients with prior neutropenia. Arterial blood gases may indicate hypoxemia with a decline in PaO_2 and an increase in the arterial-alveolar ($a - A$) gradient. Arterial blood gas measurements not only aid in making the diagnosis of PCP, but also provide important information for staging the severity of the disease and directing treatment (see below). A definitive diagnosis of PCP requires demonstration of the organism in samples obtained from induced sputum, bronchoalveolar lavage, transbronchial biopsy, or open lung biopsy. PCR has been used to detect specific DNA sequences for *P. jiroveci* in clinical specimens where histologic examinations have failed to make a diagnosis.

In addition to pneumonia, a number of other clinical problems have been reported in HIV-infected patients as a result of infection with *P. jiroveci*. Otic involvement may be seen as a primary infection, presenting as a polypoid mass involving the external auditory canal. In patients receiving aerosolized pentamidine for prophylaxis against PCP, one may see a variety of extrapulmonary manifestations of *P. jiroveci*. These include ophthalmic lesions of the choroid, a necrotizing vasculitis that resembles Burger's disease, bone marrow hypoplasia, and intestinal obstruction. Other organs that have been involved include lymph nodes, spleen, liver, kidney, pancreas, pericardium, heart, thyroid, and adrenals. Organ infection may be associated with cystic lesions that may appear calcified on CT or ultrasound.

The standard treatment for PCP or disseminated pneumocystosis is trimethoprim/sulfamethoxazole (TMP/SMX). A high incidence of side effects, particularly skin rash and bone marrow suppression, is seen with TMP/SMX in patients with HIV infection. Alternative treatments for mild to moderate PCP include dapsone/trimethoprim and clindamycin/primaquine. Intravenous pentamidine is the treatment of choice for severe disease in the patient unable to tolerate TMP/SMX. For patients with a $\text{PaO}_2 < 70$ mmHg or with an $a - A$ gradient >35 mmHg, adjunct glucocorticoid therapy should be used in addition to specific antimicrobials. Overall, treatment should be for 21 days and followed by secondary prophylaxis. Prophylaxis for PCP is indicated for any HIV-infected individual who has experienced a prior bout of PCP, any patient with a CD4+ T-cell count of $<200/\mu\text{L}$ or a CD4 percentage <15 , any patient with unexplained fever for >2 weeks, and any patient with a history of oropharyngeal candidiasis. The preferred regimen for prophylaxis is TMP/SMX, one double-strength tablet daily. This regimen also provides protection against toxoplasmosis and some bacterial respiratory pathogens. For patients who cannot tolerate TMP/SMX, alternatives for prophylaxis include dapsone plus pyrimethamine plus leucovorin, aerosolized pentamidine administered by the Respigard II nebulizer, and atovaquone. Primary or secondary prophylaxis for PCP can be discontinued in those patients treated with combination ARV therapy who maintain good suppression of HIV (<50 copies per milliliter) and CD4+ T-cell counts $>200/\mu\text{L}$ for 3–6 months.

M. tuberculosis, once thought to be on its way to extinction in the United States, experienced a resurgence associated with the HIV epidemic (Chap. 66). Worldwide, approximately one-third of all AIDS-related deaths are associated with TB. In the United States ~5% of AIDS patients have active TB. HIV infection increases the risk of developing active TB by a factor of 100. For the patient with untreated HIV infection and a positive PPD skin test, the rate of reactivation TB is 7–10% per year. Untreated TB can accelerate the course of HIV infection. Levels of plasma HIV RNA increase in the setting of active TB and decline in the setting of successful TB treatment. Active TB is most common in patients 25–44 years of age, in African Americans and Hispanics, in patients in New York City and Miami, and in patients in developing countries. In these demographic groups, 20–70% of the new cases of active TB are in patients with HIV infection. The epidemic of TB embedded in the epidemic of HIV infection probably represents the greatest health risk to the general public and the health care profession associated with the HIV epidemic. In contrast to infection with atypical mycobacteria such as MAC, active TB often develops relatively early in the course of HIV infection and may be an early clinical sign of HIV disease. In one study, the median CD4+ T-cell count at presentation of TB was $326/\mu\text{L}$. The clinical manifestations of TB in HIV-infected patients are quite varied and generally show different patterns as a function of the CD4+ T-cell count. In patients with relatively high CD4+ T-cell counts, the typical pattern of pulmonary reactivation occurs in which patients present with fever, cough, dyspnea on exertion, weight loss, night sweats, and a chest x-ray revealing cavitary apical disease of the upper lobes. In patients with lower CD4+ T-cell counts, disseminated disease is more common. In these patients, the chest x-ray may reveal diffuse or lower lobe bilateral reticulonodular infiltrates consistent with miliary spread, pleural effusions, and hilar and/or mediastinal adenopathy. Infection may be present in bone, brain, meninges, gastrointestinal tract, lymph nodes (particularly cervical lymph nodes), and viscera. Approximately 60–80% of patients have pulmonary disease, and 30–40% have extrapulmonary disease. Respiratory isolation and a negative-pressure room should be used for patients in whom a diagnosis of pulmonary TB is being considered. This approach is critical to limit nosocomial and community spread of infection. Culture of the organism from an involved site provides a definitive diagnosis. Blood cultures are positive in 15% of patients. This figure is higher in patients with lower CD4 +T-cell counts. In the setting of fulminant disease, one cannot rely upon the accuracy of a negative PPD skin test to rule out a diagnosis of TB. TB is one of the conditions associated with HIV infection for which cure is possible with appropriate therapy. Therapy for TB is generally the same in the HIV-infected patient as in the HIV-negative patient (Chap. 66). Due to the possibility of multidrug resistant or extensively drug-resistant TB, drug susceptibility testing should be performed to guide therapy. Due to pharmacokinetic interactions, adjusted doses of rifabutin

should be substituted for rifampin in patients receiving the HIV protease inhibitors or nonnucleoside reverse transcriptase inhibitors. Treatment is most effective in programs that involve directly observed therapy. Initiation of ARV therapy and/or anti-TB therapy may be associated with clinical deterioration due to immune reconstitution inflammatory syndrome (IRIS) reactions. These are most common in patients initiating both treatments at the same time, occur several weeks after initiation of therapy, and are seen more frequently in patients with advanced HIV disease. Effective prevention of active TB can be a reality if the health care professional is aggressive in looking for evidence of latent TB by making sure that all patients with HIV infection receive a PPD skin test or evaluation with an interferon- γ release assay. Anergy testing is not of value in this setting. HIV-infected individuals with a skin test reaction of >5 mm, a positive interferon- γ release assay or those who are close household contacts of persons with active TB should receive treatment with 9 months of isoniazid.

Atypical mycobacterial infections are also seen with an increased frequency in patients with HIV infection. Infections with at least 12 different mycobacteria have been reported, including *M. bovis* and representatives of all four Runyon groups. The most common atypical mycobacterial infection is with *M. avium* or *M. intracellulare* species—MAC. Infections with MAC are seen mainly in patients in the United States and are rare in Africa. It has been suggested that prior infection with *M. tuberculosis* decreases the risk of MAC infection. MAC infections probably arise from organisms that are ubiquitous in the environment, including both soil and water. The presumed portals of entry are the respiratory and gastrointestinal tract. MAC infection is a late complication of HIV infection, predominantly occurring in patients with CD4+ T-cell counts of $<50/\mu\text{L}$. The average CD4+ T-cell count at the time of diagnosis is $10/\mu\text{L}$. The most common presentation is disseminated disease with fever, weight loss, and night sweats. At least 85% of patients with MAC infection are mycobacteremic, and large numbers of organisms can often be demonstrated on bone marrow biopsy. The chest x-ray is abnormal in $\sim 25\%$ of patients, with the most common pattern being that of a bilateral, lower lobe infiltrate suggestive of miliary spread. Alveolar or nodular infiltrates and hilar and/or mediastinal adenopathy can also occur. Other clinical findings include endobronchial lesions, abdominal pain, diarrhea, and lymphadenopathy. The diagnosis is made by the culture of blood or involved tissue. The finding of two consecutive sputum samples positive for MAC is highly suggestive of pulmonary infection. Cultures may take 2 weeks to turn positive. Therapy consists of a macrolide, usually clarithromycin, with ethambutol. Some physicians elect to add a third drug from among rifabutin, ciprofloxacin, or amikacin in patients with extensive disease. Therapy is generally for life; however, with the use of highly active antiretroviral therapy (HAART), it is possible to discontinue therapy in patients with sustained suppression of HIV replication and CD4+ T-cell counts $>100/\mu\text{L}$ for 3–6 months.

Primary prophylaxis for MAC is indicated in patients with HIV infection and CD4+ T-cell counts $<50/\mu\text{L}$. This may be discontinued in patients in whom HAART induces a sustained suppression of viral replication and increases in CD4+ T-cell counts to $>100/\mu\text{L}$ for 3–6 months.

Rhodococcus equi is a gram-positive pleomorphic acid-fast non-spore-forming bacillus that can cause pulmonary and/or disseminated infection in patients with HIV infection. Fever and cough are the most common presenting signs. Radiographically, one may see cavitary lesions and consolidation. Blood cultures are often positive. Treatment is based upon antimicrobial sensitivity testing.

Fungal infections of the lung, in addition to PCP, can be seen in patients with AIDS. Patients with pulmonary cryptococcal disease present with fever, cough, dyspnea, and in some cases, hemoptysis. A focal or diffuse interstitial infiltrate is seen on chest x-ray in $>90\%$ of patients. In addition, one may see lobar disease, cavitary disease, pleural effusions, and hilar or mediastinal adenopathy. Over half of patients are fungemic, and 90% of patients have concomitant CNS infection. *Coccidioides immitis* is a mold that is endemic in the southwest United States. It can cause a reactivation pulmonary syndrome in patients with HIV infection. Most patients with this condition will have CD4+ T-cell counts $<250/\mu\text{L}$. Patients present with fever, weight loss, cough, and extensive, diffuse reticulonodular infiltrates on chest x-ray. One may also see nodules, cavities, pleural effusions, and hilar adenopathy. Although serologic testing is of value in the immunocompetent host, serologies are negative in 25% of HIV-infected patients with coccidioidal infection. Invasive aspergillosis is not an AIDS-defining illness and is generally not seen in patients with AIDS in the absence of neutropenia or administration of glucocorticoids. *Aspergillus* infection may have an unusual presentation in the respiratory tract of patients with AIDS where it gives the appearance of a pseudomembranous tracheobronchitis. Primary pulmonary infection of the lung may be seen with *histoplasmosis*. The most common pulmonary manifestation of histoplasmosis, however, is in the setting of disseminated disease, presumably due to reactivation. In this setting, respiratory symptoms are usually minimal, with cough and dyspnea occurring in 10–30% of patients. The chest x-ray is abnormal in $\sim 50\%$ of patients, showing either a diffuse interstitial infiltrate or diffuse small nodules.

Two forms of *idiopathic interstitial pneumonia* have been identified in patients with HIV infection: lymphoid interstitial pneumonitis (LIP) and nonspecific interstitial pneumonitis (NIP). LIP, a common finding in children, is seen in about 1% of adult patients with untreated HIV infection. This disorder is characterized by a benign infiltrate of the lung and is thought to be part of the polyclonal activation of lymphocytes seen in the context of HIV and EBV infections. Transbronchial biopsy is diagnostic in 50% of the cases, with an open-lung biopsy required for diagnosis in the remainder of cases. This condition is generally self-limited and no specific treatment is necessary. Severe cases have been managed

with brief courses of glucocorticoids. Although rarely a clinical problem since the use of HAART, evidence of NIP may be seen in up to half of all patients with untreated HIV infection. Histologically, interstitial infiltrates of lymphocytes and plasma cells in a perivascular and peribronchial distribution are present. When symptomatic, patients present with fever and nonproductive cough occasionally accompanied by mild chest discomfort. Chest x-ray is usually normal or may reveal a faint interstitial pattern. Similar to LIP, NIP is a self-limited process for which no therapy is indicated other than appropriate management of the underlying HIV infection. HIV-related pulmonary arterial hypertension (HIV-PAH) is seen in ~0.5% of HIV-infected individuals. Patients may present with an array of symptoms including shortness of breath, fatigue, syncope, chest pain, and signs of right-sided heart failure. Chest x-ray reveals dilated pulmonary vessels and right-sided cardiomegaly with right ventricular hypertrophy seen on electrocardiogram. ARV therapy does not appear to be of clear benefit, and the prognosis is quite poor, with a median survival in the range of 2 years.

Neoplastic diseases of the lung including KS and lymphoma are discussed below in the section on malignancies.

Diseases of the Cardiovascular System

Heart disease is a relatively common postmortem finding in HIV-infected patients (25–75% in autopsy series). Cardiovascular disease may be seen as a direct consequence of HIV infection or as a consequence of ARV therapy as part of the lipodystrophy syndrome. As a primary consequence of HIV infection, the most common clinically significant finding is a dilated cardiomyopathy associated with congestive heart failure (CHF), referred to as *HIV-associated cardiomyopathy*. This generally occurs as a late complication of HIV infection and, histologically, displays elements of myocarditis. For this reason, some have advocated treatment with intravenous immunoglobulin (IVIg). HIV can be directly demonstrated in cardiac tissue in this setting, and there is debate over whether or not it plays a direct role in this condition. Patients present with typical findings of CHF, namely edema and shortness of breath. Patients with HIV infection may also develop cardiomyopathy as side effects of IFN- α or nucleoside analogue therapy. These are reversible once therapy is stopped. KS, cryptococcosis, Chagas' disease, and toxoplasmosis can involve the myocardium, leading to cardiomyopathy. In one series, most patients with HIV infection and a treatable myocarditis were found to have myocarditis associated with toxoplasmosis. Most of these patients also had evidence of CNS toxoplasmosis. Thus MRI or double-dose contrast CT scan of the brain should be included in the workup of any patient with advanced HIV infection and cardiomyopathy.

A variety of other cardiovascular problems are found in patients with HIV infection. Pericardial effusions may be seen in the setting of advanced HIV infection. Predisposing factors include TB, CHF, mycobacterial infection, cryptococcal infection, pulmonary infection, lymphoma,

and KS. Although pericarditis is quite rare, in one series, 5% of patients with HIV disease had pericardial effusions that were considered to be moderate or severe. Tamponade and death have occurred in association with pericardial KS, presumably owing to acute hemorrhage. Nonbacterial thrombotic endocarditis has been reported and should be considered in patients with unexplained embolic phenomena. Intravenous pentamidine, when given rapidly, can result in hypotension as a consequence of cardiovascular collapse. A high percentage of patients have hypertriglyceridemia and elevations in serum cholesterol, and coronary artery disease has been a relatively frequent finding at autopsy. This problem appears to be becoming even more prevalent as a side effect of HAART and in particular in patients with co-infection with HCV. Although the clinical significance of these findings has not been precisely defined, recent data suggest a linear relationship between time on HAART and development of ischemic heart disease. In one large series, the overall rate of myocardial infarction (MI) was 3.5/1000 years, 28% of these events were fatal, and MI was responsible for 7% of all deaths in the cohort. The risk of MI increased by 26% per year of HAART. This small increase in the risk of death from MI in the setting of HAART has to be balanced against the marked increase in overall survival brought about by HAART. Efforts to decrease the risk of cardiovascular diseases by minimizing the time on HAART were associated with a paradoxical increase in the rate of cardiovascular disease, suggesting that the pathogenesis of cardiovascular diseases in the setting of HIV infection is multifactorial, with HIV infection and the resulting immune activation and coagulopathy likely playing a significant role.

Diseases of the Oropharynx and Gastrointestinal System

Oropharyngeal and gastrointestinal diseases are common features of HIV infection. They are most frequently due to secondary infections. In addition, oral and gastrointestinal lesions may occur with KS and lymphoma.

Oral lesions, including *thrush*, *hairy leukoplakia*, and *aphthous ulcers* (Fig. 90-32), are particularly common in patients with untreated HIV infection. Thrush, due to *Candida* infection, and oral hairy leukoplakia, presumed due to EBV, are usually indicative of fairly advanced immunologic decline; they generally occur in patients with CD4+ T-cell counts of <300/ μ L. In one study, 59% of patients with oral candidiasis went on to develop AIDS in the next year. Thrush appears as a white, cheesy exudate, often on an erythematous mucosa in the posterior oropharynx. Although most commonly seen on the soft palate, early lesions are often found along the gingival border. The diagnosis is made by direct examination of a scraping for pseudohyphal elements. Culturing is of no diagnostic value, as most patients with HIV infection will have a positive throat culture for *Candida* even in the absence of thrush. Oral hairy leukoplakia presents as white, frondlike lesions, generally along the lateral borders of the tongue and sometimes on the adjacent buccal mucosa (Fig. 90-32). Despite its name, oral hairy

**FIGURE 90-32**

Various oral lesions in HIV-infected individuals. A. Thrush. **B.** Hairy leukoplakia. **C.** Aphthous ulcer. **D.** Kaposi's sarcoma.

leukoplakia is not considered a premalignant condition. Lesions are associated with florid replication of EBV. Although usually more disconcerting as a sign of HIV-associated immunodeficiency than a clinical problem in need of treatment, severe cases have been reported to respond to topical podophyllin or systemic therapy with anti-herpesvirus agents. Aphthous ulcers of the posterior oropharynx are also seen with regularity in patients with HIV infection (Fig. 90-32). These lesions are of unknown etiology and can be quite painful and interfere with swallowing. Topical anesthetics provide immediate symptomatic relief of short duration. The fact that thalidomide is an effective treatment for this condition suggests that the pathogenesis may involve the action of tissue-destructive cytokines. Palatal, glossal, or gingival ulcers may also result from cryptococcal disease or histoplasmosis.

Esophagitis (Fig. 90-33) may present with odynophagia and retrosternal pain. Upper endoscopy is generally required to make an accurate diagnosis. Esophagitis may

be due to *Candida*, CMV, or HSV. Although CMV tends to be associated with a single large ulcer, HSV infection is more often associated with multiple small ulcers. The esophagus may also be the site of KS and lymphoma. Like the oral mucosa, the esophageal mucosa may have large, painful ulcers of unclear etiology that may respond to thalidomide. Although achlorhydria is a common problem in patients with HIV infection, other gastric problems are generally rare. Among the conditions involving the stomach are KS and lymphoma. Infections of the small and large intestine leading to diarrhea, abdominal pain, and occasionally fever are among the most significant gastrointestinal problems in HIV-infected patients. They include infections with bacteria, protozoa, and viruses.

Bacteria may be responsible for secondary infections of the gastrointestinal tract. Infections with enteric pathogens such as *Salmonella*, *Shigella*, and *Campylobacter* are more common in homosexual men and are often more severe and more apt to relapse in patients with HIV infection. Patients with untreated HIV have

**FIGURE 90-33**

Barium swallow of a patient with *Candida* esophagitis. The flow of barium along the mucosal surface is grossly irregular.

approximately a 20-fold increased risk of infection with *S. typhimurium*. They may present with a variety of non-specific symptoms including fever, anorexia, fatigue, and malaise of several weeks' duration. Diarrhea is common but may be absent. Diagnosis is made by culture of blood and stool. Long-term therapy with ciprofloxacin is the recommended treatment. HIV-infected patients also have an increased incidence of *S. typhi* infection in areas of the world where typhoid is a problem. *Shigella* spp., particularly *S. flexneri*, can cause severe intestinal disease in HIV-infected individuals. Up to 50% of patients will develop bacteremia. *Campylobacter* infections occur with an increased frequency in patients with HIV infection. Although *C. jejuni* is the strain most frequently isolated, infections with many other strains have been reported. Patients usually present with crampy abdominal pain, fever, and bloody diarrhea. Infection may present as proctitis. Stool examination reveals the presence of fecal leukocytes. Systemic infection can occur, with up to 10% of infected patients exhibiting bacteremia. Most strains are sensitive to erythromycin. Abdominal pain and diarrhea may be seen with MAC infection.

Fungal infections may also be a cause of diarrhea in patients with HIV infection. Histoplasmosis, coccidioidomycosis, and penicilliosis have all been identified as a cause of fever and diarrhea in patients with HIV infection. Peritonitis has been seen with *C. immitis*.

Cryptosporidia, microsporidia, and *Isospora belli* (Chap. 122) are the most common opportunistic protozoa that infect the gastrointestinal tract and cause diarrhea in HIV-infected patients. Cryptosporidial infection may present in a variety of ways, ranging from a self-limited or intermittent diarrheal illness in patients in the

early stages of HIV infection to a severe, life-threatening diarrhea in severely immunodeficient individuals. In patients with untreated HIV infection and CD4+ T-cell counts of $<300/\mu\text{L}$, the incidence of cryptosporidiosis is ~1% per year. In 75% of cases, the diarrhea is accompanied by crampy abdominal pain, and 25% of patients have nausea and/or vomiting. Cryptosporidia may also cause biliary tract disease in the HIV-infected patient, leading to cholecystitis with or without accompanying cholangitis. The diagnosis of cryptosporidial diarrhea is made by stool examination. The diarrhea is noninflammatory, and the characteristic finding is the presence of oocysts that stain with acid-fast dyes. Therapy is predominantly supportive, and marked improvements have been reported in the setting of effective ARV therapy. Treatment with up to 2000 mg/d of nitazoxanide (NTZ) is associated with improvement in symptoms or a decrease in shedding of organisms in about half of patients. Its overall role in the management of this condition remains unclear. Patients can minimize their risk of developing cryptosporidiosis by avoiding contact with human and animal feces and by not drinking untreated water from lakes or rivers.

Microsporidia are small, unicellular, obligate intracellular parasites that reside in the cytoplasm of enteric cells (Chap. 122). The main species causing disease in humans is *Enterocytozoon bienersi*. The clinical manifestations are similar to those described for cryptosporidia and include abdominal pain and diarrhea. The small size of the organism may make it difficult to detect; however, with the use of chromotrope-based stains, organisms can be identified in stool samples by light microscopy. Definitive diagnosis generally depends on electron-microscopic examination of a stool specimen, intestinal aspirate, or intestinal biopsy specimen. In contrast to cryptosporidia, microsporidia have been noted in a variety of extraintestinal locations, including the eye, muscle, and liver, and have been associated with conjunctivitis and hepatitis. Albendazole, 400 mg bid, has been reported to be of benefit in some patients.

I. belli is a coccidian parasite (Chap. 122) most commonly found as a cause of diarrhea in patients from the Caribbean and Africa. Its cysts appear in the stool as large, acid-fast structures that can be differentiated from those of cryptosporidia on the basis of size, shape, and number of sporocysts. The clinical syndromes of *Isospora* infection are identical to those caused by cryptosporidia. The important distinction is that infection with *Isospora* is generally relatively easy to treat with TMP/SMX. Although relapses are common, a thrice-weekly regimen of TMP/SMX appears adequate to prevent recurrence.

CMV colitis was once seen as a consequence of advanced immunodeficiency in 5–10% of patients with AIDS. It is much less common with the advent of HAART. CMV colitis presents as diarrhea, abdominal pain, weight loss, and anorexia. The diarrhea is usually nonbloody, and the diagnosis is achieved through endoscopy and biopsy. Multiple mucosal ulcerations are seen at endoscopy, and biopsies reveal characteristic intranuclear inclusion bodies. Secondary bacteremias may result as a consequence of thinning of the bowel wall.

Treatment is with either ganciclovir or foscarnet for 3–6 weeks. Relapses are common, and maintenance therapy is typically necessary in patients whose HIV infection is poorly controlled. Patients with CMV disease of the gastrointestinal tract should be carefully monitored for evidence of CMV retinitis.

In addition to disease caused by specific secondary infections, patients with HIV infection may also experience a chronic diarrheal syndrome for which no etiologic agent other than HIV can be identified. This entity is referred to as *AIDS enteropathy* or *HIV enteropathy*. It is most likely a direct result of HIV infection in the gastrointestinal tract. Histologic examination of the small bowel in these patients reveals low-grade mucosal atrophy with a decrease in mitotic figures, suggesting a hyporegenerative state. Patients often have decreased or absent small-bowel lactase and malabsorption with accompanying weight loss.

The initial evaluation of a patient with HIV infection and diarrhea should include a set of stool examinations, including culture, examination for ova and parasites, and examination for *Clostridium difficile* toxin. Approximately 50% of the time this workup will demonstrate infection with pathogenic bacteria, mycobacteria, or protozoa. If the initial stool examinations are negative, additional evaluation, including upper and/or lower endoscopy with biopsy, will yield a diagnosis of microsporidial or mycobacterial infection of the small intestine ~30% of the time. In patients for whom this diagnostic evaluation is nonrevealing, a presumptive diagnosis of HIV enteropathy can be made if the diarrhea has persisted for >1 month. An algorithm for the evaluation of diarrhea in patients with HIV infection is given in Fig. 90-34.

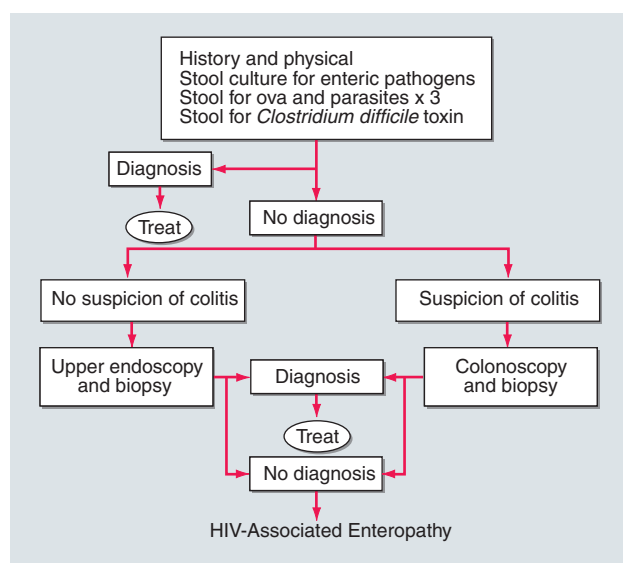

FIGURE 90-34

Algorithm for the evaluation of diarrhea in a patient with HIV infection. HIV-associated enteropathy is a diagnosis of exclusion and can be made only after other, generally treatable, forms of diarrheal illness have been ruled out.

FIGURE 90-35

Severe, erosive perirectal herpes simplex in a patient with AIDS.

Rectal lesions are common in HIV-infected patients, particularly the perirectal ulcers and erosions due to the reactivation of HSV (Fig. 90-35). These may appear quite atypical, as denuded skin without vesicles, and they respond well to treatment with acyclovir, famciclovir, or foscarnet. Other rectal lesions encountered in patients with HIV infection include condylomata acuminata, KS, and intraepithelial neoplasia (see below).

Hepatobiliary Disease

Diseases of the hepatobiliary system are a major problem in patients with HIV infection. It has been estimated that approximately one-third of the deaths of patients with HIV infection are in some way related to liver disease. Although this is predominantly a reflection of the problems encountered in the setting of co-infection with hepatitis B or C, it is also a reflection of the hepatic injury, ranging from hepatic steatosis to hypersensitivity reactions to immune reconstitution, that can be seen in the context of ARV therapy.

The prevalence of co-infection with HIV and hepatitis viruses varies by geographic region. In the United States, ~90% of HIV-infected individuals have evidence of infection with HBV; 6–14% have chronic HBV infection; 5–50% of patients are co-infected with HCV; and co-infection with hepatitis D, E, and/or G viruses is common. Among IV drug users with HIV infection, rates of HCV infection range from 70–95%. HIV infection has a significant impact on the course of hepatitis virus infection. It is associated with approximately a threefold increase in the development of persistent hepatitis B surface antigenemia. Patients infected with both HBV and HIV have decreased evidence of inflammatory liver

disease. The presumption that this is due to the immunosuppressive effects of HIV infection is supported by the observations that this situation can be reversed, and one may see the development of more severe hepatitis after the initiation of effective ARV therapy. In studies of the impact of HIV on HBV infection, four- to tenfold increases in liver-related mortality have been noted in patients with HIV and active HBV infection compared with rates in patients with either infection alone. There is a slight increase in overall mortality in HIV-infected individuals who are also hepatitis B surface antigen (HBsAg) positive. IFN- α is less successful as a treatment of HBV in patients with HIV co-infection, and lamivudine, emtricitabine, or adefovir/tenofovir and entecavir alone or in combination are useful in the treatment of hepatitis B in patients with HIV infection. It is important to remember that all the above-mentioned drugs also have activity against HIV and should not be used as single agents in patients with HIV infection, in order to avoid the rapid development of resistant quasiespecies of HIV. HCV infection is more severe in the patient with HIV infection; it does not appear to affect overall mortality in HIV-infected individuals when other variables such as age, baseline CD4+ T-cell count, and use of HAART are taken into account. In the setting of HIV and HCV co-infection, levels of HCV are approximately tenfold higher than in the HIV-negative patient with HCV infection and there is a tenfold increased risk of death due to liver disease in co-infected patients. Treatment for HCV infection consists of pegylated IFN- α and ribavirin. If a 2-log drop in levels of HCV RNA is not seen within 12 weeks, it is unlikely that therapy will be of value. Hepatitis A virus infection is not seen with an increased frequency in patients with HIV infection. It is recommended that all patients with HIV infection who have not experienced natural infection be immunized with hepatitis A and/or hepatitis B vaccines. Infection with hepatitis G virus, also known as GB virus C, is seen in ~50% of patients with HIV infection. For reasons that are currently unclear, there are data to suggest that patients with HIV infection co-infected with this virus have a decreased rate of progression to AIDS.

A variety of other infections may also involve the liver. Granulomatous hepatitis may be seen as a consequence of mycobacterial or fungal infections, particularly MAC infection. Hepatic masses may be seen in the context of TB, peliosis hepatis, or fungal infection. Among the fungal opportunistic infections, *C. immitis* and *Histoplasma capsulatum* are those most likely to involve the liver. Biliary tract disease in the form of papillary stenosis or sclerosing cholangitis has been reported in the context of cryptosporidiosis, CMV infection, and KS.

Many of the drugs used to treat HIV infection are metabolized by the liver and can cause liver injury. Fatal hepatic reactions have been reported with a wide array of ARVs, including nucleoside analogues, nonnucleoside analogues, and protease inhibitors. Nucleoside analogues work by inhibiting DNA synthesis. This can result in toxicity to mitochondria, which can lead to disturbances in oxidative metabolism. This may manifest as hepatic steatosis and, in severe cases, lactic acidosis and fulminant

liver failure. It is important to be aware of this condition and to watch for it in patients with HIV infection receiving nucleoside analogues. It is reversible if diagnosed early and the offending agent(s) discontinued. Nevirapine has been associated with at times fatal fulminant and cholestatic hepatitis, hepatic necrosis, and hepatic failure. Indinavir may cause mild to moderate elevations in serum bilirubin in 10–15% of patients in a syndrome similar to Gilbert's syndrome. A similar pattern of hepatic injury may be seen with atazanavir. In the patient receiving HAART with an unexplained increase in hepatic transaminases, strong consideration should be given to drug toxicity. *Pancreatic injury* is most commonly a consequence of drug toxicity, notably that secondary to pentamidine or dideoxynucleosides. Although up to half of patients in some series have biochemical evidence of pancreatic injury, <5% of patients show any clinical evidence of pancreatitis that is not linked to a drug toxicity.

Diseases of the Kidney and Genitourinary Tract

Diseases of the kidney or genitourinary tract may be a direct consequence of HIV infection, due to an opportunistic infection or neoplasm, or related to drug toxicity. *HIV-associated nephropathy* was first described in IDUs and was initially thought to be IDU nephropathy in patients with HIV infection; it is now recognized as a true direct complication of HIV infection. Although the majority of patients have CD4+ T-cell counts <200/ μ L, HIV-associated nephropathy can be an early manifestation of HIV infection and is also seen in children. Over 90% of reported cases have been in African-American or Hispanic individuals; the disease is not only more prevalent in these populations, but is also more severe and is the third leading cause of end-stage renal failure among African Americans aged 20–64 in the United States. Proteinuria is the hallmark of this disorder. Overall, microalbuminuria is seen in ~20% of untreated HIV-infected patients; significant proteinuria is seen in closer to 2%. Edema and hypertension are rare. Ultrasound examination reveals enlarged, hyperechogenic kidneys. A definitive diagnosis is obtained through renal biopsy. Histologically, focal segmental glomerulosclerosis is present in 80%, and mesangial proliferation in 10–15% of cases. Before effective antiretroviral therapy, this disease was characterized by relatively rapid progression to end-stage renal disease, and patients with HIV-associated nephropathy should be treated for their HIV infection regardless of CD4+ T-cell count. Treatment with angiotensin-converting enzyme (ACE) inhibitors and/or prednisone, 60 mg/d, has also been reported to be of benefit in some cases. The incidence of this disease in patients receiving adequate ARV therapy has not been well defined; however, the impression is that it has decreased in frequency and severity. It is the leading cause of end-stage renal disease in patients with HIV infection.

Among the drugs commonly associated with renal damage in patients with HIV disease are pentamidine, amphotericin, adefovir, cidofovir, tenofovir, and foscarnet.

TMP/SMX may compete for tubular secretion with creatinine and cause an increase in the serum creatinine level. Sulfadiazine may crystallize in the kidney and result in an easily reversible form of renal shutdown. One of the most common drug-induced renal complications is indinavir-associated renal calculi. This condition is seen in ~10% of patients receiving this HIV protease inhibitor. It may present with a variety of manifestations, ranging from asymptomatic hematuria to renal colic. Adequate hydration is the mainstay of treatment and prevention for this condition.

Genitourinary tract infections are seen with a high frequency in patients with HIV infection; they present with skin lesions, dysuria, hematuria, and/or pyuria and are managed in the same fashion as in patients without HIV infection. Infections with HSV are covered below under dermatologic disorders. Infections with *T. pallidum*, the etiologic agent of *syphilis*, play an important role in the HIV epidemic. In HIV-negative individuals, genital syphilitic ulcers as well as the ulcers of chancroid are major predisposing factors for heterosexual transmission of HIV infection. Although most HIV-infected individuals with syphilis have a typical presentation, a variety of formerly rare clinical problems may be encountered in the setting of dual infection. Among them are *lues maligna*, an ulcerating lesion of the skin due to a necrotizing vasculitis; unexplained fever; nephrotic syndrome; and neurosyphilis. The most common presentation of syphilis in the HIV-infected patient is that of *condylomata lata*, a form of secondary syphilis. Neurosyphilis may be asymptomatic or may present as acute meningitis, neuroretinitis, deafness, or stroke. The rate of neurosyphilis may be as high as 1% in patients with HIV infection. As a consequence of the immunologic abnormalities seen in the setting of HIV infection, diagnosis of syphilis through standard serologic testing may be challenging. On the one hand, a significant number of patients have false-positive Venereal Disease Research Laboratory (VDRL) tests due to polyclonal B cell activation. On the other hand, the development of a new positive VDRL may be delayed in patients with new infections, and the anti-fluorescent treponema antibody (anti-FTA) test may be negative due to immunodeficiency. Thus dark-field examination of appropriate specimens should be performed in any patient in whom syphilis is suspected, even if the patient has a negative VDRL. Similarly, any patient with a positive serum VDRL test, neurologic findings, and an abnormal spinal fluid examination should be considered to have neurosyphilis, regardless of the CSF VDRL result. In any setting, patients treated for syphilis need to be carefully monitored to ensure adequate therapy.

Vulvovaginal candidiasis is a common problem in women with HIV infection. Symptoms include pruritus, discomfort, dyspareunia, and dysuria. Vulvar infection may present as a morbilliform rash that may extend to the thighs. Vaginal infection is usually associated with a white discharge, and plaques may be seen along an erythematous vaginal wall. Diagnosis is made by microscopic examination of the discharge for pseudohyphal elements in a 10% potassium hydroxide solution. Mild

disease can be treated with topical therapy. More serious disease can be treated with fluconazole. Other causes of vaginitis include *Trichomonas* and mixed bacteria.

Diseases of the Endocrine System and Metabolic Disorders

A variety of endocrine and metabolic disorders are seen in the context of HIV infection. Between 33 and 75% of patients with HIV infection receiving HAART develop a syndrome often referred to as *lipodystrophy*, consisting of elevations in plasma triglycerides, total cholesterol, and apolipoprotein B, as well as hyperinsulinemia and hyperglycemia. Many of the patients have been noted to have a characteristic set of body habitus changes associated with fat redistribution, consisting of truncal obesity coupled with peripheral wasting (**Fig. 90-36**). Truncal obesity is apparent as an increase in abdominal girth related to increases in mesenteric fat, a dorsocervical fat pad ("buffalo hump") reminiscent of patients with Cushing's syndrome, and enlargement of the breasts. The peripheral wasting or lipoatrophy is particularly noticeable in the face and buttocks and by the prominence of the veins in the legs. These changes may develop at any time ranging from ~6 weeks to several years after the initiation of HAART. Approximately 20% of the patients with HIV-associated lipodystrophy meet the criteria for the *metabolic syndrome* as defined by The International Diabetes Federation or The U.S. National Cholesterol Education Program Adult Treatment Panel III. The lipodystrophy syndrome has been reported in association with regimens containing a variety of different drugs, and although initially reported in the setting of protease inhibitor therapy, it appears similar changes can also be induced by potent protease-sparing regimens. It has been suggested that the lipoatrophy changes are particularly severe in patients receiving thymidine analogues. National Cholesterol Education Program (NCEP) guidelines should be followed in the management of these lipid abnormalities. Due to concerns regarding drug interactions, the most commonly utilized agents in this setting are gemfibrozil and atorvastatin. In addition to these abnormalities, patients with HIV infection treated with HAART have been found to have an increased incidence of osteonecrosis or avascular necrosis of the hip and shoulders. In a study of asymptomatic patients, 4.4% were found to have evidence of osteonecrosis on MRI. This complication has been associated with the use of lipid-lowering agents, systemic glucocorticoids, or testosterone; bodybuilding exercise; alcohol consumption; and the presence of anticardiolipin antibodies. Osteoporosis has been reported in 7% of women with HIV infection, with 41% of women demonstrating some degree of osteopenia. In addition, lactic acidosis is associated with ARV therapy. This is most commonly seen with nucleoside analogue reverse transcriptase inhibitors and can be fatal (see below).

Patients with advanced HIV disease may develop hyponatremia due to the syndrome of inappropriate antidiuretic hormone (vasopressin) secretion (SIADH) as a consequence of increased free water intake and

**FIGURE 90-36**

Characteristics of lipodystrophy. **A.** Truncal obesity and buffalo hump. **B.** Facial wasting. **C.** Accumulation of intraabdominal fat on CT scan.

decreased free water excretion. SIADH is usually seen in conjunction with pulmonary or CNS disease. Low serum sodium may also be due to adrenal insufficiency; concomitant high serum potassium should alert one to this possibility. Adrenal gland disease may be due to mycobacterial infections, CMV disease, cryptococcal disease, histoplasmosis, or ketoconazole toxicity.

Thyroid function may be altered in 10–15% of patients with HIV infection. Both hypo- and hyperthyroidism may be seen. The predominant abnormality is subclinical hypothyroidism. In the setting of HAART, up to 10% of patients have been noted to have elevated thyroid-stimulating hormone levels, suggesting that this may be a manifestation of immune reconstitution. Immune-reconstitution Graves' disease may occur as a late (9–48 months) complication of HAART. In advanced HIV disease, infection of the thyroid gland may occur with opportunistic pathogens, including *P. jiroveci*, CMV, mycobacteria, *Toxoplasma gondii*, and *Cryptococcus neoformans*. These infections are generally associated with a nontender, diffuse enlargement of the thyroid gland. Thyroid function is usually normal. Diagnosis is made by fine-needle aspirate or open biopsy.

Advanced HIV disease is associated with *hypogonadism* in ~50% of men. Although this is generally a complication

of underlying illness, testicular dysfunction may also be a side effect of ganciclovir therapy. In some surveys, up to two-thirds of patients report decreased libido and one-third complain of impotence. Androgen-replacement therapy should be considered in patients with symptomatic hypogonadism. HIV infection does not seem to have a significant effect on the menstrual cycle outside the setting of advanced disease.

Rheumatologic Diseases

Immunologic and rheumatologic disorders are common in patients with HIV infection and range from excessive immediate-type hypersensitivity reactions to an increase in the incidence of reactive arthritis to conditions characterized by a diffuse infiltrative lymphocytosis. The occurrence of these phenomena is an apparent paradox in the setting of the profound immunodeficiency and immunosuppression that characterizes HIV infection.

Drug allergies are the most significant allergic reactions occurring in HIV-infected patients and appear to become more common as the disease progresses. They occur in up to 65% of patients who receive therapy with TMP/SMX for PCP. In general, these drug reactions are characterized by erythematous, morbilliform eruptions

that are pruritic, tend to coalesce, and are often associated with fever. Nonetheless, ~33% of patients can be maintained on the offending therapy, and thus these reactions are not an immediate indication to stop the drug. Anaphylaxis is extremely rare in patients with HIV infection, and patients who have a cutaneous reaction during a single course of therapy can still be considered candidates for future treatment or prophylaxis with the same agent. The one exception to this is the nucleoside analogue abacavir, where fatal hypersensitivity reactions have been reported with rechallenge. This hypersensitivity is strongly associated with the HLA-B57 haplotype and a hypersensitivity reaction to abacavir is an absolute contraindication to future therapy. For other agents, including TMP/SMX, desensitization regimens are moderately successful. Although the mechanisms underlying these allergic-type reactions remain unknown, patients with HIV infection have been noted to have elevated IgE levels that increase as the CD4+ T-cell count declines. The numerous examples of patients with multiple drug reactions suggest that a common pathway is involved.

HIV infection shares many similarities with a variety of autoimmune diseases, including a substantial polyclonal B-cell activation that is associated with a high incidence of antiphospholipid antibodies, such as anti-cardiolipin antibodies, VDRL antibodies, and lupus-like anticoagulants. In addition, HIV-infected individuals have an increased incidence of antinuclear antibodies. Despite these serologic findings, there is no evidence that HIV-infected individuals have an increase in two of the more common autoimmune diseases, i.e., systemic lupus erythematosus and rheumatoid arthritis. In fact, it has been observed that these diseases may be somewhat ameliorated by the concomitant presence of HIV infection, suggesting that an intact CD4+ T-cell limb of the immune response plays an integral role in the pathogenesis of these conditions. Similarly, there are anecdotal reports of patients with common variable immunodeficiency, characterized by hypogammaglobulinemia, who have had a normalization of Ig levels after the development of HIV infection, suggesting a possible role for overactive CD4+ T-cell immunity in certain forms of that syndrome. The one autoimmune disease that may occur with an increased frequency in patients with HIV infection is a variant of primary Sjögren's syndrome. Patients with HIV infection may develop a syndrome consisting of parotid gland enlargement, dry eyes, and dry mouth that is associated with lymphocytic infiltrates of the salivary gland and lung. In contrast to Sjögren's syndrome, in which these infiltrates are composed predominantly of CD4+ T cells, in patients with HIV infection, the infiltrates are composed predominantly of CD8+ T cells. In addition, although patients with Sjögren's syndrome are mainly women who have autoantibodies to Ro and La and who frequently have HLA-DR3 or -B8 MHC haplotypes, HIV-infected individuals with this syndrome are usually African-American men who do not have anti-Ro or anti-La and who most often are HLA-DR5. This syndrome appears to be less common with the increased use of effective ARV therapy. The

term *diffuse infiltrative lymphocytosis syndrome* (DILS) has been proposed to describe this entity and to distinguish it from Sjögren's syndrome.

Approximately one-third of HIV-infected individuals experience arthralgias; furthermore, 5–10% are diagnosed as having some form of reactive arthritis, such as Reiter's syndrome or psoriatic arthritis. These syndromes occur with increasing frequency as the competency of the immune system declines. This association may be related to an increase in the number of infections with organisms that may trigger a reactive arthritis with progressive immunodeficiency or to a loss of important regulatory T cells. Reactive arthritides in HIV-infected individuals generally respond well to standard treatment; however, therapy with methotrexate has been associated with an increase in the incidence of opportunistic infections and should be used with caution and only in severe cases.

HIV-infected individuals also experience a variety of joint problems without obvious cause that are referred to generically as *HIV- or AIDS-associated arthropathy*. This syndrome is characterized by subacute oligoarticular arthritis developing over a period of 1–6 weeks and lasting 6 weeks to 6 months. It generally involves the large joints, predominantly the knees and ankles, and is nonerosive with only a mild inflammatory response. X-rays of the joint are nonrevealing. Nonsteroidal anti-inflammatory drugs are only marginally helpful; however, relief has been noted with the use of intraarticular glucocorticoids. A second form of arthritis also thought to be secondary to HIV infection is called *painful articular syndrome*. This condition, reported as occurring in as many as 10% of AIDS patients, presents as an acute, severe, sharp pain in the affected joint. It affects primarily the knees, elbows, and shoulders; lasts 2–24 h; and may be severe enough to require narcotic analgesics. The cause of this arthropathy is unclear; however, it is thought to result from a direct effect of HIV on the joint. This condition is reminiscent of the fact that other lentiviruses, in particular the caprine arthritis-encephalitis virus, are capable of directly causing arthritis.

A variety of other immunologic or rheumatologic diseases have been reported in HIV-infected individuals, either de novo or in association with opportunistic infections or drugs. Using the criteria of widespread musculoskeletal pain of at least 3 months' duration and the presence of at least 11 of 18 possible tender points by digital palpation, 11% of an HIV-infected cohort containing 55% IDUs were diagnosed as having *fibromyalgia*. Although the incidence of frank arthritis was less in this population than in other studied populations that consisted predominantly of homosexual men, these data support the concept that there are musculoskeletal problems that occur as a direct result of HIV infection. In addition, there have been reports of leukocytoclastic vasculitis in the setting of zidovudine therapy. CNS angiitis and polymyositis have also been reported in HIV-infected individuals. Septic arthritis is surprisingly rare, especially given the increased incidence of staphylococcal bacteremias seen in this population. When septic arthritis has been reported, it has usually

been due to *Staphylococcus aureus*, systemic fungal infections with *C. neoformans*, *Sporothrix schenckii*, or *H. capsulatum* or to systemic mycobacterial infection with *M. tuberculosis*, *M. haemophilum*, *M. avium*, or *M. kansasii*.

As noted above, 4.4% of patients with HIV infection were found to have some evidence of osteonecrosis by MRI during systematic screening of asymptomatic patients. The percentage of patients with symptomatic osteonecrosis has been estimated to be as high as 1%. Although this problem was first recognized in the setting of HAART, it has been difficult to establish a cause-and-effect relationship. Alcohol consumption and a history of glucocorticoid use have been particularly associated with this condition in patients with HIV infection.

Immune Reconstitution Inflammatory Syndrome

After the initiation of effective ARV therapy, a paradoxical worsening of preexisting, untreated, or partially treated opportunistic infections may be noted (Table 90-9). These IRISs are particularly common in patients with underlying untreated mycobacterial infections. They are seen in anywhere from 10–50% of patients, depending upon the clinical setting, and are most common in patients starting therapy with CD4+ T-cell counts <50 cells/ μ L who have a precipitous drop in HIV RNA levels after the initiation of HAART. Signs and symptoms may appear anywhere from 2 weeks to 2 years after the initiation of HAART and can include localized lymphadenitis, prolonged fever, pulmonary infiltrates, increased intracranial pressure, uveitis, and Graves' disease. The clinical course can be protracted and severe cases can be fatal. The underlying mechanism appears to be related to a phenomenon similar to type IV hypersensitivity reactions and reflects the immediate improvements in immune function that occur as levels of HIV RNA drop and the immunosuppressive effects of HIV infection are controlled. In severe cases, the use of immunosuppressive drugs such as glucocorticoids may be required to blunt the inflammatory component of these reactions while specific antimicrobial therapy takes effect.

Diseases of the Hematopoietic System

Disorders of the hematopoietic system including lymphadenopathy, anemia, leukopenia, and/or thrombocytopenia are common throughout the course of HIV

TABLE 90-10

CAUSES OF BONE MARROW SUPPRESSION IN PATIENTS WITH HIV INFECTION

| | |
|--------------------------|-------------------------------|
| HIV infection | Medications |
| Mycobacterial infections | Zidovudine |
| Fungal infections | Dapsone |
| B19 parvovirus infection | Trimethoprim/sulfamethoxazole |
| Lymphoma | Pyrimethamine |
| | 5-Flucytosine |
| | Ganciclovir |
| | Interferon- α |
| | Trimetrexate |
| | Foscarnet |

infection and may be the direct result of HIV, manifestations of secondary infections and neoplasms, or side effects of therapy (Table 90-10). Direct histologic examination and culture of lymph node or bone marrow tissue are often diagnostic. A significant percentage of bone marrow aspirates from patients with HIV infection have been reported to contain lymphoid aggregates, the precise significance of which is unknown. Initiation of HAART will lead to reversal of most hematologic complications that are the direct result of HIV infection.

Some patients, otherwise asymptomatic, may develop *persistent generalized lymphadenopathy* as an early clinical manifestation of HIV infection. This condition is defined as the presence of enlarged lymph nodes (>1 cm) in two or more extrainguinal sites for >3 months without an obvious cause. The lymphadenopathy is due to marked follicular hyperplasia in the node in response to HIV infection. The nodes are generally discrete and freely movable. This feature of HIV disease may be seen at any point in the spectrum of immune dysfunction and is not associated with an increased likelihood of developing AIDS. Paradoxically, a loss in lymphadenopathy or a decrease in lymph node size outside the setting of ARV therapy may be a prognostic marker of disease progression. In patients with CD4+ T-cell counts >200/ μ L, the differential diagnosis of lymphadenopathy includes KS, TB, Castleman's disease, and lymphoma. In patients with more advanced disease, lymphadenopathy may also be due to atypical mycobacterial infection, toxoplasmosis, systemic fungal infection, or bacillary angiomatosis. Although indicated in patients with CD4+ T-cell counts <200/ μ L, lymph node biopsy is not indicated in patients with early-stage disease unless there are signs and symptoms of systemic illness, such as fever and weight loss, or unless the nodes begin to enlarge, become fixed, or coalesce. Monoclonal gammopathy of unknown significance (MGUS), defined as the presence of a serum monoclonal IgG, IgA, or IgM in the absence of a clear cause, has been reported in 3% of patients with HIV infection. The overall clinical significance of this finding in patients with HIV infection is unclear, although it has been associated with other viral infections, non-Hodgkin's lymphoma, and plasma cell malignancy.

Anemia is the most common hematologic abnormality in HIV-infected patients and in the absence of a specific treatable cause is independently associated with a poor

TABLE 90-9

CHARACTERISTICS OF IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME (IRIS)

- Paradoxical worsening of clinical condition after the initiation of antiretroviral therapy
- Occurs weeks to months after the initiation of antiretroviral therapy
- Most common in patients starting therapy with a CD4+ T-cell count under 50/ μ L who experience a precipitous drop in viral load
- Frequently seen in the setting of tuberculosis
- Can be fatal

prognosis. Although generally mild, anemia can be quite severe and require chronic blood transfusions. Among the specific reversible causes of anemia in the setting of HIV infection are drug toxicity, systemic fungal and mycobacterial infections, nutritional deficiencies, and parvovirus B19 infections. Zidovudine may block erythroid maturation, before its effects on other marrow elements. A characteristic feature of zidovudine therapy is an elevated mean corpuscular volume (MCV). Another drug used in patients with HIV infection that has a selective effect on the erythroid series is dapsone. This drug can cause a serious hemolytic anemia in patients who are deficient in glucose-6-phosphate dehydrogenase and can create a functional anemia in others through induction of methemoglobinemia. Folate levels are usually normal in HIV-infected individuals; however, vitamin B₁₂ levels may be depressed as a consequence of achlorhydria or malabsorption. True autoimmune hemolytic anemia is rare, although ~20% of patients with HIV infection may have a positive direct antiglobulin test as a consequence of polyclonal B-cell activation. Infection with parvovirus B19 may also cause anemia. It is important to recognize this possibility given the fact that it responds well to treatment with IVIg. Erythropoietin levels in patients with HIV infection and anemia are generally less than expected given the degree of anemia. Treatment with erythropoietin at doses of 100 µg/kg three times a week may result in an increase in hemoglobin levels. An exception to this is a subset of patients with zidovudine-associated anemia in whom erythropoietin levels may be quite high.

During the course of HIV infection, neutropenia may be seen in approximately half of patients. In most instances it is mild; however, it can be severe and can put patients at risk of spontaneous bacterial infections. This is most frequently seen in patients with severely advanced HIV disease and in patients receiving any of a number of potentially myelosuppressive therapies. In the setting of neutropenia, diseases that are not commonly seen in HIV-infected patients, such as aspergillosis or mucormycosis, may occur. The potential role of colony-stimulating factors in the management of patients with HIV infection has undergone extensive evaluation. Both granulocyte colony-stimulating factor (G-CSF) and GM-CSF increase neutrophil counts in patients with HIV infection regardless of the cause of the neutropenia. Earlier concerns about the potential of these agents to also increase levels of HIV were not confirmed in controlled clinical trials.

Thrombocytopenia may be an early consequence of HIV infection. Approximately 3% of patients with untreated HIV infection and CD4+ T-cell counts $\geq 400/\mu\text{L}$ have platelet counts $< 150,000/\mu\text{L}$. For untreated patients with CD4+ T-cell counts $< 400/\mu\text{L}$, this incidence increases to 10%. Thrombocytopenia is rarely a serious clinical problem in patients with HIV infection and generally responds well to ARV therapy. Clinically, it resembles the thrombocytopenia seen in patients with idiopathic thrombocytopenic purpura. Immune complexes containing anti-gp120 antibodies and anti-anti-gp120 antibodies have been noted in the

circulation and on the surface of platelets in patients with HIV infection. Patients with HIV infection have also been noted to have a platelet-specific antibody directed toward a 25-kDa component of the surface of the platelet. Other data suggest that the thrombocytopenia in patients with HIV infection may be due to a direct effect of HIV on megakaryocytes. Whatever the cause, it is very clear that the most effective medical approach to this problem has been the use of HAART. For patients with platelet counts $< 20,000/\mu\text{L}$ a more aggressive approach combining IVIg or anti-Rh Ig for an immediate response with ARV therapy for a more lasting response is appropriate. Rituximab has been used with some success in otherwise refractory cases. Splenectomy is a rarely needed option and is reserved for patients refractory to medical management. Because of the risk of serious infection with encapsulated organisms, all patients with HIV infection about to undergo splenectomy should be immunized with pneumococcal polysaccharide. It should be noted that, in addition to causing an increase in the platelet count, removal of the spleen will result in an increase in the peripheral blood lymphocyte count, making CD4+ T-cell counts unreliable. In this setting, the clinician should rely on the CD4+ T-cell percent for making diagnostic decisions with respect to the likelihood of opportunistic infections. A CD4+ T-cell percent of 15 is approximately equivalent to a CD4+ T-cell count of $200/\mu\text{L}$. In patients with early HIV infection, thrombocytopenia has also been reported as a consequence of classic thrombotic thrombocytopenic purpura. This clinical syndrome, consisting of fever, thrombocytopenia, hemolytic anemia, and neurologic and renal dysfunction, is a rare complication of early HIV infection. As in other settings, the appropriate management is the use of salicylates and plasma exchange. Other causes of thrombocytopenia include lymphoma, mycobacterial infections, and fungal infections.

Approximately 4% of patients with HIV infection experience venous thrombotic events such as deep vein thrombosis or pulmonary embolism. Among the factors associated with clinical thrombosis are age over 45, history of an opportunistic infection, and estrogen use.

Abnormalities of the coagulation cascade including decreased protein S activity, increases in factor VIII, and the presence of anticardiolipin antibodies have been reported in patients with HIV infection.

Elevations in D-dimer appear predictive of a poor clinical outcome.

Dermatologic Diseases

Dermatologic problems occur in $> 90\%$ of patients with HIV infection. From the macular, roseola-like rash seen with the acute seroconversion syndrome to extensive end-stage KS, cutaneous manifestations of HIV disease can be seen throughout the course of HIV infection. Among the more common nonneoplastic problems are seborrheic dermatitis, folliculitis, and opportunistic infections. Extrapulmonary pneumocystosis may cause a necrotizing vasculitis. Neoplastic conditions are covered below in the section on malignant diseases.

Seborrheic dermatitis occurs in 3% of the general population and in up to 50% of patients with HIV infection. Seborrheic dermatitis increases in prevalence and severity as the CD4+ T-cell count declines. In HIV-infected patients, seborrheic dermatitis may be aggravated by concomitant infection with *Pityrosporum*, a yeastlike fungus; use of topical antifungal agents has been recommended in cases refractory to standard topical treatment.

Folliculitis is among the most prevalent dermatologic disorders in patients with HIV infection and is seen in ~20% of patients. It is more common in patients with CD4+ T-cell counts <200 cells/ μ L. One form of folliculitis, *eosinophilic pustular folliculitis*, is a rare dermatologic condition that is seen with increased frequency in patients with HIV infection. It presents as multiple, urticarial perifollicular papules that may coalesce into plaque-like lesions. Skin biopsy reveals an eosinophilic infiltrate of the hair follicle, which in certain cases has been associated with the presence of a mite. Patients typically have an elevated serum IgE level and may respond to treatment with topical antihelminthics. Pruritus is a common symptom in patients with HIV infection and can lead to prurigo nodularis. Patients with HIV infection have also been reported to develop a severe form of *Norwegian scabies* with hyperkeratotic psoriasiform lesions.

Both *psoriasis* and *ichthyosis*, although they are not reported to be increased in frequency, may be particularly severe when they occur in patients with HIV infection. Preexisting psoriasis may become guttate in appearance and more refractory to treatment in the setting of HIV infection.

Reactivation herpes zoster (shingles) is seen in 10–20% of patients with HIV infection. This reactivation syndrome of varicella-zoster virus indicates a modest decline in immune function and may be the first indication of clinical immunodeficiency. In one series, patients who developed shingles did so an average of 5 years after HIV infection. In a cohort of patients with HIV infection and localized zoster, the subsequent rate of the development of AIDS was 1% per month. In that study, AIDS was more likely to develop if the outbreak of zoster was associated with severe pain, extensive skin involvement, or involvement of cranial or cervical dermatomes. The clinical manifestations of reactivation zoster in HIV-infected patients, although indicative of immunologic compromise, are not as severe as those seen in other immunodeficient conditions. Thus, although lesions may extend over several dermatomes and frank cutaneous dissemination may be seen, visceral involvement has not been reported. In contrast to patients without a known underlying immunodeficiency state, patients with HIV infection tend to have recurrences of zoster with a relapse rate of ~20%. Acyclovir or famciclovir is the treatment of choice. Foscarnet may be of value in patients with acyclovir-resistant virus.

Infection with *herpes simplex virus* in HIV-infected individuals is associated with recurrent orolabial, genital, and perianal lesions as part of recurrent reactivation syndromes (Chap. 80). As HIV disease progresses and the CD4+ T-cell count declines, these infections become more frequent and severe. Lesions often appear as beefy

red, are exquisitely painful, and have a tendency to occur high in the gluteal cleft (Fig. 90-35). Perirectal HSV may be associated with proctitis and anal fissures. HSV should be high in the differential diagnosis of any HIV-infected patient with a poorly healing, painful perirectal lesion. In addition to recurrent mucosal ulcers, recurrent HSV infection in the form of *herpetic whitlow* can be a problem in patients with HIV infection, presenting with painful vesicles or extensive cutaneous erosion. Acyclovir or famciclovir is the treatment of choice in these settings. Of note is the fact that even subclinical reactivation of herpes simplex may be associated with increases in plasma HIV RNA levels. In a cohort of patients from Burkina Faso seropositive for HIV-1 and HSV-2 with CD4+ T-cell counts >200 cells/ μ L, chronic use of valacyclovir was associated with a 0.5-log decrease in HIV viral load. Thus consideration should be given to chronic suppressive therapy in patients with recurrent outbreaks of herpesvirus.

Diffuse skin eruptions due to *Molluscum contagiosum* may be seen in patients with advanced HIV infection. These flesh-colored, umbilicated lesions may be treated with local therapy. They tend to regress with effective ARV therapy. Similarly, *condyloma acuminatum* lesions may be more severe and more widely distributed in patients with low CD4+ T-cell counts. Atypical mycobacterial infections may present as erythematous cutaneous nodules, as may fungal infections, *Bartonella*, *Acanthamoeba*, and KS.

The skin of patients with HIV infection is often a target organ for drug reactions. Although most skin reactions are mild and not necessarily an indication to discontinue therapy, patients may have particularly severe cutaneous reactions, including erythroderma and *Stevens-Johnson syndrome*, as a reaction to drugs, particularly sulfa drugs, the nonnucleoside reverse transcriptase inhibitors, abacavir, amprenavir, darunavir, fosamprenavir, and tipranavir. Similarly, patients with HIV infection are often quite photosensitive and burn easily after exposure to sunlight or as a side effect of radiation therapy.

HIV infection and its treatment may be accompanied by cosmetic changes of the skin that are not of great clinical importance but may be troubling to patients. Yellowing of the nails and straightening of the hair, particularly in African-American patients, have been reported as a consequence of HIV infection. Zidovudine therapy has been associated with elongation of the eyelashes and the development of a bluish discoloration to the nails, again more common in African-American patients. Therapy with clofazimine may cause a yellow-orange discoloration of the skin and urine.

Neurologic Diseases

Clinical disease of the nervous system accounts for a significant degree of morbidity in a high percentage of patients with HIV infection (Table 90-11). The neurologic problems that occur in HIV-infected individuals may be either primary to the pathogenic processes of HIV infection or secondary to opportunistic infections or neoplasms (see above). Among the more frequent opportunistic diseases that involve the CNS are toxoplasmosis,

TABLE 90-11

NEUROLOGIC DISEASES IN PATIENTS WITH HIV INFECTION

| | |
|--|---|
| Opportunistic infections | Myelopathy |
| Toxoplasmosis | Vacuolar myelopathy |
| Cryptococcosis | Pure sensory ataxia |
| Progressive multifocal leukoencephalopathy | Paresthesia/dysesthesia |
| Cytomegalovirus | Peripheral neuropathy |
| Syphilis | Acute inflammatory demyelinating polyneuropathy (Guillain-Barré syndrome) |
| <i>Mycobacterium tuberculosis</i> | Chronic inflammatory demyelinating polyneuropathy (CIDP) |
| HTLV-I infection | Mononeuritis multiplex |
| Neoplasms | Distal symmetric polyneuropathy |
| Primary CNS lymphoma | Myopathy |
| Kaposi's sarcoma | |
| Result of HIV-1 infection | |
| Aseptic meningitis | |
| HIV-associated neurocognitive impairment, including HIV encephalopathy/AIDS dementia complex | |

cryptococcosis, progressive multifocal leukoencephalopathy, and primary CNS lymphoma. Other less common problems include mycobacterial infections; syphilis; and infection with CMV, HTLV-I, *T. cruzi*, or *Acanthamoeba*. Overall, secondary diseases of the CNS occur in approximately one-third of patients with AIDS. These data antedate the widespread use of combination ARV therapy, and this frequency is considerably less in patients receiving effective ARV drugs. Primary processes related to HIV infection of the nervous system are reminiscent of those seen with other lentiviruses, such as the Visna-Maedi virus of sheep.

Neurologic problems directly attributable to HIV occur throughout the course of infection and may be inflammatory, demyelinating, or degenerative in nature. The term *HIV-associated neurocognitive impairment* (HNCI) is used to describe a spectrum of disorders that range from asymptomatic to apparent only through extensive neuropsychiatric testing to clinically severe. The most severe form, the *AIDS dementia complex*, or *HIV encephalopathy*, is considered an AIDS-defining illness. Most HIV-infected patients have some neurologic problem during the course of their disease. As noted in the section on pathogenesis, damage to the CNS may be a direct result of viral infection of the CNS macrophages or glial cells or may be secondary to the release of neurotoxins and potentially toxic cytokines such as IL-1 β , TNF- α , IL-6, and TGF- β . It has been reported that HIV-infected individuals with the E4 allele for apo E are at increased risk for AIDS encephalopathy and peripheral neuropathy. Virtually all patients with HIV infection have some degree of nervous system involvement with the virus. This is evidenced by the fact that CSF findings are abnormal in ~90% of patients, even during the asymptomatic phase of HIV infection. CSF abnormalities include pleocytosis (50–65% of patients), detection of viral RNA

(~75%), elevated CSF protein (35%), and evidence of intrathecal synthesis of anti-HIV antibodies (90%). It is important to point out that evidence of infection of the CNS with HIV does not imply impairment of cognitive function. The neurologic function of an HIV-infected individual should be considered normal unless clinical signs and symptoms suggest otherwise.

Aseptic meningitis may be seen in any but the very late stages of HIV infection. In the setting of acute primary infection patients may experience a syndrome of headache, photophobia, and meningismus. Rarely, an acute encephalopathy due to encephalitis may occur. Cranial nerve involvement may be seen, predominantly cranial nerve VII but occasionally V and/or VIII. CSF findings include a lymphocytic pleocytosis, elevated protein level, and normal glucose level. This syndrome, which cannot be clinically differentiated from other viral meningitides (Chap. 30), usually resolves spontaneously within 2–4 weeks; however, in some patients, signs and symptoms may become chronic. Aseptic meningitis may occur any time in the course of HIV infection; however, it is rare after the development of AIDS. This fact suggests that clinical aseptic meningitis in the context of HIV infection is an immune-mediated disease.

C. neoformans is the leading infectious cause of meningitis in patients with AIDS (Chap. 106). It is the initial AIDS-defining illness in ~2% of patients and generally occurs in patients with CD4+ T-cell counts <100/ μ L. Cryptococcal meningitis is particularly common in patients with AIDS in Africa, occurring in ~20% of patients. Most patients present with a picture of subacute meningoencephalitis with fever, nausea, vomiting, altered mental status, headache, and meningeal signs. The incidence of seizures and focal neurologic deficits is low. The CSF profile may be normal or may show only modest elevations in WBC or protein levels and decreases in glucose. In addition to meningitis, patients may develop cryptococcomas and cranial nerve involvement. Approximately one-third of patients also have pulmonary disease. Uncommon manifestations of cryptococcal infection include skin lesions that resemble *molluscum contagiosum*, lymphadenopathy, palatal and glossal ulcers, arthritis, gastroenteritis, myocarditis, and prostatitis. The prostate gland may serve as a reservoir for smoldering cryptococcal infection. The diagnosis of cryptococcal meningitis is made by identification of organisms in spinal fluid with India ink examination or by the detection of cryptococcal antigen. A biopsy may be needed to make a diagnosis of CNS cryptococcoma. Treatment is with IV amphotericin B, at a dose of 0.7 mg/kg daily, with flucytosine, 25 mg/kg qid for 2 weeks, followed by fluconazole, 400 mg/d PO for 10 weeks, and then fluconazole, 200 mg/d until the CD4+ T-cell count has increased to >200 cells/ μ L for 6 months in response to HAART. Repeated lumbar puncture may be required to manage increased intracranial pressure. Symptoms may recur with initiation of HAART as an immune reconstitution syndrome (see above). Other fungi that may cause meningitis in patients with HIV infection are *C. immitis* and *H. capsulatum*. Meningoencephalitis has also been reported due to *Acanthamoeba* or *Naegleria*.

HIV encephalopathy, also called HIV-associated dementia or AIDS dementia complex, consists of a constellation of signs and symptoms of CNS disease. Although this is generally a late complication of HIV infection that progresses slowly over months, it can be seen in patients with CD4+ T-cell counts >350 cells/ μ L. A major feature of this entity is the development of dementia, defined as a decline in cognitive ability from a previous level. It may present as impaired ability to concentrate, increased forgetfulness, difficulty reading, or increased difficulty performing complex tasks. Initially these symptoms may be indistinguishable from findings of situational depression or fatigue. In contrast to “cortical” dementia (such as Alzheimer’s disease), aphasia, apraxia, and agnosia are uncommon, leading some investigators to classify HIV encephalopathy as a “subcortical dementia” (see below). In addition to dementia, patients with HIV encephalopathy may also have motor and behavioral abnormalities. Among the motor problems are unsteady gait, poor balance, tremor, and difficulty with rapid alternating movements. Increased tone and deep tendon reflexes may be found in patients with spinal cord involvement. Late stages may be complicated by bowel and/or bladder incontinence. Behavioral problems include apathy and lack of initiative, with progression to a vegetative state in some instances. Some patients develop a state of agitation or mild mania. These changes usually occur without significant changes in level of alertness. This is in contrast to the finding of somnolence in patients with dementia due to toxic/metabolic encephalopathies.

HIV encephalopathy is the initial AIDS-defining illness in ~3% of patients with HIV infection and thus only rarely precedes clinical evidence of immunodeficiency. Clinically significant encephalopathy eventually develops in ~25% of patients with AIDS. As immunologic function declines, the risk and severity of HIV encephalopathy increase. Autopsy series suggest that

80–90% of patients with HIV infection have histologic evidence of CNS involvement. Several classification schemes have been developed for grading HIV encephalopathy; a commonly used clinical staging system is outlined in [Table 90-12](#).

The precise cause of HIV encephalopathy remains unclear, although the condition is thought to be a result of a combination of direct effects of HIV on the CNS and associated immune activation. HIV has been found in the brains of patients with HIV encephalopathy by Southern blot, in situ hybridization, PCR, and electron microscopy. Multinucleated giant cells, macrophages, and microglial cells appear to be the main cell types harboring virus in the CNS. Histologically, the major changes are seen in the subcortical areas of the brain and include pallor and gliosis, multinucleated giant cell encephalitis, and vacuolar myelopathy. Less commonly, diffuse or focal spongiform changes occur in the white matter. Areas of the brain involved in motor, language, and judgment are most severely affected.

There are no specific criteria for a diagnosis of HIV encephalopathy, and this syndrome must be differentiated from a number of other diseases that affect the CNS of HIV-infected patients ([Table 90-11](#)). The diagnosis of dementia depends upon demonstrating a decline in cognitive function. This can be accomplished objectively with the use of a Mini-Mental Status Examination (MMSE) in patients for whom prior scores are available. For this reason, it is advisable for all patients with a diagnosis of HIV infection to have a baseline MMSE. However, changes in MMSE scores may be absent in patients with mild HIV encephalopathy. Imaging studies of the CNS, by either MRI or CT, often demonstrate evidence of cerebral atrophy ([Fig. 90-37](#)). MRI may also reveal small areas of increased density on T2-weighted images. Lumbar puncture is an important element of the evaluation of patients with HIV infection and neurologic

TABLE 90-12**CLINICAL STAGING OF HIV ENCEPHALOPATHY (AIDS DEMENTIA COMPLEX)**

| STAGE | DEFINITION |
|-----------------------------------|--|
| Stage 0 (normal) | Normal mental and motor function |
| Stage 0.5 (equivocal/subclinical) | Absent, minimal, or equivocal symptoms without impairment of work or capacity to perform activities of daily living. Mild signs (snout response, slowed ocular or extremity movements) may be present. Gait and strength are normal. |
| Stage 1 (mild) | Able to perform all but the more demanding aspects of work or activities of daily living but with unequivocal evidence (signs or symptoms that may include performance on neuropsychological testing) of functional, intellectual, or motor impairment. Can walk without assistance. |
| Stage 2 (moderate) | Able to perform basic activities of self-care but cannot work or maintain the more demanding aspects of daily life. Ambulatory, but may require a single prop. |
| Stage 3 (severe) | Major intellectual incapacity (cannot follow news or personal events, cannot sustain complex conversation, considerable slowing of all output) or motor disability (cannot walk unassisted, usually with slowing and clumsiness of arms as well). |
| Stage 4 (end-stage) | Nearly vegetative. Intellectual and social comprehension and output are at a rudimentary level. Nearly or absolutely mute. Paraparetic or paraplegic with urinary and fecal incontinence. |

**FIGURE 90-37**

AIDS dementia complex. Postcontrast CT scan through the lateral ventricles of a 47-year-old man with AIDS, altered mental status, and dementia. The lateral and third ventricles and the cerebral sulci are abnormally prominent. Mild white matter hypodensity is also seen adjacent to the frontal horns of the lateral ventricles.

abnormalities. It is generally most helpful in ruling out or making a diagnosis of opportunistic infections. In HIV encephalopathy, patients may have the nonspecific findings of an increase in CSF cells and protein level. Although HIV RNA can often be detected in the spinal fluid and HIV can be cultured from the CSF, this finding is not specific for HIV encephalopathy. There appears to be no correlation between the presence of HIV in the CSF and the presence of HIV encephalopathy. Elevated levels of macrophage chemoattractant protein (MCP-1), β_2 -microglobulin, neopterin, and quinolinic acid (a metabolite of tryptophan reported to cause CNS injury) have been noted in the CSF of patients with HIV

encephalopathy. These findings suggest that these factors as well as inflammatory cytokines may be involved in the pathogenesis of this syndrome.

Combination ARV therapy is of benefit in patients with HIV encephalopathy. Improvement in neuropsychiatric test scores has been noted for both adult and pediatric patients treated with ARVs. The rapid improvement in cognitive function noted with the initiation of ARV therapy suggests that at least some component of this problem is quickly reversible, again supporting at least a partial role of soluble mediators in the pathogenesis. It should also be noted that these patients have an increased sensitivity to the side effects of neuroleptic drugs. The use of these drugs for symptomatic treatment is associated with an increased risk of extrapyramidal side effects; therefore, patients with HIV encephalopathy who receive these agents must be monitored carefully.

Seizures may be a consequence of opportunistic infections, neoplasms, or HIV encephalopathy (Table 90-13). The seizure threshold is often lower than normal in patients with advanced HIV infection due to the frequent presence of electrolyte abnormalities. Seizures are seen in 15–40% of patients with cerebral toxoplasmosis, 15–35% of patients with primary CNS lymphoma, 8% of patients with cryptococcal meningitis, and 7–50% of patients with HIV encephalopathy. Seizures may also be seen in patients with CNS tuberculosis, aseptic meningitis, and progressive multifocal leukoencephalopathy. Seizures may be the presenting clinical symptom of HIV disease. In one study of 100 patients with HIV infection presenting with a first seizure, cerebral mass lesions were the most common cause, responsible for 32 of the 100 new-onset seizures. Of these 32 cases, 28 were due to toxoplasmosis and 4 to lymphoma. HIV encephalopathy accounted for an additional 24 new-onset seizures. Cryptococcal meningitis was the third most common diagnosis, responsible for 13 of the 100 seizures. In 23 cases, no cause could be found, and it is possible that these cases represent a subcategory of HIV encephalopathy. Of these 23 cases, 16 (70%) had two or more seizures, suggesting that anticonvulsant therapy is indicated in all patients with HIV infection and seizures unless a rapidly correctable cause is found. Although phenytoin remains the initial treatment of choice, hypersensitivity reactions to this drug have been

TABLE 90-13**CAUSES OF SEIZURES IN PATIENTS WITH HIV INFECTION**

| DISEASE | OVERALL CONTRIBUTION TO FIRST SEIZURE, % | FRACTION OF PATIENTS WHO HAVE SEIZURES, % |

reported in >10% of patients with AIDS, and therefore the use of phenobarbital or valproic acid must be considered as alternatives.

Patients with HIV infection may present with *focal neurologic deficits* from a variety of causes. The most common causes are toxoplasmosis, progressive multifocal leukoencephalopathy, and CNS lymphoma. Other causes include cryptococcal infections (discussed above; also Chap. 106), stroke, and reactivation Chagas' disease.

Toxoplasmosis has been one of the most common causes of secondary CNS infections in patients with AIDS, but its incidence is decreasing in the era of HAART. It is most common in patients from the Caribbean and from France. Toxoplasmosis is generally a late complication of HIV infection and usually occurs in patients with CD4+ T-cell counts <200/ μ L. Cerebral toxoplasmosis is thought to represent a reactivation syndrome. It is 10 times more common in patients with antibodies to the organism than in patients who are seronegative. Patients diagnosed with HIV infection should be screened for IgG antibodies to *T. gondii* during the time of their initial workup. Those who are seronegative should be counseled about ways to minimize the risk of primary infection including avoiding the consumption of undercooked meat and careful hand washing after contact with soil or changing the cat litter box. The most common clinical presentation of cerebral toxoplasmosis in patients with HIV infection is fever, headache, and focal neurologic deficits. Patients may present with seizure, hemiparesis, or aphasia as a manifestation of these focal deficits or with a picture more influenced by the accompanying cerebral edema and characterized by confusion, dementia, and lethargy, which can progress to coma. The diagnosis is usually suspected on the basis of MRI findings of multiple lesions in multiple locations, although in some cases only a single lesion is seen. Pathologically, these lesions generally exhibit inflammation and central necrosis and, as a result, demonstrate ring enhancement on contrast MRI (Fig. 90-38) or, if MRI is unavailable or contraindicated, on double-dose contrast CT. There is usually evidence of surrounding edema. In addition to toxoplasmosis, the differential diagnosis of single or multiple enhancing mass lesions in the HIV-infected patient includes primary CNS lymphoma (see below) and, less commonly, TB or fungal or bacterial abscesses. The definitive diagnostic procedure is brain biopsy. However, given the morbidity that can accompany this procedure, it is usually reserved for the patient who has failed 2–4 weeks of empirical therapy. If the patient is seronegative for *T. gondii*, the likelihood that a mass lesion is due to toxoplasmosis is <10%. In that setting, one may choose to be more aggressive and perform a brain biopsy sooner. Standard treatment is sulfadiazine and pyrimethamine with leucovorin as needed for a minimum of 4–6 weeks. Alternative therapeutic regimens include clindamycin in combination with pyrimethamine; atovaquone plus pyrimethamine; and azithromycin plus pyrimethamine plus rifabutin. Relapses are common, and it is recommended that patients with a history of prior toxoplasmic encephalitis receive maintenance therapy with sulfadiazine, pyrimethamine, and leucovorin as long as their CD4+ T-cell counts remain <200 cells/ μ L. Patients with CD4+ T-cell counts <100/ μ L and IgG antibody to *Toxoplasma* should

FIGURE 90-38

Central nervous system toxoplasmosis. A coronal post-contrast T1-weighted MR scan demonstrates a peripheral enhancing lesion in the left frontal lobe, associated with an eccentric nodular area of enhancement (arrow); this so-called eccentric target sign is typical of toxoplasmosis.

receive primary prophylaxis for toxoplasmosis. Fortunately, the same daily regimen of a single double-strength tablet of TMP/SMX used for *P. jiroveci* prophylaxis provides adequate primary protection against toxoplasmosis. Secondary prophylaxis/maintenance therapy for toxoplasmosis may be discontinued in the setting of effective ARV therapy and increases in CD4+ T-cell counts to >200/ μ L for 6 months.

JC virus, a human polyomavirus that is the etiologic agent of *progressive multifocal leukoencephalopathy* (PML), is an important opportunistic pathogen in patients with AIDS (Chap. 29). Although ~70% of the general adult population have antibodies to JC virus, indicative of prior infection, <10% of healthy adults show any evidence of ongoing viral replication. PML is the only known clinical manifestation of JC virus infection. It is a late manifestation of AIDS and is seen in ~4% of patients with AIDS. The lesions of PML begin as small foci of demyelination in subcortical white matter that eventually coalesce. The cerebral hemispheres, cerebellum, and brainstem may all be involved. Patients typically have a protracted course with multifocal neurologic deficits, with or without changes in mental status. Approximately 20% of patients experience seizures. Ataxia, hemiparesis, visual field defects, aphasia, and sensory defects may occur. MRI typically reveals multiple, nonenhancing white matter lesions that may coalesce and have a predilection for the occipital and parietal lobes. The lesions show signal hyperintensity on T2-weighted images and diminished signal on T1-weighted images. The measurement of JC virus DNA levels in CSF has a diagnostic sensitivity of 76% and a specificity

of close to 100%. Before the availability of potent ARV combination therapy, the majority of patients with PML died within 3–6 months of the onset of symptoms. Paradoxical worsening of PML has been seen with initiation of HAART as an immune reconstitution syndrome. There is no specific treatment for PML; however, a minimal median survival of 18 months and survival of >7 years have been reported in patients with PML treated with HAART for their HIV disease. Unfortunately, only ~50% of patients with HIV infection and PML show neurologic improvement with HAART. Studies with other antiviral agents such as cidofovir have failed to show clear benefit. Factors influencing a favorable prognosis for PML in the setting of HIV infection include a CD4+ T-cell count >100/ μ L at baseline and the ability to maintain an HIV viral load of <500 copies per milliliter. Baseline HIV-1 viral load does not have independent predictive value of survival. PML is one of the few opportunistic infections that continues to occur with some frequency despite the widespread use of HAART.

Reactivation American trypanosomiasis may present as acute meningoencephalitis with focal neurologic signs, fever, headache, vomiting, and seizures. In South America, reactivation of *Chagas' disease* is considered to be an AIDS-defining condition and may be the initial AIDS-defining condition. Lesions appear radiographically as single or multiple hypodense areas, typically with ring enhancement and edema. They are found predominantly in the subcortical areas, a feature that differentiates them from the deeper lesions of toxoplasmosis. *Trypanosoma cruzi* amastigotes, or trypanosomes, can be identified from biopsy specimens or CSF. Other CSF findings include elevated protein and a mild (<100 cells/ μ L) lymphocytic pleocytosis. Organisms can also be identified by direct examination of the blood. Treatment consists of benzimidazole (2.5 mg/kg bid) or nifurtimox (2 mg/kg qid) for at least 60 days, followed by maintenance therapy for the duration of immunodeficiency with either drug at a dose of 5 mg/kg three times a week. As is the case with cerebral toxoplasmosis, successful therapy with ARVs may allow discontinuation of therapy for Chagas' disease.

Stroke may occur in patients with HIV infection. In contrast to the other causes of focal neurologic deficits in patients with HIV infection, the symptoms of a stroke are sudden in onset. Among the secondary infectious diseases in patients with HIV infection that may be associated with stroke are vasculitis due to cerebral varicella zoster or neurosyphilis and septic embolism in association with fungal infection. Other elements of the differential diagnosis of stroke in the patient with HIV infection include atherosclerotic cerebral vascular disease, thrombotic thrombocytopenic purpura, and cocaine or amphetamine use.

Primary CNS lymphoma is discussed below in the section on neoplastic diseases.

Spinal cord disease, or myelopathy, is present in ~20% of patients with AIDS, often as part of HIV encephalopathy. In fact, 90% of the patients with HIV-associated myelopathy have some evidence of dementia, suggesting that similar pathologic processes may be responsible for both conditions. Three main types of spinal cord disease

are seen in patients with AIDS. The first of these is a vacuolar myelopathy, as discussed above under HIV encephalopathy. This condition is pathologically similar to subacute combined degeneration of the cord such as occurs with pernicious anemia. Although vitamin B₁₂ deficiency can be seen in patients with AIDS as a primary complication of HIV infection, it does not appear to be responsible for the myelopathy seen in the majority of patients. Vacuolar myelopathy is characterized by a subacute onset and often presents with gait disturbances, predominantly ataxia and spasticity; it may progress to include bladder and bowel dysfunction. Physical findings include evidence of increased deep tendon reflexes and extensor plantar responses. The second form of spinal cord disease involves the dorsal columns and presents as a pure sensory ataxia. The third form is also sensory in nature and presents with paresthesias and dysesthesias of the lower extremities. In contrast to the cognitive problems seen in patients with HIV encephalopathy, these spinal cord syndromes do not respond well to ARV drugs, and therapy is mainly supportive.

One important disease of the spinal cord that also involves the peripheral nerves is a *myelopathy* and *polyradiculopathy* seen in association with CMV infection. This entity is generally seen late in the course of HIV infection and is fulminant in onset, with lower extremity and sacral paresthesias, difficulty in walking, areflexia, ascending sensory loss, and urinary retention. The clinical course is rapidly progressive over a period of weeks. CSF examination reveals a predominantly neutrophilic pleocytosis, and CMV DNA can be detected by CSF PCR. Therapy with ganciclovir or foscarnet can lead to rapid improvement, and prompt initiation of foscarnet or ganciclovir therapy is important in minimizing the degree of permanent neurologic damage. Combination therapy with both drugs should be considered in patients who have been previously treated for CMV disease. Other diseases involving the spinal cord in patients with HIV infection include HTLV-I-associated myelopathy (HAM) (Chap. 89), neurosyphilis (Chap. 70), infection with herpes simplex (Chap. 80) or varicella-zoster (Chap. 81), TB (Chap. 66), and lymphoma.

Peripheral neuropathies are common in patients with HIV infection. They occur at all stages of illness and take a variety of forms. Early in the course of HIV infection, an acute inflammatory demyelinating polyneuropathy resembling Guillain-Barré syndrome may occur. In other patients, a progressive or relapsing-remitting inflammatory neuropathy resembling chronic inflammatory demyelinating polyneuropathy (CIDP) has been noted. Patients commonly present with progressive weakness, areflexia, and minimal sensory changes. CSF examination often reveals a mononuclear pleocytosis, and peripheral nerve biopsy demonstrates a perivascular infiltrate suggesting an autoimmune etiology. Plasma exchange or IVIg has been tried with variable success. Because of the immunosuppressive effects of glucocorticoids, they should be reserved for severe cases of CIDP refractory to other measures. Another autoimmune peripheral neuropathy seen in patients with AIDS is mononeuritis multiplex due to a necrotizing arteritis of peripheral nerves. The most common peripheral neuropathy in patients with

HIV infection is a *distal sensory polyneuropathy* that may be a direct consequence of HIV infection or a side effect of dideoxynucleoside therapy. Two-thirds of patients with AIDS may be shown by electrophysiologic studies to have some evidence of peripheral nerve disease. Presenting symptoms are usually painful burning sensations in the feet and lower extremities. Findings on examination include a stocking-type sensory loss to pinprick, temperature, and touch sensation and a loss of ankle reflexes. Motor changes are mild and are usually limited to weakness of the intrinsic foot muscles. Response of this condition to ARVs has been variable, perhaps because ARVs are responsible for the problem in some instances. When due to dideoxynucleoside therapy, patients with lower extremity peripheral neuropathy may complain of a sensation that they are walking on ice. Other entities in the differential diagnosis of peripheral neuropathy include diabetes mellitus, vitamin B₁₂ deficiency, and side effects from metronidazole or dapsone. For distal symmetric polyneuropathy that fails to resolve after the discontinuation of dideoxynucleosides, therapy is symptomatic; gabapentin, carbamazepine, tricyclics, or analgesics may be effective for dysesthesias. Treatment-naïve patients may respond to combination ARV therapy.

Myopathy may complicate the course of HIV infection; causes include HIV infection itself, zidovudine, and the generalized wasting syndrome. HIV-associated myopathy may range in severity from an asymptomatic elevation in creatine kinase levels to a subacute syndrome characterized by proximal muscle weakness and myalgias. Quite pronounced elevations in creatine kinase may occur in asymptomatic patients, particularly after exercise. The clinical significance of this as an isolated laboratory finding is unclear. A variety of both inflammatory and noninflammatory pathologic processes have been noted in patients with more severe myopathy, including myofiber necrosis with inflammatory cells, nemaline rod bodies, cytoplasmic bodies, and mitochondrial abnormalities. Profound muscle wasting, often with muscle pain, may be seen after prolonged zidovudine therapy. This toxic side effect of the drug is dose-dependent and is related to its ability to interfere with the function of mitochondrial polymerases. It is reversible after discontinuation of the drug. Red ragged fibers are a histologic hallmark of zidovudine-induced myopathy.

Ophthalmologic Disease

Ophthalmologic problems occur in ~50% of patients with advanced HIV infection. The most common abnormal findings on funduscopic examination are cotton-wool spots. These are hard white spots that appear on the surface of the retina and often have an irregular edge. They represent areas of retinal ischemia secondary to microvascular disease. At times they are associated with small areas of hemorrhage and thus can be difficult to distinguish from CMV retinitis. In contrast to CMV retinitis, however, these lesions are not associated with visual loss and tend to remain stable or improve over time.

One of the most devastating consequences of HIV infection is CMV retinitis. Patients at high risk of CMV

retinitis (CD4+ T-cell count <100/ μ L) should undergo an ophthalmologic examination every 3–6 months. The majority of cases of CMV retinitis occur in patients with a CD4+ T-cell count <50/ μ L. Before the availability of HAART, this CMV reactivation syndrome was seen in 25–30% of patients with AIDS. CMV retinitis usually presents as a painless, progressive loss of vision. Patients may also complain of blurred vision, “floaters,” and scintillations. The disease is usually bilateral, although typically it affects one eye more than the other. The diagnosis is made on clinical grounds by an experienced ophthalmologist. The characteristic retinal appearance is that of perivascular hemorrhage and exudate. In situations where the diagnosis is in doubt due to an atypical presentation or an unexpected lack of response to therapy, vitreous or aqueous humor sampling with molecular diagnostic techniques may be of value. CMV infection of the retina results in a necrotic inflammatory process, and the visual loss that develops is irreversible. CMV retinitis may be complicated by rhegmatogenous retinal detachment as a consequence of retinal atrophy in areas of prior inflammation. Therapy for CMV retinitis consists of oral valganciclovir, IV ganciclovir, or IV foscarnet, with cidofovir as an alternative. Combination therapy with ganciclovir and foscarnet has been shown to be slightly more effective than either ganciclovir or foscarnet alone in the patient with relapsed CMV retinitis. A 3-week induction course is followed by maintenance therapy with oral valganciclovir. If CMV disease is limited to the eye, a ganciclovir-releasing intraocular implant, periodic injections of the antisense nucleic acid preparation fomivirsen, or intravitreal injections of ganciclovir or foscarnet may be considered; some choose to combine intraocular implants with oral valganciclovir. Intravitreal injections of cidofovir are generally avoided due to the increased risk of uveitis and hypotony. Maintenance therapy is continued until the CD4+ T-cell count remains >100–150/ μ L for >6 months. The majority of patients with HIV infection and CMV disease develop some degree of uveitis with the initiation of ARV therapy. The etiology of this is unknown; however, it has been suggested that this may be due to the generation of an enhanced immune response to CMV as an IRIS (see above). In some instances this has required the use of topical glucocorticoids.

Both HSV and varicella zoster virus can cause a rapidly progressing, bilateral necrotizing retinitis referred to as the *acute retinal necrosis syndrome*, or *progressive outer retinal necrosis* (PORN). This syndrome, in contrast to CMV retinitis, is associated with pain, keratitis, and iritis. It is often associated with orolabial HSV or trigeminal zoster. Ophthalmologic examination reveals widespread pale gray peripheral lesions. This condition is often complicated by retinal detachment. It is important to recognize and treat this condition with IV acyclovir as quickly as possible to minimize the loss of vision.

Several other secondary infections may cause ocular problems in HIV-infected patients. *P. jiroveci* can cause a lesion of the choroid that may be detected as an incidental finding on ophthalmologic examination. These lesions are typically bilateral, are from half to twice the

disc diameter in size, and appear as slightly elevated yellow-white plaques. They are usually asymptomatic and may be confused with cotton-wool spots. Chorioretinitis due to toxoplasmosis can be seen alone or, more commonly, in association with CNS toxoplasmosis. KS may involve the eyelid or conjunctiva, whereas lymphoma may involve the retina.

Additional Disseminated Infections and Wasting Syndrome

Infections with species of the small, gram-negative rickettsia-like organism *Bartonella* (Chap. 61) are seen with increased frequency in patients with HIV infection. Although not considered an AIDS-defining illness by the CDC, many experts view infection with *Bartonella* as indicative of a severe defect in cell-mediated immunity. It is usually seen in patients with CD4+ T-cell counts <100/ μ L. Among the clinical manifestations of *Bartonella* infection are bacillary angiomatosis, cat-scratch disease, and trench fever. *Bacillary angiomatosis* is usually due to infection with *B. henselae*. It is characterized by a vascular proliferation that leads to a variety of skin lesions that have been confused with the skin lesions of KS. In contrast to the lesions of KS, the lesions of bacillary angiomatosis generally blanch, are painful, and typically occur in the setting of systemic symptoms. Infection can extend to the lymph nodes, liver (peliosis hepatis), spleen, bone, heart, CNS, respiratory tract, and gastrointestinal tract. *Cat-scratch disease* generally begins with a papule at the site of inoculation. This is followed several weeks later by the development of regional adenopathy and malaise. Infection with *B. quintana* is transmitted by lice and has been associated with case reports of trench fever, endocarditis, adenopathy, and bacillary angiomatosis. The organism is quite difficult to culture, and diagnosis often relies upon identifying the organism in biopsy specimens using the Warthin-Starry or similar stains. Treatment is with either erythromycin or doxycycline for at least 3 months.

Histoplasmosis is an opportunistic infection that is seen most frequently in patients in the Mississippi and Ohio River valleys, Puerto Rico, the Dominican Republic, and South America. These are all areas in which infection with *H. capsulatum* is endemic (Chap. 103). Because of this limited geographic distribution, the percentage of AIDS cases in the United States with histoplasmosis is only ~0.5. Histoplasmosis is generally a late manifestation of HIV infection; however, it may be the initial AIDS-defining condition. In one study, the median CD4+ T-cell count for patients with histoplasmosis and AIDS was 33/ μ L. Although disease due to *H. capsulatum* may present as a primary infection of the lung, disseminated disease, presumably due to reactivation, is the most common presentation in HIV-infected patients. Patients usually present with a 4- to 8-week history of fever and weight loss. Hepatosplenomegaly and lymphadenopathy are each seen in about 25% of patients. CNS disease, either meningitis or a mass lesion, is seen in 15% of patients. Bone marrow involvement is common, with thrombocytopenia, neutropenia, and anemia occurring in 33% of patients. Approximately 7% of patients have

mucocutaneous lesions consisting of a maculopapular rash and skin or oral ulcers. Respiratory symptoms are usually mild, with chest x-ray showing a diffuse infiltrate or diffuse small nodules in ~50% of cases. Diagnosis is made by culturing the organisms from blood, bone marrow, or tissue. Treatment is typically with amphotericin B, 0.7–1.0 mg/kg daily to a total dose of 1 g followed by maintenance therapy with itraconazole. In the setting of mild infection, it may be appropriate to treat with itraconazole alone.

After the spread of HIV infection to southeast Asia, disseminated infection with the fungus *Penicillium marneffei* was recognized as a complication of HIV infection and is considered an AIDS-defining condition in those parts of the world where it occurs. *P. marneffei* is the third most common AIDS-defining illness in Thailand, following TB and cryptococcosis. It is more frequently diagnosed in the rainy than the dry season. Clinical features include fever, generalized lymphadenopathy, hepatosplenomegaly, anemia, thrombocytopenia, and papular skin lesions with central umbilication. Treatment is with amphotericin B followed by itraconazole.

Visceral leishmaniasis (Chap. 119) is recognized with increasing frequency in patients with HIV infection who live in or travel to areas endemic for this protozoal infection transmitted by sandflies. The clinical presentation is one of hepatosplenomegaly, fever, and hematologic abnormalities. Lymphadenopathy and other constitutional symptoms may be present. A chronic, relapsing course is seen in two-thirds of co-infected patients. Organisms can be isolated from cultures of bone marrow aspirates. Histologic stains may be negative, and antibody titers are of little help. Patients with HIV infection usually respond well initially to standard therapy with amphotericin B or pentavalent antimony compounds. Eradication of the organism is difficult, however, and relapses are common.

Patients with HIV infection are at increased risk of clinical malaria. This is particularly true for patients from nonendemic areas with presumed primary infection and in patients with lower CD4+ T-cell counts. HIV-positive individuals with CD4+ T-cell counts <300 cells/ μ L have a poorer response to malaria treatment than others. Coinfection with malaria is associated with a modest increase in HIV viral load. The risk of malaria may be decreased with TMP/SMX prophylaxis.

Generalized wasting is an AIDS-defining condition; it is defined as involuntary weight loss of >10% associated with intermittent or constant fever and chronic diarrhea or fatigue lasting >30 days in the absence of a defined cause other than HIV infection. It is the initial AIDS-defining condition in ~10% of patients with AIDS in the United States and is an indication for initiation of HAART. A constant feature of this syndrome is severe muscle wasting with scattered myofiber degeneration and occasional evidence of myositis. Glucocorticoids may be of some benefit; however, this approach must be carefully weighed against the risk of compounding the immunodeficiency of HIV infection. Androgenic steroids, growth hormone, and total parenteral nutrition have been used as therapeutic interventions with variable success.

Neoplastic Diseases

The neoplastic diseases clearly seen with an increased frequency in patients with HIV infection are KS and non-Hodgkin's lymphoma. In addition, there also appears to be an increased incidence of Hodgkin's disease; multiple myeloma; leukemia; melanoma; and cervical, brain, testicular, oral, lung, and anal cancers. Recent years have witnessed a marked reduction in the incidence of KS (Fig. 90-31) and improvements in the outcomes of HIV-infected patients with non-AIDS-defining malignancies. These changes are primarily due to the use of potent ARV therapy. Rates of non-Hodgkin's lymphoma have declined as well; however, this decline has not been as dramatic as the decline in rates of KS. In contrast, HAART has had little effect on human papilloma virus (HPV)-associated malignancies. As patients with HIV infection live longer, a wider array of cancers are being seen in this population of patients. Although some may only reflect known risk factors (i.e., smoking) that are increased in patients with HIV infection, some may be a direct consequence of HIV.

Kaposi's sarcoma is a multicentric neoplasm consisting of multiple vascular nodules appearing in the skin, mucous membranes, and viscera. The course ranges from indolent, with only minor skin or lymph node involvement, to fulminant, with extensive cutaneous and visceral involvement. In the initial period of the AIDS epidemic, KS was a prominent clinical feature of the first cases of AIDS, occurring in 79% of the patients diagnosed in 1981. By 1989 it was seen in only 25% of cases, by 1992 the number had decreased to 9%, and by 1997 the number was <1%. HHV-8 or KSHV has been strongly implicated as a viral cofactor in the pathogenesis of KS (see above).

Clinically, KS has varied presentations and may be seen at any stage of HIV infection, even in the presence of a normal CD4+ T-cell count. The initial lesion may be a small, raised reddish-purple nodule on the skin (Fig. 90-39), a discoloration on the oral mucosa (Fig. 90-32D), or a swollen lymph node. Lesions often appear

in sun-exposed areas, particularly the tip of the nose, and have a propensity to occur in areas of trauma (Koebner phenomenon). Because of the vascular nature of the tumors and the presence of extravasated red blood cells in the lesions, their colors range from reddish to purple to brown and often take the appearance of a bruise, with yellowish discoloration and tattooing. Lesions range in size from a few millimeters to several centimeters in diameter and may be either discrete or confluent. KS lesions most commonly appear as raised macules; however, they can also be papular, particularly in patients with higher CD4+ T-cell counts. Confluent lesions may give rise to surrounding lymphedema and may be disfiguring when they involve the face and disabling when they involve the lower extremities or the surfaces of joints. Apart from skin, lymph nodes, gastrointestinal tract, and lung are the organ systems most commonly affected by KS. Lesions have been reported in virtually every organ, including the heart and the CNS. In contrast to most malignancies, in which lymph node involvement implies metastatic spread and a poor prognosis, lymph node involvement may be seen very early in KS and is of no special clinical significance. In fact, some patients may present with disease limited to the lymph nodes. These are generally patients with relatively intact immune function and thus the patients with the best prognosis. Pulmonary involvement with KS generally presents with shortness of breath. Some 80% of patients with pulmonary KS also have cutaneous lesions. The chest x-ray characteristically shows bilateral lower lobe infiltrates that obscure the margins of the mediastinum and diaphragm (Fig. 90-40). Pleural effusions are seen in 70% of cases of pulmonary KS, a fact that is often helpful in the differential diagnosis. Gastrointestinal

FIGURE 90-39

| PARAMETER | GOOD RISK (STAGE 0): ALL OF THE FOLLOWING | POOR RISK (STAGE 1): ANY OF THE FOLLOWING |
|----------------------|--|---|
| Tumor (T) | Confined to skin and/or lymph nodes and/or minimal oral disease | Tumor-associated edema or ulceration Extensive oral lesions Gastrointestinal lesions Nonnodal visceral lesions |
| Immune system (I) | CD4+ T-cell count $\geq 200/\mu\text{L}$ | CD4+ T-cell count $< 200/\mu\text{L}$ |
| Systemic illness (S) | No B symptoms ^a Karnofsky performance status ≥ 70 No history of opportunistic infection, neurologic disease, lymphoma, or thrush | B symptoms ^a present Karnofsky performance status < 70 History of opportunistic infection, neurologic disease, lymphoma, or thrush |

^aDefined as unexplained fever, night sweats, $>10\%$ involuntary weight loss, or diarrhea persisting for more than 2 weeks.

involvement is seen in 50% of patients and usually takes one of two forms: (1) mucosal involvement, which may lead to bleeding that can be severe; these patients sometimes also develop symptoms of gastrointestinal obstruction if lesions become large; and (2) biliary tract involvement. KS lesions may infiltrate the gallbladder and biliary tree, leading to a clinical picture of obstructive jaundice similar to that seen with sclerosing cholangitis. Several staging systems have been proposed for KS. One in common use was developed by the National Institute of Allergy and Infectious Diseases AIDS Clinical Trials Group; it distinguishes patients on the basis of tumor extent, immunologic function, and presence or absence of systemic disease (Table 90-14).

A diagnosis of KS is based upon biopsy of a suspicious lesion. Histologically one sees a proliferation of spindle cells and endothelial cells, extravasation of red blood cells, hemosiderin-laden macrophages, and, in early cases, an inflammatory cell infiltrate. Included in the differential diagnosis are lymphoma (particularly for oral lesions), bacillary angiomatosis, and cutaneous mycobacterial infections.

Management of KS (Table 90-15) should be carried out in consultation with an expert since definitive treatment guidelines do not exist. In the majority of cases, effective ARV therapy will go a long way in achieving control. Indeed, spontaneous regressions have been reported in the setting of HAART. For patients in whom tumor persists or in whom control of HIV replication is not possible, a variety of options exist. In some cases, lesions remain quite indolent, and many of these patients can be managed with no specific treatment. Fewer than 10% of AIDS patients with KS die as a consequence of their malignancy, and death from secondary infections is considerably more common. Thus, whenever possible, one should avoid treatment regimens that may further suppress the immune system and increase susceptibility to opportunistic infections. Treatment is

indicated under two main circumstances. The first is when a single lesion or a limited number of lesions are causing significant discomfort or cosmetic problems, such as with prominent facial lesions, lesions overlying a joint, or lesions in the oropharynx that interfere with swallowing or breathing. Under these circumstances, treatment with localized radiation, intralesional vinblastine, or cryotherapy may be helpful. It should be noted that patients with HIV infection are particularly sensitive to the side effects of radiation therapy. This is especially true with respect to the development of radiation-induced mucositis; doses of radiation directed at mucosal surfaces, particularly in the head and neck region, should be adjusted accordingly. The use of systemic therapy, either IFN- α or chemotherapy, should be considered in patients with a large number of lesions or in patients with visceral involvement. The single most important

| Radiation treatment |

determinant of response appears to be the CD4+ T-cell count. This relationship between response rate and baseline CD4+ T-cell count is particularly true for IFN- α . The response rate for patients with CD4+ T-cell counts $>600/\mu\text{L}$ is $\sim 80\%$, whereas the response rate for patients with counts $<150/\mu\text{L}$ is $<10\%$. In contrast to the other systemic therapies, IFN- α provides an added advantage of having ARV activity; thus it may be the appropriate first choice for single-agent systemic therapy for early patients with disseminated disease. A variety of chemotherapeutic agents have also been shown to have activity against KS. Three of them, liposomal daunorubicin, liposomal doxorubicin, and paclitaxel, have been approved by the FDA for this indication. Liposomal daunorubicin is approved as first-line therapy for patients with advanced KS. It has fewer side effects than conventional chemotherapy. In contrast, liposomal doxorubicin and paclitaxel are approved only for KS patients who have failed standard chemotherapy. Response rates vary from 23–88%, appear to be comparable to what had been achieved earlier with combination chemotherapy regimens, and are greatly influenced by CD4+ T-cell count.

Lymphomas occur with an increased frequency in patients with congenital or acquired T-cell immunodeficiencies. AIDS is no exception; at least 6% of all patients with AIDS develop lymphoma at some time during the course of their illness. This is a 120-fold increase in incidence compared with that of the general population. In contrast to the situation with KS, primary CNS lymphoma, and most opportunistic infections, the incidence of AIDS-associated systemic lymphomas has not experienced as dramatic a decrease as a consequence of the widespread use of effective ARV therapy. Lymphoma occurs in all risk groups, with the highest incidence in patients with hemophilia and the lowest incidence in patients from the Caribbean or Africa with heterosexually acquired infection. Lymphoma is a late manifestation of HIV infection, generally occurring in patients with CD4+ T-cell counts $<200/\mu\text{L}$. As HIV disease progresses, the risk of lymphoma increases. In contrast to KS, which occurs at a relatively constant rate throughout the course of HIV disease, the attack rate for lymphoma increases exponentially with increasing duration of HIV infection and decreasing level of immunologic function. At 3 years after a diagnosis of HIV infection, the risk of lymphoma is 0.8% per year; by 8 years after infection, it is 2.6% per year. As individuals with HIV infection live longer as a consequence of improved ARV therapy and better treatment and prophylaxis of opportunistic infections, it is anticipated that the incidence of lymphomas may increase.

Three main categories of lymphoma are seen in patients with HIV infection: grade III or IV immunoblastic lymphoma, Burkitt's lymphoma, and primary CNS lymphoma. Approximately 90% of these lymphomas are B cell in phenotype, and half contain EBV DNA. These tumors may be either monoclonal or oligoclonal in nature and are probably in some way related to the pronounced polyclonal B-cell activation seen in patients with AIDS.

Immunoblastic lymphomas account for $\sim 60\%$ of the cases of lymphoma in patients with AIDS. These are generally high grade and would have been classified as diffuse histiocytic lymphomas in earlier classification schemes. This tumor is more common in older patients, increasing in incidence from 0% in HIV-infected individuals <1 year old to $>3\%$ in those >50 . One variant of immunoblastic lymphoma is body cavity lymphoma. This malignancy presents with lymphomatous pleural, pericardial, and/or peritoneal effusions in the absence of discrete nodal or extranodal masses. The tumor cells do not express surface markers for B cells or T cells. HHV-8 DNA sequences have been found in the genomes of the malignant cells from patients with body cavity lymphomas (see above).

Small noncleaved cell lymphoma (Burkitt's lymphoma) accounts for $\sim 20\%$ of the cases of lymphoma in patients with AIDS. It is most frequent in patients 10–19 years old and usually demonstrates characteristic *c-myc* translocations from chromosome 8 to chromosomes 14 or 22. Burkitt's lymphoma is not commonly seen in the setting of immunodeficiency other than HIV-associated immunodeficiency, and the incidence of this particular tumor is more than 1000-fold higher in the setting of HIV infection than in the general population. In contrast to African Burkitt's lymphoma, where 97% of the cases contain EBV genome, only 50% of HIV-associated Burkitt's lymphomas are EBV-positive.

Primary CNS lymphoma accounts for $\sim 20\%$ of the cases of lymphoma in patients with HIV infection. In contrast to HIV-associated Burkitt's lymphoma, primary CNS lymphomas are usually positive for EBV. In one study, the incidence of Epstein-Barr positivity was 100%. This malignancy does not have a predilection for any particular age group. The median CD4+ T-cell count at the time of diagnosis is $\sim 50/\mu\text{L}$. Thus CNS lymphoma generally presents at a later stage of HIV infection than systemic lymphoma. This fact may at least in part explain the poorer prognosis for this subset of patients.

The clinical presentation of lymphoma in patients with HIV infection is quite varied, ranging from focal seizures to rapidly growing mass lesions in the oral mucosa (Fig. 90-41) to persistent unexplained fever. At

FIGURE 90-41

Diffuse histiocytic lymphoma involving the hard palate of a patient with AIDS.

**FIGURE 90-42**

Central nervous system lymphoma. Postcontrast T1-weighted MR scan in a patient with AIDS, an altered mental status, and hemiparesis. Multiple enhancing lesions, some ring-enhancing, are present. The left Sylvian lesion shows gyral and subcortical enhancement, and the lesions in the caudate and splenium (arrowheads) show enhancement of adjacent endymal surfaces.

least 80% of patients present with extranodal disease, and a similar percentage have B-type symptoms of fever, night sweats, or weight loss. Virtually any site in the body may be involved. The most common extranodal site is the CNS, which is involved in approximately one-third of all patients with lymphoma. Approximately 60% of these cases are primary CNS lymphoma. Primary CNS lymphoma generally presents with focal neurologic deficits, including cranial nerve findings, headaches, and/or seizures. MRI or CT generally reveals a limited number (one to three) of 3- to 5-cm lesions (Fig. 90-42). The lesions often show ring enhancement on contrast administration and may occur in any location. Locations that are most commonly involved with CNS lymphoma are deep in the white matter. Contrast enhancement is usually less pronounced than that seen with toxoplasmosis. The main diseases in the differential diagnosis are cerebral toxoplasmosis and cerebral Chagas' disease. In addition to the 20% of lymphomas in HIV-infected individuals that are primary CNS lymphomas, CNS disease is also seen in HIV-infected patients with systemic lymphoma. Approximately 20% of patients with systemic lymphoma have CNS disease in the form of leptomeningeal involvement. This fact underscores the importance of lumbar puncture in the staging evaluation of patients with systemic lymphoma.

Systemic lymphoma is seen at earlier stages of HIV infection than primary CNS lymphoma. In one series the mean CD4+ T-cell count was 189/ μ L. In addition

to lymph node involvement, systemic lymphoma may commonly involve the gastrointestinal tract, bone marrow, liver, and lung. Gastrointestinal tract involvement is seen in ~25% of patients. Any site in the gastrointestinal tract may be involved, and patients may complain of difficulty swallowing or abdominal pain. The diagnosis is usually suspected on the basis of CT or MRI of the abdomen. Bone marrow involvement is seen in ~20% of patients and may lead to pancytopenia. Liver and lung involvement are each seen in ~10% of patients. Pulmonary disease may present as either a mass lesion, multiple nodules, or an interstitial infiltrate.

Both conventional and unconventional approaches have been employed in an attempt to treat HIV-related lymphomas. Systemic lymphoma is generally treated by the oncologist with combination chemotherapy. Earlier disappointing figures are being replaced with more optimistic results for the treatment of systemic lymphoma following the availability of more effective combination ARV therapy. As in most situations in patients with HIV disease, those with the higher CD4+ T-cell counts tend to do better. Response rates as high as 72% with a median survival of 33 months and disease-free intervals up to 9 years have been reported. Treatment of primary CNS lymphoma remains a significant challenge. Treatment is complicated by the fact that this illness usually occurs in patients with advanced HIV disease. Palliative measures such as radiation therapy provide some relief. The prognosis remains poor in this group, with a 2-year survival of 29%.

Multicentric Castleman's disease is an HHV-8 associated lymphoproliferative disorder that is seen with an increased frequency in patients with HIV infection. Although not a true malignancy, it shares many features with lymphoma, including generalized lymphadenopathy, hepatosplenomegaly, and systemic symptoms of fever, fatigue, and weight loss. Pulmonary symptoms may be seen in ~50% of patients. Kaposi's sarcoma is present in 75–82% of cases. Lymph node biopsies reveal a predominance of interfollicular plasma cells and/or germinal centers with vascularization and an "onion skin" appearance (hyaline vascular). Before the availability of HAART, HIV-infected patients with multicentric Castleman's disease had a 15-fold increased risk of developing non-Hodgkin's lymphoma compared with HIV-infected patients in general. Treatment typically involves chemotherapy. Anecdotal reports of success with rituximab suggest that more specific treatment may be successful, although in one series, treatment with rituximab was associated with worsening of coexisting KS. The median survival of patients with treated multicentric Castleman's disease pre-HAART was 14 months. This has increased to 4 years in the era of HAART.

Evidence of infection with *human papilloma virus* (HPV), associated with *intraepithelial dysplasia of the cervix* or *anus*, is approximately twice as common in HIV-infected individuals as in the general population and can lead to intraepithelial neoplasia and eventually invasive cancer. In separate studies, HIV-infected men were examined for evidence of anal dysplasia, and Papanicolaou (Pap) smears were found to be abnormal in 20–80%. These changes

tend to persist and are generally not affected by HAART, raising the possibility of a subsequent transition to a more malignant condition. Although the incidence of an abnormal Pap smear of the cervix is ~5% in otherwise healthy women, the incidence of abnormal cervical smears in women with HIV infection is 30–60%, and *invasive cervical cancer* is included as an AIDS-defining condition. Thus far, however, only small increases in the incidence of cervical or anal cancer have been seen as a consequence of HIV infection. However, given this high rate of dysplasia, a comprehensive gynecologic and rectal examination, including Pap smear, is indicated at the initial evaluation and 6 months later for all patients with HIV infection. If these examinations are negative at both time points, the patient should be followed with yearly evaluations. If an initial or repeat Pap smear shows evidence of severe inflammation with reactive squamous changes, the next Pap smear should be performed at 3 months. If, at any time, a Pap smear shows evidence of squamous intraepithelial lesions, colposcopic examination with biopsies as indicated should be performed. The 2-year survival rate for HIV infected patients with invasive cervical cancer is 64% compared with 79% in non-HIV-infected patients. The most common HPV genotypes in the general population and the genotypes upon which current HPV vaccines are based are 16 and 18. This is not the case in the HIV-infected population, where other genotypes such as 56 and 53 predominate. This raises concerns as to the potential effectiveness of the current HPV vaccines for HIV-infected patients.

IDIOPATHIC CD4+ T LYMPHOCYTOPENIA

A syndrome was recognized in 1992 that was characterized by an absolute CD4+ T-cell count of <300/ μ L or <20% of total T cells on a minimum of two occasions at least 6 weeks apart; no evidence of HIV-1, HIV-2, HTLV-I, or HTLV-II on testing; and the absence of any defined immunodeficiency or therapy associated with decreased levels of CD4+ T cells. By mid-1993, ~100 patients had been described. After extensive multicenter investigations, a series of reports were published in early 1993, which together allowed a number of conclusions. Idiopathic CD4+ lymphocytopenia (ICL) is a very rare syndrome, as determined by studies of blood donors and cohorts of HIV-seronegative men who have sex with men. Cases were clearly identified as early as 1983, and cases remarkably similar to ICL had been identified decades ago. The definition of ICL based on CD4+ T-cell counts coincided with the ready availability of testing for CD4+ T cells in patients suspected of being immunosuppressed. Although, as a result of immune deficiency, certain patients with ICL develop some of the opportunistic diseases (particularly cryptococcosis) seen in HIV-infected patients, the syndrome is demographically, clinically, and immunologically unlike HIV infection and AIDS. Fewer than half of the reported ICL patients had risk factors for HIV infection, and there were wide geographic and age distributions. The

fact that a significant proportion of patients did have risk factors probably reflects a selection bias, in that physicians who take care of HIV-infected patients are more likely to monitor CD4+ T cells. Approximately one-third of the patients are women, compared with 16% of women among HIV-infected individuals in the United States. Many patients with ICL remained clinically stable, and their condition did not deteriorate progressively as is common with seriously immunodeficient HIV-infected patients. Certain patients with ICL even experienced spontaneous reversal of the CD4+ T lymphocytopenia. Immunologic abnormalities in ICL are somewhat different from those of HIV infection. ICL patients often also have decreases in CD8+ T cells and in B cells. Furthermore, immunoglobulin levels were either normal or, more commonly, decreased in patients with ICL, compared with the usual hypergammaglobulinemia of HIV-infected individuals. Finally, virologic studies revealed no evidence of HIV-1, HIV-2, HTLV-I, or HTLV-II or of any other mononuclear cell-tropic virus. Furthermore, there was no epidemiologic evidence to suggest that a transmissible microbe was involved. The cases of ICL were widely dispersed, with no clustering. Close contacts and sexual partners who were studied were clinically well and were serologically, immunologically, and virologically negative for HIV. ICL is a heterogeneous syndrome, and it is highly likely that there is no common cause; however, there may be common causes among subgroups of patients that are currently unrecognized.

Patients who present with laboratory data consistent with ICL should be worked up for underlying diseases that could be responsible for the immune deficiency. If no underlying cause is detected, no specific therapy should be initiated. However, if opportunistic diseases occur, they should be treated appropriately (see above). Depending on the level of the CD4+ T-cell count, patients should receive prophylaxis for the commonly encountered opportunistic infections.

Rx Treatment: AIDS AND RELATED DISORDERS

GENERAL PRINCIPLES OF PATIENT MANAGEMENT The CDC guidelines call for the testing for HIV infection to be a part of routine medical care. It is recommended that the patient be informed of the intention to test as is the case with other routine laboratory determinations and be given the opportunity to “opt out.” Such an approach is critical to the goal of identifying as many infected individuals as possible since ~25% of the >1 million individuals in the United States who are HIV-infected are not aware of their status. Under these circumstances of routine testing, although desirable, pretest counseling may not always be built into the testing process. However, no matter how well prepared a patient is for adversity, the discovery of a diagnosis of HIV infection is a devastating event. Thus physicians should be sensitive to this fact and, where possible, execute some degree of pretest counseling to at least partially prepare

the patient should the results demonstrate the presence of HIV infection. After a diagnosis of HIV infection, the health care provider should be prepared to activate support systems immediately for the newly diagnosed patient. These should include an experienced social worker or nurse who can spend time talking to the person and ensuring that he or she is emotionally stable. Most communities have HIV support centers that can be of great help in these difficult situations.

The treatment of patients with HIV infection requires not only a comprehensive knowledge of the possible disease processes that may occur and up-to-date knowledge of and experience with ARV therapy, but also the ability to deal with the problems of a chronic, potentially life-threatening illness. A comprehensive knowledge of internal medicine is required to deal with the changing spectrum of illness associated with HIV infection. Great advances have been made in the treatment of patients with HIV infection. The appropriate use of potent combination ARV therapy and other treatment and prophylactic interventions is of critical importance in providing each patient with the best opportunity to live a long and healthy life despite the presence of HIV infection. In contrast to the earlier days of this epidemic, a diagnosis of HIV infection need no longer be equated with an inevitably fatal disease. In addition to medical interventions, the health care provider has a responsibility to provide each patient with appropriate counseling and education concerning their disease as part of a comprehensive care plan. Patients must be educated about the potential transmissibility of their infection and about the fact that although health care providers may refer to levels of the virus as “undetectable,” this is more a reflection of the sensitivity of the assay being used to measure the virus than a comment on the presence or absence of the virus. It is important for patients to be aware that the virus is still present and capable of being transmitted at all stages of HIV disease. Thus there need to be frank discussions concerning sexual practices and the sharing of needles. The treating physician must not only be aware of the latest medications available for patients with HIV infection, but must also educate patients concerning the natural history of their illness and listen and be sensitive to their fears and concerns. As with other diseases, therapeutic decisions should be made in consultation with the patient, when possible, and with the patient’s proxy if the patient is incapable of making decisions. In this regard, it is recommended that all patients with HIV infection, and in particular those with CD4+ T-cell counts <200/μL, designate a trusted individual with durable power of attorney to make medical decisions on their behalf, if necessary.

After a diagnosis of HIV infection, there are several examinations and laboratory studies that should be performed to help determine the extent of disease and provide baseline standards for future reference (Table 90-16). In addition to routine chemistry, fasting lipid profile, fasting glucose and hematology screening panels, Pap smear, and chest x-ray, one

TABLE 90-16

INITIAL EVALUATION OF THE PATIENT WITH HIV INFECTION

History and physical examination
 Routine chemistry and hematology
 Lipid profile and fasting glucose
 CD4+ T-lymphocyte count
 Two plasma HIV RNA levels
 HIV resistance testing
 RPR test
 Anti-*Toxoplasma* antibody titer
 PPD skin test
 Mini-mental status examination
 Serologies for hepatitis A, hepatitis B, and hepatitis C
 Immunization with pneumococcal polysaccharide;
 influenza as indicated
 Immunization with hepatitis A and hepatitis B if
 seronegative
 Counseling regarding natural history and transmission
 Help contacting others who might be infected

Note: VDRL, Venereal Disease Research Laboratory; PPD, purified protein derivative.

should also obtain a CD4+ T-cell count, two separate plasma HIV RNA levels, an HIV resistance test, an RPR or VDRL test, an anti-*Toxoplasma* antibody titer, and serologies for hepatitis A, B, and C. A PPD test should be done, and an MMSE performed and recorded. Patients should be immunized with pneumococcal polysaccharide and, if seronegative for these viruses, with hepatitis A and hepatitis B vaccines. The status of hepatitis C infection should be determined. In addition, patients should be counseled with regard to sexual practices and needle sharing, and counseling should be offered to those whom the patient knows or suspects may also be infected. Once these baseline activities are performed, short- and long-term medical management strategies should be developed based upon the most recent information available and modified as new information becomes available. The field of HIV medicine is changing rapidly, and it is difficult to remain fully up to date. Fortunately there are a series of excellent sites on the Internet that are frequently updated, and they provide the most recent information on a variety of topics, including consensus panel reports on treatment (Table 90-17).

ANTIRETROVIRAL THERAPY Combination antiretroviral therapy (ART), or highly active antiretroviral therapy (HAART), is the cornerstone of management of patients with HIV infection. After the initiation of widespread use of HAART in the United States in 1995–1996, marked declines have been noted in the incidence of most AIDS-defining conditions (Fig. 90-31). Suppression of HIV replication is an important component in prolonging life as well as in improving the quality of life in patients with HIV infection. Adequate suppression requires strict adherence to prescribed regimens of ARV

Note: CDC, Centers for Disease Control and Prevention.

drugs. This has been facilitated by the coformulations of ARVs and the development of once-daily regimens. Unfortunately, many of the most important questions related to the treatment of HIV disease currently lack definitive answers. Among them are the questions of when should therapy be started, what is the best initial regimen, when should a given regimen be changed, and what should it be changed to when a change is made. Notwithstanding these uncertainties, the physician and patient must come to a mutually agreeable plan based

upon the best available data. In an effort to facilitate this process, the U.S. Department of Health and Human Services has published a series of frequently updated guidelines including the "Principles of Therapy of HIV Infection," "Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents," and "Guidelines for the Prevention of Opportunistic Infections in Persons Infected with Human Immunodeficiency Virus." At present, an extensive clinical trials network, involving both clinical investigators and patient advocates, is in place attempting to develop improved approaches to therapy. Consortia comprising representatives of academia, industry, independent foundations, and the federal government are involved in the process of drug development, including a wide-ranging series of clinical trials. As a result, new therapies and new therapeutic strategies are continually emerging. New drugs are often available through expanded access programs before official licensure. Given the complexity of this field, decisions regarding ARV therapy are best made in consultation with experts. Currently available drugs for the treatment of HIV infection fall into four categories: those that inhibit the viral reverse transcriptase enzyme, those that inhibit the viral protease enzyme, those that inhibit the viral integrase enzyme, and those that interfere with viral entry (Table 90-18, Fig. 90-43).

The FDA-approved reverse transcriptase inhibitors include the *nucleoside analogues* zidovudine, didanosine, zalcitabine, stavudine, lamivudine, abacavir, and

ANTIRETROVIRAL DRUGS USED IN THE TREATMENT OF HIV INFECTION

| DRUG | STATUS | INDICATION | DOSE IN COMBINATION | SUPPORTING DATA | TOXICITY |
|---|----------------------------------|---|---|---|--|
| Reverse Transcriptase Inhibitors | | | | | |
| Zidovudine (AZT, azidothymidine, Retrovir, 3'-azido-3'-deoxythymidine) | Licensed | Treatment of HIV infection in combination with other antiretroviral agents Prevention of maternal-fetal HIV transmission | 200 mg q8h or 300 mg bid | 19 vs 1 death in original placebo-controlled trial in 281 patients with AIDS or ARC. Decreased progression to AIDS in patients with CD4+ T-cell counts <500/ μ L, $n = 2051$ In pregnant women with CD4+ T-cell count $\geq 200/\mu$ L, AZT PO beginning at weeks 14–34 of gestation plus IV drug during labor and delivery plus PO AZT to infant for 6 wk decreased transmission of HIV by 67.5% (from 25.5% to 8.3%), $n = 363$ Clinically superior to AZT as monotherapy in 913 patients with prior AZT therapy. Clinically superior to AZT and comparable to AZT + ddI and AZT + ddC in 1067 AZT-naïve patients with CD4+ T-cell counts of 200–500/ μ L | Anemia, granulocytopenia, myopathy, lactic acidosis, hepatomegaly with steatosis, headache, nausea |
| Didanosine (Videx, Videx EC, ddI, dideoxyinosine, 2',3'-dideoxyinosine) | Licensed | For treatment of HIV infection in combination with other antiretroviral agents | Buffered: Requires 2 tablets to achieve adequate buffering of stomach acid; should be administered on an empty stomach ≥ 60 kg: 200 mg bid <60 kg: 125 mg bid Enteric coated: ≥ 60 kg: 400 mg qd <60 kg: 250 mg qd | Clinically superior to AZT as monotherapy in 913 patients with prior AZT therapy. Clinically superior to AZT and comparable to AZT + ddI and AZT + ddC in 1067 AZT-naïve patients with CD4+ T-cell counts of 200–500/ μ L | Pancreatitis, peripheral neuropathy, abnormalities on liver function tests, lactic acidosis, hepatomegaly with steatosis |
| Zalcitabine (ddC, HIVID, 2',3'-dideoxycytidine) | Licensed Discontinued in 2006 | In combination with other antiretroviral agents for the treatment of HIV infection | 0.75 mg tid | Clinically inferior to AZT monotherapy as initial treatment. Clinically as good as ddI in advanced patients intolerant to AZT. In combination with AZT, was clinically superior to AZT alone in patients with AIDS or CD4+ T-cell count <350/ μ L | Peripheral neuropathy, pancreatitis, lactic acidosis, hepatomegaly with steatosis, oral ulcers |
| Stavudine (d4T, Zerit, 2',3'-didehydro-3'-dideoxythymidine) | Licensed | Treatment of HIV-infected patients in combination with other antiretroviral agents | ≥ 60 kg: 40 mg bid <60 kg: 30 mg bid | Superior to AZT with respect to changes in CD4+ T-cell counts in 359 patients who had received ≥ 24 wk of AZT. After 12 wk of randomization, the CD4+ T-cell count had decreased in AZT-treated controls by a mean of 22/ μ L, whereas in stavudine-treated patients, it had increased by a mean of 22/ μ L | Peripheral neuropathy, pancreatitis, lactic acidosis, hepatomegaly with steatosis, ascending neuromuscular weakness, lipodystrophy |

TABLE 90-18 (CONTINUED)

ANTIRETROVIRAL DRUGS USED IN THE TREATMENT OF HIV INFECTION

| DRUG | STATUS | INDICATION | DOSE IN COMBINATION | SUPPORTING DATA | TOXICITY |
|--|----------|--|---------------------------------------|---|---|
| Lamivudine (Epivir, 2'3'-dideoxy-3'-thiacytidine, 3TC) | Licensed | In combination with other antiretroviral agents for the treatment of HIV infection | 150 mg bid 300 mg qd | Superior to AZT alone with respect to changes in CD4 counts in 495 patients who were zidovudine-naïve and 477 patients who were zidovudine-experienced. Overall CD4+ T-cell counts for the zidovudine group were at baseline by 24 wk, whereas in the group treated with zidovudine plus lamivudine, they were 10–50 cells/μL above baseline. 54% decrease in progression to AIDS/death compared with AZT alone | Hepatotoxicity |
| Emtricitabine (FTC, Emtriva) | Licensed | In combination with other antiretroviral agents for the treatment of HIV infection | 200 mg qd | Comparable to d4T in combination with ddI and efavirenz in 571 treatment-naïve patients. Similar to 3TC in combination with AZT or d4T + NNRT1 or PI in 440 patients doing well for at least 12 weeks on a 3TC regimen | Hepatotoxicity |
| Abacavir (Ziagen) | Licensed | For treatment of HIV infection in combination with other antiretroviral agents | 300 mg bid | Abacavir + AZT + 3TC equivalent to indinavir + AZT + 3TC with regard to viral load suppression (~60% in each group with <400 HIV RNA copies/mL plasma) and CD4 cell increase (~100/μL in each group) at 24 weeks | Hypersensitivity reaction (can be fatal); fever, rash, nausea, vomiting, malaise or fatigue, and loss of appetite |
| Tenofovir (Viread) | Licensed | For use in combination with other antiretroviral agents when treatment is indicated | 300 mg qd | Reduction of ~0.6 log in HIV-1 RNA levels when added to background regimen in treatment-experienced patients | Potential for renal toxicity |
| Delavirdine (Rescriptor) | Licensed | For use in combination with appropriate antiretrovirals when treatment is warranted | 400 mg tid | Delavirdine + AZT superior to AZT alone with regard to viral load suppression at 52 weeks | Skin rash, abnormalities in liver function tests |
| Nevirapine (Viramune) | Licensed | In combination with other antiretroviral agents for treatment of progressive HIV infection | 200 mg/d × 14 days then 200 mg bid | Increases in CD4+ T-cell count, decrease in HIV RNA when used in combination with nucleosides | Skin rash, hepatotoxicity |

| | | | | | |
|---|--------------------------------|---|---|---|--|
| Efavirenz (Sustiva) | Licensed | For treatment of HIV infection in combination with other antiretroviral agents | 600 mg qhs | Efavirenz + AZT + 3TC comparable to indinavir + AZT + 3TC with regard to viral load suppression (a higher percentage of the efavirenz group achieved viral load <50 copies/mL; however, the discontinuation rate in the indinavir group was unexpectedly high, accounting for most treatment “failures”); CD4 cell increase (~140/μL in each group) at 24 weeks | Rash, dysphoria, elevated liver function tests, drowsiness, abnormal dreams, depression |
| Etravirine | Expanded access 1-866-889-2074 | Pending | Pending | Pending | Rash, headache, dizziness, nausea, diarrhea |
| Protease Inhibitors | | | | | |
| Saquinavir mesylate (Invirase—hard gel capsule) | Licensed | In combination with other antiretroviral agents when therapy is warranted | 1000 mg + 100 mg ritonavir bid | Increases in CD4+ T-cell counts, reduction in HIV RNA most pronounced in combination therapy with ddC. 50% reduction in first AIDS-defining event or death in combination with ddC compared with either agent alone | Diarrhea, nausea, headaches, hyperglycemia, fat redistribution, lipid abnormalities |
| (Fortovase—soft gel capsule) | Licensed Discontinued 2006 | For use in combination with other antiretroviral agents when treatment is warranted | 1200 mg tid | Reduction in the mortality rate and AIDS-defining events for patients who received hard-gel formulation in combination with ddC | Diarrhea, nausea, abdominal pain, headaches, hyperglycemia, fat redistribution, lipid abnormalities |
| Ritonavir (Norvir) | Licensed | In combination with other antiretroviral agents for treatment of HIV infection when treatment is warranted | 600 mg bid | Reduction in the cumulative incidence of clinical progression or death from 34 to 17% in patients with CD4+ T-cell count <100/μL treated for a median of 6 months | Nausea, abdominal pain, hyperglycemia, fat redistribution, lipid abnormalities, may alter levels of many other drugs, including saquinavir |
| Indinavir sulfate (Crixivan) | Licensed | For treatment of HIV infection in combination with other antiretroviral agents when antiretroviral treatment is warranted | 800 mg q8h or 800 mg + 100 mg ritonavir bid or 1000 mg q8h when used with efavirenz or nevirapine | Increase in CD4+ T-cell count by 100/μL and 2-log decrease in HIV RNA levels when given in combination with zidovudine and lamivudine. Decrease of 50% in risk of progression to AIDS or death when given with zidovudine and lamivudine compared with zidovudine and lamivudine alone | Nephrolithiasis, indirect hyperbilirubinemia, hyperglycemia, fat redistribution, lipid abnormalities |

TABLE 90-18 (CONTINUED)
ANTIRETROVIRAL DRUGS USED IN THE TREATMENT OF HIV INFECTION

| DRUG | STATUS | INDICATION | DOSE IN COMBINATION | SUPPORTING DATA | TOXICITY |
|--------------------------------|----------|---|---|--|--|
| Nelfinavir mesylate (Viracept) | Licensed | For treatment of HIV infection in combination with other antiretroviral agents when antiretroviral therapy is warranted | 750 mg tid or 1250 mg bid | 2.0-log decline in HIV RNA when given in combination with stavudine | Diarrhea, loose stools, hyperglycemia, fat redistribution, lipid abnormalities May contain traces of the potential carcinogen/teratogen ethyl methane sulfonate |
| Amprenavir (Agenerase) | Licensed | In combination with other antiretroviral agents for treatment of HIV infection | 1200 mg bid or 600 mg + 100 mg ritonavir bid or 1200 mg + 200 mg ritonavir qd | In treatment-naïve patients, amprenavir + AZT + 3TC superior to AZT + 3TC with regard to viral load suppression (53% vs 11% with <400 HIV RNA copies/mL plasma at 24 weeks). CD4+ T-cell responses similar between treatment groups. In treatment-experienced patients, amprenavir + NRTIs similar to indinavir + NRTIs with regard to viral load suppression (43% vs 53% with <400 HIV RNA copies/mL plasma at 24 weeks). CD4+ T-cell responses superior in the indinavir + NRTIs group | Nausea, vomiting, diarrhea, rash, oral paresthesias, elevated liver function tests, hyperglycemia, fat redistribution, lipid abnormalities |
| Fosamprenavir (Lexiva) | Licensed | | 1400 mg bid or 700 mg + 100 mg ritonavir bid | | |
| Lopinavir/ritonavir (Kaletra) | Licensed | For treatment of HIV infection in combination with other antiretroviral agents | 400 mg/100 mg bid | In treatment-naïve patients, lopinavir/ritonavir + d4T + 3TC superior to nelfinavir + d4T + 3TC with regard to viral load suppression (79% vs 64% with <400 HIV RNA copies/mL at 40 weeks). CD4+ T-cell increases similar in both groups | Diarrhea, hyperglycemia, fat redistribution, lipid abnormalities |
| Atazanavir (Reyataz) | Licensed | For treatment of HIV infection in combination with other antiretroviral agents | 400 mg qd or 300 mg qd + Ritonavir 100 mg qd when given with efavirenz | Comparable to efavirenz when given in combination with AZT + 3TC in a study of 810 treatment-naïve patients. Comparable to nelfinavir when given in combination with d4T + 3TC in a study of 467 treatment-naïve patients | Hyperbilirubinemia, PR prolongation, nausea, vomiting, hyperglycemia, fat maldistribution |
| Tipranavir (Aptivus) | Licensed | In combination with 200 mg ritonavir for combination therapy in treatment-experienced adults | 500 mg + 200 mg ritonavir twice daily | At 24 weeks, patients with prior extensive exposure to ARVs showed a -0.8-log change in HIV RNA levels and a 34 cell increase in CD4+ T cells compound to -0.25 log and 4 cells in the control arm. Inferior to lopinavir/ritonavir in a randomized, controlled trial in naïve patients | Diarrhea, nausea, fatigue, headache, skin rash, hepatotoxicity, intracranial hemorrhage |

| | | | | | |
|----------------------------|----------|--|--|---|---|
| Darunavir (Prezista) | Licensed | In combination with 100 mg ritonavir for combination therapy in treatment-experienced adults | 600 mg + 100 mg ritonavir twice daily with food | At 24 weeks, patients with prior extensive exposure to antiretrovirals treated with a new combination including darunavir showed a –1.89-log change in HIV RNA levels and a 92 cell increase in CD4+ T cells compared with –0.48 log and 17 cells in the control arm | Diarrhea, nausea, headache |
| Entry Inhibitors | | | | | |
| Enfuvirtide (Fuzeon) | Licensed | In combination with other agents in treatment-experienced patients with evidence of HIV-1 replication despite ongoing antiretroviral therapy | 90 mg SC bid | In treatment of experienced patients, superior to placebo when added to new optimized background (37% vs 16% with <400 HIV RNA copies/mL at 24 weeks; + 71 vs + 35 CD4+ T cells at 24 weeks) | Local injection reactions, hypersensitivity reactions, increased rate of bacterial pneumonia |
| Maraviroc (Selzentry) | Licensed | In combination with other antiretroviral agents in treatment experienced adults infected with only CCR5-tropic HIV-1 that is resistant to multiple antiretroviral agents | 150–600 mg bid depending upon concomitant medications (see text) | At 24 weeks, among 635 patients with CCR5-tropic virus and HIV-1 RNA >5000 copies/mL despite at least 6 months of prior therapy with at least one agent from 3 of the 4 antiretroviral drug classes, 61% of patients randomized to maraviroc achieved HIV RNA levels <400 copies/mL compared to 28% of patients randomized to placebo | Hepatotoxicity, nasopharyngitis, fever, cough, rash, abdominal pain, dizziness, fever, musculoskeletal symptoms |
| Integrase Inhibitor | | | | | |
| Raltegravir (Isentress) | Licensed | In combination with other antiretroviral agents in treatment experienced patients with evidence of ongoing HIV-1 replication | 400 mg bid | At 24 weeks, among 436 patients with three-class drug resistance, 76% of patients randomized to receive raltegravir achieved HIV RNA levels <400 copies/mL compared with 41% of patients randomized to receive placebo | Nausea, rash |

Note: ARC, AIDS-related complex; NRTIs, nonnucleoside reverse transcriptase inhibitors.

emtricitabine; the *nucleotide analogue* tenofovir; and the *nonnucleoside reverse transcriptase inhibitors* nevirapine, delavirdine, and efavirenz (Fig. 90-43; Table 90-18). These were the first class of drugs that were licensed for the treatment of HIV infection. They are indicated for this use as part of combination regimens. It should be stressed that none of these drugs should be used as monotherapy for HIV infection due to the relative ease with which drug resistance may develop under such circumstances. Thus, when lamivudine or tenofovir are used to treat hepatitis B infection in the setting of HIV infection, one should ensure that the patient is also on additional ARV medication. The reverse transcriptase inhibitors block the HIV replication cycle at the point of RNA-dependent DNA synthesis, the reverse transcription step. Although the nonnucleoside reverse transcriptase inhibitors are quite selective for the HIV-1 reverse transcriptase, the nucleoside and nucleotide analogues inhibit a variety of DNA polymerization reactions in addition to those of the HIV-1 reverse transcriptase. For this reason, serious side effects are more varied with the nucleoside analogues and include mitochondrial damage that can lead to hepatic steatosis and lactic acidosis as well as peripheral neuropathy and pancreatitis. One of the more recently recognized problems that has been encountered with the widespread use of HAART therapy has been a syndrome of hyperlipidemia, glucose intolerance/insulin resistance, and fat redistribution often referred to as *lipodystrophy syndrome* (discussed above under metabolic abnormalities).

Zidovudine (AZT; 3'-azido-2',3'-dideoxythymidine) was the first drug approved for the treatment of HIV infection and is the prototype nucleoside analogue. These compounds, in which the hydroxyl group in the 3' position of the ribose moiety is substituted with a hydrogen or other chemical group, act as DNA chain terminators owing to their inability to form a 3'-5' phosphodiester linkage with another nucleoside. They bind much more avidly to the active site of the RNA-dependent DNA polymerase of HIV (reverse transcriptase) than to the active site of mammalian cell DNA polymerases; this explains their selective effect on HIV replication. Zidovudine also has a relatively high avidity for the DNA polymerase- γ of human mitochondria. This may contribute to the development of the fatty liver and the myopathy sometimes observed in patients taking zidovudine. As with all the nucleoside analogues, the active form of zidovudine is the triphosphate, and the rate of phosphorylation, a thymidine kinase-dependent pathway, may be different in different cells. This may explain why zidovudine is more effective at inhibiting HIV replication in some cells than others. The clinical benefit of zidovudine was clearly established in 1986 in a phase II, randomized, placebo-controlled trial in patients with advanced HIV disease. However, although treatment of patients with early stages of HIV infection with zidovudine monotherapy was associated with increases in CD4+ T-cell count, it was not associated with a better overall outcome than waiting until later to treat. Subsequent trials established the ability of this drug to

dramatically decrease the incidence of perinatal transmission of HIV from infected mother to infant. Eventually a series of studies demonstrated the superiority of combination ARV regimens over zidovudine alone, and combination therapy (discussed below) remains the standard of treatment today. Among the side effects of zidovudine at the initiation of therapy are fatigue, malaise, nausea, and headache. These side effects often subside over time. Patients on zidovudine may develop a macrocytic anemia, neutropenia, myopathy, cardiomyopathy, and lactic acidosis associated with fatty infiltration of the liver. As with every ARV drug, HIV has the ability to develop resistance to zidovudine. Zidovudine resistance has been reported to occur ~6 months after the initiation of zidovudine monotherapy. More recently, zidovudine-resistant viruses have been noted in patients with acute infection before the initiation of therapy, implying that zidovudine-resistant viruses can be transmitted from person to person. Resistance emerges more rapidly in late-stage patients, presumably as a consequence of a greater degree of viral replication and thus a greater opportunity for mutation. A variety of amino acid changes including substitutions, insertions, and deletions have been reported to confer zidovudine resistance (Fig. 90-44). One combination preparation, Combivir, consists of zidovudine and lamivudine, whereas another, Trizivir, consists of zidovudine, lamivudine, and abacavir.

Didanosine (ddI; 2',3'-dideoxyinosine) was the second drug licensed for the treatment of HIV infection, followed shortly thereafter by zalcitabine. Didanosine is metabolized to dideoxyadenosine in vivo. It is best absorbed on an empty stomach at a high pH. The toxicity profile of didanosine is quite different from that of zidovudine. The most common toxicity is a painful sensory peripheral neuropathy that occurs in ~30% of patients receiving >400 mg/d. It generally resolves with discontinuation of the drug and may not recur if the drug is resumed at a reduced dose. At higher doses than are currently used, one may see pancreatitis in ~10% of patients. Pancreatitis associated with didanosine therapy can be fatal. Didanosine should be discontinued if a patient experiences abdominal pain consistent with pancreatitis or if an elevated serum amylase or lipase level is found in association with an edematous pancreas on ultrasound. Didanosine is contraindicated in patients with a prior history of pancreatitis, regardless of etiology. A higher incidence of didanosine-associated toxicities has been seen when it is used in combination with stavudine, hydroxyurea, ribavirin, or tenofovir.

Zalcitabine (ddC; 2',3'-dideoxycytidine) is rarely used today in the management of patients with HIV infection and was discontinued from the U.S. market in 2006. Among the nucleoside analogues licensed for the treatment of HIV infection, it is probably the weakest. The main toxicities of ddC are peripheral neuropathy and pancreatitis.

Stavudine (d4T; 2',3'-didehydro-3'-deoxythymidine) was the fourth drug licensed for the treatment of HIV

repeat; NAMS indicates nRTI-associated mutations; nRTI indicates nucleoside reverse transcriptase inhibitor; NNRTI indicates nonnucleoside reverse transcriptase inhibitor; PI indicates protease inhibitor. of the Drug Resistance Mutations in HIV-1: 2007. Topics in HIV Medicine. 2007; 15(4):119–125. Updated information (and thorough explanatory notes) is available at www.iasusa.org.]

infection and was discontinued from the U.S. market in 2006. Like zidovudine, stavudine is a thymidine analogue. These two drugs are antagonistic in vitro and in vivo and should not be given together. Stavudine has been associated with a higher incidence of mitochondrial toxicity than the other licensed nucleoside analogues. Peripheral neuropathy, lipoatrophy, lactic acidosis, and hepatic steatosis are the main toxicities of stavudine.

Lamivudine (3TC; 2',3'-dideoxy-3'-thiacytidine) is the fifth of the nucleoside analogues to be licensed in the United States. In actual practice, lamivudine or the closely related drug emtricitabine is a frequent element of many different combination regimens currently in use. These two drugs and the nucleotide reverse transcriptase inhibitor tenofovir (see below) also have activity against hepatitis B virus. For this reason, flares of hepatitis may be seen in co-infected patients starting and or stopping these agents due to the confounding issues of direct effects of treatment and the potential for the IRIS (see above). To prevent the development of resistant strains of HIV, these drugs should never be used on their own for the treatment of hepatitis B in the patient with HIV infection. Lamivudine is available either alone or in coformulations including zidovudine and/or abacavir (Table 90-19). One reason behind the excellent synergy seen between lamivudine and the other nucleoside analogues may be that strains of HIV resistant to lamivudine (M184V substitution) appear to have enhanced sensitivity to other nucleosides, and thus development of dual resistance is more difficult. In addition, there is a suggestion that 3TC-resistant strains of HIV may be less virulent and are less able to generate new mutants than are strains of HIV that are 3TC-sensitive. Lamivudine is among the best tolerated and least toxic nucleoside analogues.

Emtricitabine (FTC; 5-fluoro-1-(2R,5S)-[2-(hydroxymethyl)-1,3-oxathiolan-5-y]cytosine) is the negative enantiomer of a thio analogue of cytidine with a fluorine in the 5 position. It is licensed for use in combination with other ARV agents for treatment of HIV-1 infection in adults. Compared with lamivudine, it is similar in activity and has a longer half-life. It is available either alone or coformulated with tenofovir or tenofovir and efavirenz (Table 90-19). Resistance to emtricitabine is associated

with the M184V mutation in reverse transcriptase. Viruses showing the K65R mutation in reverse transcriptase may have reduced susceptibility to emtricitabine.

Abacavir {(1S,cis)-4-[2-amino-6-(cyclopropylamino)-9H-purin-9-yl]-2-cyclopentene-1-methanol sulfate (salt)(2:1)} is a synthetic carbocyclic analogue of the nucleoside guanosine. It is licensed to be used in combination with other ARV agents for the treatment of HIV-1 infection. Hypersensitivity reactions that may occur with initial therapy or rechallenge have been reported in ~4% of patients treated with this drug, and patients developing signs or symptoms of hypersensitivity such as fever, skin rash, fatigue, and gastrointestinal symptoms should discontinue the drug and not restart it. Fatal hypersensitivity reactions have been reported with rechallenge. Abacavir hypersensitivity appears to occur with a higher frequency in patients who are HLA-B57. It has been recommended that patients be screened for HLA-B57 before initiation of abacavir and that abacavir only be used as a last resort in patients who are HLA-B57 positive. Abacavir-resistant strains of HIV are typically also resistant to lamivudine, didanosine, and zalcitabine. Abacavir is formulated alone as well as in combination with lamivudine or zidovudine and lamivudine.

Tenofovir disoproxil fumarate (9-[(R)-2-[[bis[(isopropoxycarbonyl)oxy]methoxy]phosphinyl]methoxy]propyl]adenine fumarate (1:1)) is an acyclic nucleoside phosphonate diester analogue of adenosine monophosphate. It undergoes diester hydrolysis to form the nucleoside monophosphate tenofovir and is the first nucleotide analogue to be licensed for treatment of HIV infection. It is indicated in combination with other ARV agents for the treatment of HIV-1 infection. HIV isolates with increased resistance typically express a K65R mutation in reverse transcriptase and a three- to fourfold reduction in sensitivity to tenofovir. Tenofovir is primarily eliminated by the kidneys, and renal impairment including a Fanconi-like syndrome with hypophosphatemia may occur. Tenofovir is contraindicated in patients with renal impairment. Coadministration with didanosine leads to a 60% increase in didanosine levels, and thus doses of didanosine need to be adjusted and patients monitored carefully if these two drugs are used in combination. In addition, CD4+ T-cell increases may be blunted in patients on this combination. Coadministration of tenofovir with atazanavir leads to a decrease in atazanavir levels, and thus low-dose ritonavir (see below) needs to be added when these drugs are used in combination. Tenofovir is available alone and coformulated with emtricitabine or emtricitabine and efavirenz.

Nevirapine, delavirdine, efavirenz, and etravirine are nonnucleoside inhibitors of the HIV-1 reverse transcriptase. They are licensed for use in combination with nucleoside analogues for the treatment of HIV-infected adults. Coformulations that include efavirenz or nevirapine are available (Table 90-19). These agents inhibit reverse transcriptase by binding to regions of the enzyme outside the active site and causing conformational changes in the enzyme that render it inactive.

TABLE 90-19

COMBINATION FORMULATIONS OF ANTIRETROVIRAL DRUGS

| NAME | COMBINATION |
|-----------------------|---------------------------------------|
| Combivir | Zidovudine + lamivudine |
| Epzicom | Zidovudine + abacavir |
| Trizivir | Zidovudine + lamivudine + abacavir |
| Truvada | Tenofovir + emtricitabine |
| Atripla | Tenofovir + emtricitabine + efavirenz |
| Triomune ^a | Stavudine + lamivudine + nevirapine |

^aNot licensed in the United States.

Although these agents are active in the nanomolar range, they are also very selective for the reverse transcriptase of HIV-1, have no activity against HIV-2, and, when used as monotherapy, are associated with the rapid emergence of drug-resistant mutants (Table 90-18; Fig. 90-44). Efavirenz is administered once a day, nevirapine and etravirine twice a day, and delavirdine three times a day. All four drugs are associated with the development of a maculopapular rash, generally seen within the first few weeks of therapy. Although it is possible to treat through this rash, it is important to be sure that one is not dealing with a more severe eruption such as Stevens-Johnson syndrome by looking carefully for signs of mucosal involvement, significant fever, or painful lesions with desquamation. Severe, life-threatening, and in some cases fatal hepatotoxicity, including fulminant and cholestatic hepatitis, hepatic necrosis, and hepatic failure, have been reported in patients treated with nevirapine. There is a suggestion that this is more common in women with higher CD4+ T-cell counts. Many patients treated with efavirenz note a feeling of light-headedness, dizziness, or out of sorts after the initiation of therapy. Some complain of vivid dreams. These symptoms tend to disappear after several weeks of therapy. Aside from difficulties with dreams, taking efavirenz at bedtime may minimize the side effects. Efavirenz may cause fetal harm when administered during the first trimester to a pregnant woman. Women of childbearing potential should undergo pregnancy testing before initiation of efavirenz. Efavirenz is commonly used in combination with two nucleoside analogues as part of initial treatment regimens. Etravirine is a diarylpyrimidine derivative that is currently available on expanded access for treatment of HIV infection in combination with other agents. In contrast to the other nonnucleoside reverse transcriptase inhibitors, which all exhibit cross-resistance, etravirine may be active against strains of HIV that are resistant to other nonnucleoside reverse transcriptase inhibitors. Among its side effects are rash, headache, nausea, and diarrhea.

The HIV-1 protease inhibitors (saquinavir, indinavir, ritonavir, nelfinavir, amprenavir, fosamprenavir, lopinavir/ritonavir, atazanavir, tipranavir, and darunavir) are a major part of the therapeutic armamentarium of ARVs. When used as part of initial regimens in combination with reverse transcriptase inhibitors, these agents have been shown to be capable of suppressing levels of HIV replication to under 50 copies per milliliter in the majority of patients for a minimum of 5 years. As in the case of reverse transcriptase inhibitors, resistance to protease inhibitors can develop rapidly in the setting of monotherapy, and thus these agents should be used only as part of combination therapeutic regimens. A summary of known resistance mutations for protease inhibitors is shown in Fig. 90-44.

Saquinavir was the first of the HIV-1 protease inhibitors to be licensed. It is typically given with low doses of ritonavir to obtain therapeutic levels. Saquinavir is metabolized by the cytochrome P450 system in both the gastrointestinal tract and the liver. Low-dose ritonavir

results in inhibition of cytochrome P450 action. Thus when both drugs are administered together, there is an increase in saquinavir levels. This use of low doses of ritonavir to provide pharmacodynamic boosting of other agents is a common strategy in HIV therapy. Saquinavir is among the best-tolerated protease inhibitors.

Ritonavir was the first protease inhibitor for which clinical efficacy was demonstrated. In a study of 1090 patients with CD4+ T-cell counts <100/ μ L who were randomized to receive either placebo or ritonavir in addition to any other licensed medications, patients receiving ritonavir had a reduction in the cumulative incidence of clinical progression or death from 34 to 17%. Mortality decreased from 10.1 to 5.8%. At full doses, ritonavir is poorly tolerated. Among the main side effects are nausea, diarrhea, abdominal pain, hyperlipidemia, and circumoral paresthesia. Ritonavir has a high affinity for several isoforms of cytochrome P450, and its use can result in large increases in the plasma concentrations of drugs metabolized by this pathway. Among the agents affected in this manner are most other protease inhibitors, macrolide antibiotics, R-warfarin, ondansetron, rifabutin, most calcium channel blockers, glucocorticoids, and some of the chemotherapeutic agents used to treat KS and/or lymphomas. In addition, ritonavir may increase the activity of glucuronyltransferases, thus decreasing the levels of drugs metabolized by this pathway. Overall, great care must be taken when prescribing additional drugs to patients taking protease inhibitors in general and ritonavir in particular. As mentioned above, the pharmacodynamic boosting property of ritonavir, seen with doses as low as 100–200 mg once or twice a day, is often used in the setting of combination ARV therapy for HIV infection to derive more convenient regimens. For example, when given with low-dose ritonavir, saquinavir and indinavir can both be given on twice-a-day schedules and taken with food.

Indinavir was the first protease inhibitor used in combination with dual nucleoside therapy. The combination of zidovudine, lamivudine, and indinavir was the first “triple combination” shown to have a profound effect on HIV replication. The main side effects of indinavir are nephrolithiasis (seen in 4% of patients) and asymptomatic indirect hyperbilirubinemia (seen in 10%). Indinavir is predominantly metabolized by the liver. The dose should be lowered in patients with cirrhosis. Levels of indinavir are decreased during concurrent therapy with rifabutin, efavirenz, or nevirapine and increased during concurrent therapy with ketoconazole, delavirdine, or ritonavir. Dosages should be modified appropriately in these circumstances (Table 90-18).

Nelfinavir was approved in 1997 and *amprenavir* was approved in 1999 for the treatment of adult or pediatric HIV infection when ARV therapy is warranted. As with most of the newer ARV agents, these approvals were based on randomized, controlled trials that demonstrated decreases in plasma HIV RNA levels and increases in CD4+ T-cell counts. The presence of the potential carcinogen and teratogen ethyl methanesulfonate in nelfinavir preparations makes it a drug to be

avoided in pregnant women. Both nelfinavir and amprenavir have unique resistance profiles. Nelfinavir resistance is associated with a D30N substitution in the protease gene. Viruses harboring this single mutation retain sensitivity to other protease inhibitors. Although it has been suggested that for this reason nelfinavir is a good initial protease inhibitor, enthusiasm for its use has waned after the 48-week clinical trials data demonstrating the virologic inferiority of nelfinavir to lopinavir/ritonavir, to fosamprenavir, and to efavirenz. Protease inhibitor resistance typically involves multiple amino acid substitutions and reduced susceptibility across the class. Amprenavir resistance is associated with a unique substitution at amino acid 50 (I50V). Nelfinavir and amprenavir are both associated with gastrointestinal side effects. About 1% of patients receiving amprenavir have experienced severe and life-threatening skin reactions. An additional disadvantage of amprenavir is that the original formulation requires the patient to take 8 large capsules twice a day. Amprenavir has largely been replaced by fosamprenavir (see below).

Fosamprenavir was licensed in 2003 for the treatment of HIV infection in combination with other ARV agents in adults. It is a prodrug of amprenavir that is rapidly converted to amprenavir by cellular phosphatases. It is supplied as a 700-mg tablet. The recommended dosage is 1400 mg bid or 700 mg bid with ritonavir, 100 mg bid, or 1400 mg once a day with ritonavir, 200 mg once a day. As noted above, ritonavir-boosted fosamprenavir has been shown to be comparable to lopinavir/ritonavir and efavirenz in combination regimens.

Lopinavir/ritonavir (Kaletra) is a fixed-dose combination of the protease inhibitors lopinavir (200 mg) and ritonavir (50 mg). It was licensed in 2000 for treatment of HIV-1 infection in adults and children in combination with other agents. A main advantage of this pill is that it combines the pharmacologic enhancement of low-dose ritonavir with a second protease inhibitor in a single capsule. In a randomized, controlled trial, this combination capsule was found to be superior to nelfinavir. Its main complications are gastrointestinal upset and hyperlipidemia.

Atazanavir is an azapeptide inhibitor of the HIV-1 protease that was licensed in 2003. An advantage of atazanavir is that total cholesterol and triglyceride levels do not increase as much with atazanavir as with other protease inhibitors. This coupled with the fact that it can be given on a once-daily schedule has made atazanavir a popular component of initial treatment regimens. Atazanavir is associated with increases in serum bilirubin and prolongations of the ECG PR interval. Atazanavir-resistant isolates emerging in previously treatment-naïve individuals frequently harbor an I50L substitution. This mutation in some instances is associated with increased sensitivity to other protease inhibitors. Atazanavir requires an acidic gastric pH for absorption, and its use in combination with a proton pump inhibitor is contraindicated due to concerns about absorption. Atazanavir is an inhibitor of cytochrome P3A and its use may be associated with increased levels of calcium channel blockers,

macrolide antibiotics, HMB-CoA reductase inhibitors, and sildenafil. Levels of atazanavir are lower in the presence of tenofovir or efavirenz. In these settings, levels of atazanavir should be boosted with the use of low-dose ritonavir.

Tipranavir is a non-peptidic HIV protease inhibitor licensed in 2005. It is licensed for use in combination with 200 mg ritonavir and is indicated for combination ARV therapy of HIV-1 infection in treatment-experienced adults or in adults with evidence of HIV-1 strains resistant to multiple protease inhibitors. Tipranavir was found to be inferior to lopinavir/ritonavir in a randomized controlled trial in naïve patients. In that study, at lower doses it was virologically inferior, whereas at higher doses it exhibited a greater degree of hepatotoxicity. The main side effects of tipranavir are gastrointestinal intolerance and skin rash; the latter is seen in ~10% of patients and may be related to the sulfonamide moiety in the molecule. Tipranavir coadministered with ritonavir has also been associated with reports of intracranial hemorrhage as well as reports of clinical hepatitis and hepatic decompensation, including some fatalities in both settings. The risk of hepatotoxicity is increased in patients with hepatitis B or C co-infection.

Darunavir is a non-peptidic HIV protease inhibitor licensed in 2006 to be coadministered with 100 mg of ritonavir and other ARV agents for the treatment of HIV infection in ARV treatment-experienced adults. This indication is based on the fact that the trials leading to licensure of darunavir were carried out in treatment-experienced patients. In these studies, 46% of patients achieved a reduction in HIV RNA viral loads to <50 copies per milliliter. Studies are underway in treatment-naïve patients. Skin rash, which may be severe, is seen in 7% of patients and may be related to the sulfonamide moiety contained in the molecule. Gastrointestinal intolerance and headache are the other most frequent side effects.

Entry inhibitors act by interfering with the binding of HIV to its receptor or co-receptor or by interfering with the process of fusion (see above). The first drug in this class to be licensed was the fusion inhibitor *enfuvirtide*, or T-20, followed by the CCR5 antagonist *maraviroc*. A variety of additional small molecules that bind to HIV-1 co-receptors are currently in clinical trials.

Enfuvirtide is a linear 36-amino-acid synthetic peptide with the N-terminus acetylated and the C-terminus a carboxamide. It is composed of naturally occurring L-amino acid residues and interferes with the fusion of the viral and cellular membranes by binding to the HR1 region in the gp41 subunit of the HIV-1 envelope. This binding interferes with the coil-coil interaction required to approximate the two membranes. Resistant isolates of HIV exhibit amino acid changes in positions 36–45 of gp41. In two independent studies, patients who had persistent viremia despite prior treatment with agents from all three available classes of drugs were randomized to receive an individualized regimen (based upon prior treatment history and resistance profile) with or without enfuvirtide. The change in plasma HIV-1 RNA from baseline was

~1 log greater (−1.53 vs −0.68) in patients randomized to receive enfuvirtide. Among the drawbacks of this agent are the requirement for twice-a-day injection, the occurrence of injection site reactions in close to 100% of patients, and an increase in bacterial pneumonia in the enfuvirtide-treated patients compared to the patients in the control arm (4.68 vs 0.61 events per 100 patient years) in the phase III studies.

Maraviroc is a CCR5 antagonist that interferes with HIV binding at the stage of co-receptor engagement. It was licensed in 2007 for treatment of HIV infection in combination with other agents in treatment-experienced patients infected with only CCR5-tropic virus resistant to multiple agents. A co-receptor tropism assay should be performed if one is considering the use of maraviroc to ensure that the potential patient is harboring R5 virus. In phase III trials of treatment-experienced patients randomized to receive optimal therapy plus maraviroc or placebo, 61% of patients randomized to maraviroc achieved HIV RNA levels <400 copies/mL compared with 28% of patients randomized to placebo. An allergic reaction-associated hepatotoxicity has been reported with maraviroc. Among the most common side effects of maraviroc are dizziness due to postural hypotension, cough, fever, colds, rash, muscle and joint pain, and stomach pain. Maraviroc is a substrate of CYP3A and Pgp, and the recommend dose varies depending upon concomitant medications. In combination with nucleoside analogues, tipranavir/ritonavir, enfuvirtide and/or nevirapine the dose is 300 mg twice daily. In the presence of CYP3A inhibitors such as most protease inhibitors the dose is 150 mg twice daily and in presence of CYP3A inducers such as efavirenz, the dose is 600 mg twice daily.

The newest class of ARV compounds are the *integrase inhibitors*. *Raltegravir* is an inhibitor of the viral enzyme integrase and the first of this class to be approved. It was approved in 2007 for treatment of HIV infection in combination with other agents in treatment experienced patients. Raltegravir exhibits a wide range of activity against HIV-1 and HIV-2, including viruses with multiple resistance mutations to other classes of drugs. As with several other compounds, resistance to raltegravir comes at the expense of replicative fitness. In two phase III studies in which 436 patients with 3-class ARV drug resistance were randomized to an optimized background regimen with raltegravir or placebo, 76% of patients receiving raltegravir achieved HIV RNA levels <400 copies/mL compared with 41% of patients randomized to the placebo arm. In contrast to many other antiretroviral drugs, the side effect profile of raltegravir is minimal, with similar side effect profiles noted for the raltegravir and placebo groups.

PRINCIPLES OF THERAPY The principles of therapy for HIV infection have been articulated by a panel sponsored by the U.S. Department of Health and Human Services as a working group of the NIH Office of AIDS Research Advisory Council. These principles are summarized in [Table 90-20](#). As noted in these

TABLE 90-20**PRINCIPLES OF THERAPY OF HIV INFECTION**

1. Ongoing HIV replication leads to immune system damage and progression to AIDS.
2. Plasma HIV RNA levels indicate the magnitude of HIV replication and the rate of CD4+ T-cell destruction. CD4+ T-cell counts indicate the current level of competence of the immune system.
3. Rates of disease progression differ among individuals, and treatment decisions should be individualized based upon plasma HIV RNA levels and CD4+ T-cell counts.
4. Maximal suppression of viral replication is a goal of therapy; the greater the suppression, the less likely the appearance of drug-resistant quasiespecies.
5. The most effective therapeutic strategies involve the simultaneous initiation of combinations of effective anti-HIV drugs with which the patient has not been previously treated and that are not cross-resistant with antiretroviral agents that the patient has already received.
6. The antiretroviral drugs used in combination regimens should be used according to optimum schedules and dosages.
7. The number of available drugs is limited. Any decisions on antiretroviral therapy have a long-term impact on future options for the patient.
8. Women should receive optimal antiretroviral therapy regardless of pregnancy status.
9. The same principles apply to children and adults. The treatment of HIV-infected children involves unique pharmacologic, virologic, and immunologic considerations.
10. Compliance is an important part of ensuring maximal effect from a given regimen. The simpler the regimen, the easier it is for the patient to be compliant.

Source: Modified from *Principles of Therapy of HIV Infection*, USPHS, and the Henry J. Kaiser Family Foundation.

guidelines, eradication of HIV infection has not yet been possible. Treatment decisions must take into account the fact that one is dealing with a chronic infection. Although early therapy is generally the rule in infectious diseases, immediate treatment of every HIV-infected individual upon diagnosis may not be prudent, and therapeutic decisions must take into account the balance between risks and benefits. Although it seems reasonable to assume that the complications associated with ARV therapy could be minimized by regimens designed to minimize exposure to the drugs in question, all efforts to do so have paradoxically been associated with an increase in serious adverse events in the patients randomized to intermittent therapy suggesting that some “non-AIDS” associated serious adverse events such as heart attack and stroke may be linked to HIV replication. Thus, unless contraindicated for reasons of toxicity, patients started on ARV therapy should remain on ARV therapy.

TABLE 90-21**INDICATIONS FOR THE INITIATION OF ANTIRETROVIRAL THERAPY IN PATIENTS WITH HIV INFECTION**

- I. Acute infection syndrome
- II. Chronic infection
 - A. Symptomatic disease (including HIV-associated nephropathy)
 - B. Asymptomatic diseases
 1. CD4+ T-cell count <350/ μ L^a
 2. Pregnancy
- III. Postexposure prophylaxis

^aThis is an area of controversy. Some experts would wait until the CD4 cell count declines to 200/ μ L, some would treat everyone with a viral load >100,000 copies/mL, whereas others would treat everyone regardless of CD4+ T-cell count.

Source: *Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents*, USPHS.

At present, a reasonable course of action is to initiate ARV therapy in anyone with the acute HIV syndrome; all pregnant women; patients with symptomatic disease; and patients with asymptomatic disease with CD4+ T-cell counts <350/ μ L (**Table 90-21**). In addition, one may wish to administer a 6-week course of therapy to uninfected individuals immediately after a high-risk exposure to HIV.

Once the decision has been made to initiate therapy, the health care provider must decide which drugs to use as the first regimen. The decision regarding choice of drugs not only will affect the immediate response to therapy but also will have implications regarding options for future therapeutic regimens. The initial regimen is usually the most effective insofar as the virus has yet to develop significant resistance. The two options for initial therapy most commonly in use today are two different three-drug regimens. The first regimen utilizes two nucleoside analogues (one of which is usually lamivudine or emtricitabine) and a nonnucleoside reverse transcriptase inhibitor. The second regimen utilizes two nucleoside analogues and a protease inhibitor. Unfortunately there are no clear data at present on which to base distinctions between these two approaches. After the initiation of therapy, one should expect a 1-log (tenfold) reduction in plasma HIV RNA levels within 1–2 months and eventually a decline in plasma HIV RNA levels to <50 copies per milliliter. During this same time there should be a rise in the CD4+ T-cell count of 100–150/ μ L that is particularly brisk during the first month of therapy. Many clinicians feel that failure to achieve this endpoint is an indication for a change in therapy. Other reasons for a change in therapy include a persistently declining CD4+ T-cell count, clinical deterioration, or drug toxicity (**Table 90-22**). As in the case of initiating therapy, changing therapy may have a lasting impact on future therapeutic options. When changing therapy because of treatment failure (clinical progression or worsening laboratory parameters), it is important to attempt to provide a regimen with at least

TABLE 90-22**INDICATIONS FOR CHANGING ANTIRETROVIRAL THERAPY IN PATIENTS WITH HIV INFECTION^a**

- Less than a 1-log drop in plasma HIV RNA by 4 weeks after the initiation of therapy
- A reproducible significant increase (defined as three-fold or greater) from the nadir of plasma HIV RNA level not attributable to intercurrent infection, vaccination, or test methodology
- Persistently declining CD4+ T-cell numbers
- Clinical deterioration
- Side effects

^aGenerally speaking, a change should involve the initiation of at least two drugs felt to be effective in the given patient. The exception to this is when change is being made to manage toxicity, in which case a single substitution is reasonable.

Source: *Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents*, USPHS.

two new active drugs. This decision can be guided by resistance testing (see below). In the patient in whom a change is made for reasons of drug toxicity, a simple replacement of one drug is reasonable. It should be stressed that in attempting to sort out a drug toxicity it may be advisable to hold all therapy for a period of time to distinguish between drug toxicity and disease progression. Drug toxicity will usually begin to show signs of reversal within 1–2 weeks. Before changing a treatment regimen because of drug failure, it is important to ensure that the patient has been adherent to the prescribed regimen. As in the case of initial therapy, the simpler the new therapeutic regimen, the easier it is for the patient to be compliant. Plasma HIV RNA levels and CD4+ T-lymphocyte counts should be monitored every 3–4 months during therapy and more frequently if one is contemplating a change in regimen or immediately after a change in regimen.

In an attempt to determine an optimal therapeutic regimen, one may attempt to measure ARV drug susceptibility through genotyping or phenotyping of HIV quasi-species and determine adequacy of dosing through measurement of drug levels. Genotyping may be done through dideoxynucleotide sequencing, DNA chip hybridization, or line probe assays. Phenotypic assays typically measure the enzymatic activity of viral enzymes in the presence or absence of different concentrations of different drugs and have also been used to determine coreceptor tropism. These assays will generally detect quasi-species present at a frequency of $\geq 10\%$. The precise role of resistance testing in the management of patients with HIV infection is not yet clear. It is generally recommended that resistance testing be used in selecting initial therapy in settings where the risk of transmission of resistant virus is high (such as the United States and Europe) and in determining new regimens for patients experiencing virologic failure while on therapy. Resistance testing may be of particular value in distinguishing drug-resistant virus from poor patient compliance. Due to the rapid rate at which drug-resistant viruses revert to wild-type, it is

recommended that resistant testing performed in the setting of drug failure be carried out while the patient is still on the failing regimen. Measurement of plasma drug levels can also be used to tailor an individual treatment. The inhibitory quotient, defined as the trough blood level/IC50 of the patient's virus, is used by some to determine the adequacy of dosing of a given treatment regimen.

In addition to the licensed medications discussed above, a large number of experimental agents are being evaluated as possible therapies for HIV infection. Therapeutic strategies are being developed that interfere with virtually every step of the replication cycle of the virus (Fig. 90-3). In addition, as more is discovered about the role of the immune system in controlling viral replication, additional strategies, generically referred to as "immune-based therapies," are being developed as a complement to antiviral therapy. Among the antiviral agents in early clinical trials are additional nucleoside and nucleotide analogues, protease inhibitors, fusion inhibitors, receptor and co-receptor antagonists, and integrase inhibitors as well as new anti-viral strategies including antisense nucleic acids and maturation inhibitors. Among the immune-based therapies being evaluated are IFN- α , bone marrow transplantation, adoptive transfer of lymphocytes genetically modified to resist infection or enhance HIV-specific immunity, active immunotherapy with inactivated HIV or its components, IL-2, and IL-7.

HIV AND THE HEALTH CARE WORKER

Health care workers, especially those who deal with large numbers of HIV-infected patients, have a small but definite risk of becoming infected with HIV as a result of professional activities (see "Occupational Transmission of HIV: Health Care Workers, Laboratory Workers, and the Health Care Setting" earlier in the chapter). The first case of HIV transmission from a patient to health care worker was reported in 1984. By the end of 2002, 106 health care workers worldwide were documented as having seroconverted to HIV after occupational HIV exposure; another 238 possible occupational seroconversions had been reported. Only three of these cases were reported from Sub-Saharan Africa, where HIV is most prevalent. Hence it is likely that the global prevalence of occupationally acquired HIV infection is much higher than has been reported.

In the United States, 57 health care workers have become infected with HIV by occupational exposure; 26 have developed AIDS. The individuals who seroconverted include 19 laboratory workers (16 of whom were clinical laboratory workers), 24 nurses, 6 physicians, 2 surgical technicians, 1 dialysis technician, 1 respiratory therapist, 1 health aide, 1 embalmer/morgue technician, and 2 housekeeper/maintenance workers. The exposures included 48 percutaneous (puncture/cut injury), 5 mucocutaneous (mucous membrane and/or skin), 2 both percutaneous and mucocutaneous, and 2 unknown route of exposure. Forty-nine exposures were to HIV-infected blood, three to concentrated virus in a laboratory, one to visibly bloody fluid, and four to an unspecified fluid. As of

January 1, 2003, there had been 139 other cases of HIV infection or AIDS among health care workers who have not reported other risk factors for HIV infection and who report a history of exposure to blood, body fluids, or HIV-infected laboratory material, but for whom seroconversion after exposure was not documented. The number of these workers who actually acquired their infection through occupational exposures is not known. Taken together, the data from several large studies suggest that the risk of HIV infection after a percutaneous exposure to HIV-contaminated blood is $\sim 0.3\%$, and after a mucous membrane exposure, $\sim 0.09\%$. Although episodes of HIV transmission after nonintact skin exposure have been documented, the average risk for transmission by this route has not been precisely quantified but is estimated to be less than the risk for mucous membrane exposures. The risk for transmission after exposure to fluids or tissues other than HIV-infected blood also has not been quantified but is probably considerably lower than for blood exposures. A seroprevalence survey of 3420 orthopedic surgeons, 75% of whom practiced in an area with a relatively high prevalence of HIV infection and 39% of whom reported percutaneous exposure to patient blood, usually through an accident involving a suture needle, failed to reveal any cases of possible occupational infection, suggesting that the risk of infection with a suture needle may be considerably less than that with a blood-drawing needle.

Most cases of health care worker seroconversion occur as a result of needle-stick injuries. When one considers the circumstances that result in needle-stick injuries, it is immediately obvious that adhering to the standard guidelines for dealing with sharp objects would result in a significant decrease in this type of accident. In one study, 27% of needle-stick injuries resulted from improper disposal of the needle (over half of these were due to recapping the needle), 23% occurred during attempts to start an IV line, 22% occurred during blood drawing, 16% were associated with an IM or SC injection, and 12% were associated with giving an IV infusion.

Clinicians should consider potential occupational exposures to HIV as urgent medical concerns to ensure timely postexposure management and possible administration of postexposure ARV prophylaxis (PEP). Recommendations regarding PEP must take into account that several circumstances determine the risk of transmission of HIV after occupational exposure. In this regard, several factors have been associated with an increased risk for occupational transmission of HIV infection, including deep injury, the presence of visible blood on the instrument causing the exposure, injury with a device that had been placed in the vein or artery of the source patient, terminal illness in the source patient, and lack of postexposure ARV therapy in the exposed health care worker. Other important considerations when considering PEP in the health care worker include known or suspected pregnancy or breastfeeding, the possibility of exposure to drug-resistant virus, and toxicities of PEP regimens. Regardless of the decision to use PEP, the wound should be cleansed immediately and antiseptic applied. If a decision is made to offer PEP, U.S. Public Health Service guidelines recommend (1) a

combination of two nucleoside analogue reverse transcriptase inhibitors given for 4 weeks for less severe exposures, or (2) a combination of two nucleoside analogue reverse transcriptase inhibitors plus a third drug given for 4 weeks for more severe exposures. Most clinicians administer the latter regimen in all cases in which a decision is made to treat. Detailed guidelines are available from the *Updated U.S. Public Health Service Guidelines for the Management of Occupational Exposures to HIV and Recommendations for Postexposure Prophylaxis* (CDC, 2005). The report emphasizes the importance of adherence to PEP when it is indicated; follow-up of exposed workers to improve PEP adherences, monitoring for adverse events (including seroconversion), and expert consultation in the management of exposures.

For consultation on the treatment of occupational exposures to HIV and other bloodborne pathogens, the clinician managing the exposed patient can call the National Clinicians' Post-Exposure Prophylaxis Hotline (PEPline) at 888-HIV-4911 (888-448-4911). This service is available 24 h a day, at no charge (additional information on the Internet is available at <http://www.ucsf.edu/hiventr>). PEPline support may be especially useful in challenging situations, such as when drug-resistant HIV strains are suspected or the health care worker is pregnant.

Health care workers can minimize their risk of occupational HIV infection by following the CDC guidelines of July 1991, which include adherence to universal precautions, refraining from direct patient care if one has exudative lesions or weeping dermatitis, and disinfecting and sterilizing reusable devices employed in invasive procedures. The premise of universal precautions is that every specimen should be handled as if it came from someone infected with a bloodborne pathogen. All samples should be double-bagged, gloves should be worn when drawing blood, and spills should be immediately disinfected with bleach.

In attempting to put this small but definite risk to the health care worker in perspective, it is important to point out that ~200 health care workers die each year as a result of occupationally acquired hepatitis B infection. The tragedy in this instance is that these infections and deaths due to HBV could be greatly decreased by more extended use of the HBV vaccine. The risk of HBV infection after a needle-stick injury from a hepatitis antigen-positive patient is much higher than the risk of HIV infection (see "Transmission" earlier in the chapter). There are multiple examples of needle-stick injuries where the patient was positive for both HBV and HIV and the health care worker became infected only with HBV. For these reasons, it is advisable, given the high prevalence of HBV infection in HIV-infected individuals, that all health care workers dealing with HIV-infected patients be immunized with the HBV vaccine.

TB is another infection common to HIV-infected patients that can be transmitted to the health care worker. For this reason, all health care workers should know their PPD status, have it checked yearly, and receive 6 months of isoniazid treatment if their skin test converts to positive. In addition, all patients in whom a diagnosis of TB is being entertained should be placed immediately in respiratory isolation, pending results of

the diagnostic evaluation. The emergence of drug-resistant organisms, including the extensively drug resistant TB strains that have been identified in Africa, has made TB an increasing problem for health care workers. This is particularly true for the health care worker with preexisting HIV infection.

One of the most charged issues ever to come between health care workers and patients is that of transmission of infection from HIV-infected health care workers to their patients. This is discussed under "Occupational Transmission of HIV: Health Care Workers, Laboratory Workers, and the Health Care Setting" earlier in the chapter. Theoretically, the same universal precautions that are used to protect the health care worker from the HIV-infected patient will also protect the patient from the HIV-infected health care worker.

VACCINES

Given that human behavior, especially human sexual behavior, is extremely difficult to change, a critical modality for preventing the spread of HIV infection is the development of a safe and effective vaccine. Historically, vaccines have provided a safe, cost-effective, and efficient means of preventing illness, disability, and death from infectious diseases. Successful vaccines for the most part are predicated on the assumption that the body can mount an adequate immune response to the microbe or virus in question during natural infection, and that the vaccine will mimic the natural response to infection. Even with serious diseases such as smallpox, poliomyelitis, measles, and influenza among others, the body in the vast majority of cases clears the infectious agent and provides protection against future exposure. Unfortunately, this is not the case with HIV infection since the natural immune response to HIV infection is unable to clear the virus from the body and cases of superinfection have been reported. Some of the factors that contribute to the problematic nature of development of a preventive HIV vaccine are the high mutability of the virus, the fact that the infection can be transmitted by cell-free or cell-associated virus, the likely need for the development of effective mucosal immunity, and the fact that it has been difficult to establish the precise correlates of protective immunity to HIV infection. Some HIV-infected individuals are long-term nonprogressors (see above), and a number of individuals have been exposed to HIV multiple times but remain uninfected; these facts suggest that there are elements of an HIV-specific immune response that have the potential to be protective. Early attempts to develop a vaccine with the envelope protein gp120 aimed at inducing neutralizing antibodies in humans were performed based on the induction of neutralizing antibodies in non-human primates. The significance of the laboratory assays were unknown at the time, and the elicited antisera failed to neutralize primary isolates of HIV cultured and tested in fresh peripheral blood mononuclear cells. In this regard, two phase 3 trials were undertaken in the United States and Thailand using soluble gp120, and the vaccines failed to protect human volunteers from HIV infection. It should be pointed out that

although the ideal goal of an HIV vaccine is to prevent infection, a vaccine given to an uninfected individual that significantly alters the course of disease or the infectivity of the individual, should that person become infected, could have an impact not only on the individual in question but also on the spread of infection in the community. In this regard, a number of studies in monkeys using vaccines that induce predominantly cellular (T-cell) immune responses have not protected the animals against infection but have lowered the initial burst of viremia after acute infection as well as decreased temporarily the viral set point. Since most sexually transmitted HIV infections occur when the transmitting partner is experiencing high levels of viremia such as during the acute phase of HIV infection or during the advanced stage of disease when the viral load is high, such a vaccine, which might limit the initial burst of viremia in primary infection and decrease the established viral set point, could have benefits for the individual as well as for their sexual partners. It is clear that it will take several years of clinical trials to establish the efficacy or lack thereof of a candidate vaccine for HIV.

PREVENTION

Education, counseling, and behavior modification are the cornerstones of an HIV prevention strategy. A major problem in the United States and elsewhere is that many infections are passed on by those who do not know that they are infected. Of the >1 million persons in the United States who are HIV-infected, it is estimated that ~25% do not know their HIV status and thus may be putting others at risk by their own behavior. In this regard, the CDC has recently recommended that HIV testing become part of routine medical care and that all individuals between the ages of 13 and 64 years be informed of the testing and be tested without the need for written informed consent. The individual could “opt out” of testing, but if not, testing would be routinely administered. In addition to identifying individuals who might benefit from ARV therapy, information gathered from such an approach should serve as the basis for behavior-modification programs, both for infected individuals who may be unaware of their HIV status and who could infect others and for uninfected individuals practicing high-risk behavior. The practice of “safer sex” is the most effective way for sexually active uninfected individuals to avoid contracting HIV infection and for infected individuals to avoid spreading infection. Abstinence from sexual relations is the only absolute way to prevent sexual transmission of HIV infection. However, for many individuals this may not be feasible, and there are a number of relatively safe practices that can markedly decrease the chances of transmission of HIV infection. Partners engaged in monogamous sexual relationships who wish to be assured of safety should both be tested for HIV antibody. If both are negative, it must be understood that any divergence from monogamy puts both partners at risk; open discussion of the importance of honesty in such relationships should be encouraged.

When the HIV status of either partner is not known, or when one partner is positive, there are a number of options. Use of condoms can markedly decrease the chance of HIV transmission. It should be remembered that condoms are not 100% effective in preventing transmission of HIV infection, and there is an ~10% failure rate of condoms used for contraceptive purposes. Most condom failures result from breakage or improper usage, such as not wearing the condom for the entire period of intercourse. Latex condoms are preferable, since virus has been shown to leak through natural skin condoms. Petroleum-based gels should never be used for lubrication of the condom, since they increase the likelihood of condom rupture. Some men who have sex with men practice fellatio as a “minimal risk” activity compared with anal intercourse. It should be emphasized that receptive fellatio is definitely not safe sex, and although the incidence of transmission via fellatio is considerably less than that of rectal or vaginal intercourse, there has been documentation of transmission of HIV where receptive fellatio was the only sexual act performed (see “Transmission” earlier in the chapter). Topical microbicides for vaginal and anal use are being pursued actively as a means by which individuals could avoid infection when the insertive partner cannot be relied on to use a condom. Three clinical trials in South Africa, Uganda, and Kenya have shown that adult male circumcision results in an ~50% reduction in HIV acquisition in the circumcised subject. Clearly, this approach has considerable potential as a preventive strategy for HIV infection and is currently being pursued, particularly in developing nations, as a component of HIV prevention. Kissing is considered safe, although there is a theoretical possibility of transmission via virus in saliva. The low concentration of virus in saliva of infected individuals, as well as the presence in saliva of HIV-inhibitory proteins (see above), lessens any risk of transmission by kissing.

The most effective way to prevent transmission of HIV infection among IDUs is to stop the use of injectable drugs. Unfortunately, that is extremely difficult to accomplish unless the individual enters a treatment program. For those who will not or cannot participate in a drug treatment program and who will continue to inject drugs, the avoidance of sharing of needles and other paraphernalia (“works”) is the next best way to avoid transmission of infection. However, the cultural and social factors that contribute to the sharing of paraphernalia are complex and difficult to overcome. In addition, needles and syringes may be in short supply. Under these circumstances, paraphernalia should be cleaned after each usage with a virucidal solution, such as undiluted sodium hypochlorite (household bleach). Data from a number of studies have indicated that programs that provide sterile needles to addicts in exchange for used needles have resulted in a decrease in HIV transmission without increasing the use of injection drugs. It is important for IDUs to be tested for HIV infection and counseled to avoid transmission to their sexual partners. Secondary and tertiary spread of HIV infection by the heterosexual route within settings of a high level of

injection drug use has increased greatly in the United States, particularly among African Americans (see above). Studies are underway to determine the safety and efficacy of preexposure as well as postexposure administration of ARV drugs for the prevention of HIV infection.

Transmission of HIV via transfused blood or blood products has been decreased dramatically by a combination of screening of all blood donors for HIV infection by assays for both HIV antibody and nucleic acid and self-deferral of individuals at risk for HIV infection. In addition, clotting factor concentrates are heat-treated, essentially eliminating the risk to hemophiliacs who require these products. Autologous transfusions are preferable to transfusions from another individual. However, logistic constraints as well as the unpredictability of the need for most transfusions limit the feasibility of this approach. At present, the risk of becoming HIV-infected from a contaminated blood transfusion is approximately 1 in 1.5 million donations.

Treatment of an HIV-infected mother with ARV therapy during pregnancy and the infant during the first weeks after birth has proved very effective in dramatically decreasing mother-to-child transmission of HIV. In situations such as that seen in certain developing countries where pregnant women frequently present to a health care system during labor, administration of a short course (as little as a single dose of one drug) of ARV therapy to the mother during labor and to the infant within 48 h of birth has also been successful in decreasing the incidence of mother-to-child transmission of HIV.

HIV can be transmitted via breast milk and colostrum. The avoidance of breast-feeding may not be practical in developing countries, where nutritional concerns override the risk of HIV transmission. However, it is becoming appreciated that 5–15% of infants who were born of HIV-infected mothers and who were fortunate enough not to have been infected intrapartum or peripartum become infected via breast-feeding. Therefore, in developing countries, breast-feeding from an infected mother should be avoided if at all possible. Unfortunately, this is rarely the case, and given the disadvantages of withholding breast-feeding in developing countries (see above), health authorities in most developing countries continue to recommend breast-feeding despite the potential for HIV transmission. Treatment of the infected mother with ARV therapy, in addition to decreasing perinatal mother-to-child transmission, can also decrease transmission by breast-feeding. In developed countries such as the United States, where bottled formula and milk are readily accessible, breast-feeding is absolutely contraindicated when a mother is HIV positive.

CHAPTER 91

VIRAL GASTROENTERITIS

Umesh D. Parashar ■ Roger I. Glass

Acute infectious gastroenteritis is a common illness that affects persons of all ages worldwide. It is a leading cause of mortality among children in developing countries, accounting for an estimated 2 million deaths each year, and is responsible for up to 10–12% of all hospitalizations among children in industrialized countries, including the United States. Elderly persons, especially those with debilitating health conditions, are also at risk of severe complications and death from acute gastroenteritis. Among healthy young adults, acute gastroenteritis is rarely fatal but incurs substantial medical and social costs, including those of time lost from work.

Several enteric viruses have been recognized as important etiologic agents of acute infectious gastroenteritis (**Table 91-1**, **Fig. 91-1**). Illness caused by these viruses is characterized by the acute onset of vomiting and/or diarrhea, which may be accompanied by fever, nausea, abdominal cramps, anorexia, and malaise. As shown in **Table 91-2**, several features can help distinguish gastroenteritis caused by viruses from that caused

by bacterial agents. However, the distinction based on clinical and epidemiologic parameters alone is often difficult, and laboratory tests may be required to confirm the diagnosis.

HUMAN CALICIVIRUSES

Etiologic Agent

The Norwalk virus is the prototype strain of a group of nonenveloped, small (27–40 nm), round, icosahedral viruses with relatively amorphous surface features on visualization by electron microscopy. These viruses have been difficult to classify because they have not been adapted to cell culture, they often are shed in low titers for only a few days, and no animal models are available. Molecular cloning and characterization have demonstrated that these viruses have a single, positive-strand RNA genome ~7.5 kb in length and that they possess a single virion-associated protein—similar to that of typical caliciviruses—with a molecular mass of 60 kDa.

TABLE 91-1

VIRAL CAUSES OF GASTROENTERITIS AMONG HUMANS

| VIRUS | FAMILY | GENOME | PRIMARY AGE GROUP AT RISK | CLINICAL SEVERITY | DETECTION ASSAYS ^a |
|------------------------------|---------------|----------------------------------|---------------------------|-------------------|------------------------------------|
| Group A rotavirus | Reoviridae | Double-strand segmented RNA | Children <5 years | +++ | EM, EIA (commercial), PAGE, RT-PCR |
| Norovirus | Caliciviridae | Positive-sense single-strand RNA | All ages | ++ | EM, EIA, RT-PCR |
| Sapovirus | Caliciviridae | Positive-sense single-strand RNA | Children <5 years | + | EM, EIA, RT-PCR |
| Astrovirus | Astroviridae | Positive-sense single-strand RNA | Children <5 years | + | EM, EIA, RT-PCR |
| Adenovirus (types 40 and 41) | Adenoviridae | Double-strand DNA | Children <5 years | + / ++ | EM, EIA (commercial), PCR |

^aEIA, enzyme immunoassay; EM, electron microscopy; PAGE, polyacrylamide gel electrophoresis; PCR, polymerase chain reaction; RT-PCR, reverse-transcriptase PCR.

TABLE 91-2
CHARACTERISTICS OF GASTROENTERITIS CAUSED BY VIRAL AND BACTERIAL AGENTS

| FEATURE | VIRAL GASTROENTERITIS | BACTERIAL GASTROENTERITIS |
|-------------------|--|---|
| Setting | Incidence similar in developing and developed countries | More common in settings with poor hygiene and sanitation |
| Infectious dose | Low (10–100 viral particles) for most agents | High (>10 ⁵ bacteria) for <i>Escherichia coli</i> , <i>Salmonella</i> , <i>Vibrio</i> ; medium (10 ² –10 ⁵ bacteria) for <i>Campylobacter jejuni</i> ; low (10–100 bacteria) for <i>Shigella</i> |
| Seasonality | In temperate climates, winter seasonality for most agents; year-round occurrence in tropical areas | More common in summer or rainy months, particularly in developing countries with a high disease burden |
| Incubation period | 1–3 days for most agents; can be shorter for norovirus | 1–7 days for common agents (e.g., <i>Campylobacter</i> , <i>E. coli</i> , <i>Shigella</i> , <i>Salmonella</i>); a few hours for bacteria producing preformed toxins (e.g., <i>Staphylococcus aureus</i> , <i>Bacillus cereus</i>) |
| Reservoir | Primarily humans | Depending on species, human (e.g., <i>Shigella</i> , <i>Salmonella</i>), animal (e.g., <i>Campylobacter</i> , <i>Salmonella</i> , <i>E. coli</i>), and water (e.g., <i>Vibrio</i>) reservoirs exist. |
| Fever | Common with rotavirus and norovirus; uncommon with other agents | Common with agents causing inflammatory diarrhea (e.g., <i>Salmonella</i> , <i>Shigella</i>) |
| Vomiting | Prominent and can be the only presenting feature, especially in children | Common with bacteria producing preformed toxins; less prominent in diarrhea due to other agents |
| Diarrhea | Common; nonbloody in almost all cases | Prominent and frequently bloody with agents causing inflammatory diarrhea |
| Duration | 1–3 days for norovirus and sapovirus; 2–8 days for other viruses | 1–2 days for bacteria producing preformed toxins; 2–8 days for most other bacteria |
| Diagnosis | This is often a diagnosis of exclusion in clinical practice. Commercial enzyme immunoassays are available for detection of rotavirus and adenovirus, but identification of other agents is limited to research and public health laboratories. | Fecal examination for leukocytes and blood is helpful in differential diagnosis. Culture of stool specimens, sometimes on special media, can identify several pathogens. Molecular techniques are useful epidemiologic tools but are not routinely used in most laboratories. |
| Treatment | Supportive therapy to maintain adequate hydration and nutrition should be given. Antibiotics and antimotility agents are contraindicated. | Supportive hydration therapy is adequate for most patients. Antibiotics are recommended for patients with dysentery caused by <i>Shigella</i> or <i>Vibrio cholerae</i> and for some patients with <i>Clostridium difficile</i> colitis. |

On the basis of these molecular characteristics, these viruses are presently classified in two genera belonging to the family *Caliciviridae*: the *noroviruses* and the *sapoviruses* (previously called Norwalk-like viruses and Sapporo-like viruses, respectively).

Epidemiology

Infections with the Norwalk and related human caliciviruses are common worldwide, and most adults have antibodies to these viruses. Antibody is acquired at an earlier age in developing countries—a pattern consistent with the presumed fecal-oral mode of transmission. Infections occur year-round, although, in temperate climates, a distinct increase has been noted in cold-weather months. Noroviruses may be the most common infectious agents of mild gastroenteritis in the community and affect all age groups, whereas sapoviruses primarily cause gastroenteritis in children. Noroviruses also cause traveler's diarrhea, and outbreaks have occurred among military personnel deployed to various parts of the world. The etiologic role of noroviruses in moderate and severe gastroenteritis requiring a visit to a physician or hospitalization is still being studied. However, the limited data available indicate that norovirus may be the second most common viral agent (after rotavirus) among young children and the most common agent among older children and adults. Noroviruses are also recognized as the major cause of epidemics of gastroenteritis worldwide. In the United States, >90% of outbreaks of nonbacterial gastroenteritis are caused by noroviruses. Epidemics occur throughout the year, in all age groups, and in a variety of settings.

Virus is transmitted predominantly by the fecal-oral route but is also present in vomitus. Because an inoculum with very few viruses can be infectious, transmission can occur by aerosolization, by contact with contaminated fomites, and by person-to-person contact. Viral shedding and infectivity are greatest during the acute illness, but challenge studies with Norwalk virus in volunteers indicate that viral antigen may be shed by asymptotically infected persons and also by symptomatic persons before the onset of symptoms and for up to 2 weeks after the resolution of illness. In one study, 11 of 15 norovirus-infected children <2 years of age shed the virus for >2 weeks after onset; this group included 3 infants <6 months of age who shed virus for 42–47 days or even longer.

Pathogenesis

The exact sites and cellular receptors for attachment of viral particles have not been determined. Data suggest that carbohydrates that are similar to human histo-blood group antigens and are present on the gastroduodenal epithelium of individuals with the secretor phenotype may serve as ligands for the attachment of Norwalk virus. Additional studies must more fully elucidate norovirus-carbohydrate interactions, including potential strain-specific variations. After the infection of volunteers, reversible lesions are noted in the upper jejunum, with broadening and blunting of the villi, shortening of the microvilli, vacuolization of the lining epithelium,

crypt hyperplasia, and infiltration of the lamina propria by polymorphonuclear neutrophils and lymphocytes. The lesions persist for at least 4 days after the resolution of symptoms and are associated with malabsorption of carbohydrates and fats and a decreased level of brush-border enzymes. Adenylate cyclase activity is not altered. No histopathologic changes are seen in the stomach or colon, but gastric motor function is delayed, and this alteration is believed to contribute to the nausea and vomiting that are typical of this illness.

Clinical Manifestations

Gastroenteritis caused by Norwalk and related human caliciviruses has a sudden onset, following an average incubation period of 24 h (range, 12–72 h). The illness generally lasts 12–60 h and is characterized by one or more of the following symptoms: nausea, vomiting, abdominal cramps, and diarrhea. Vomiting is more prevalent among children, whereas a greater proportion of adults develop diarrhea. Constitutional symptoms are common, including headache, fever, chills, and myalgias. Noroviruses appear to cause more severe illness than sapoviruses, although both illnesses are less severe than that due to rotavirus. The stools are characteristically loose and watery, without blood, mucus, or leukocytes. White cell counts are generally normal; rarely, leukocytosis with relative lymphopenia may be observed. Death is a rare outcome and usually results from severe dehydration in vulnerable persons (e.g., elderly patients with debilitating health conditions).

Immunity

Approximately 50% of persons challenged with Norwalk virus become ill and acquire short-term immunity against the infecting strain. Immunity to Norwalk virus appears to correlate inversely with level of antibody; i.e., persons with higher levels of preexisting antibody to Norwalk virus are more susceptible to illness. This observation suggests that some individuals have a genetic predisposition to illness. Recent data indicate that specific ABO, Lewis, and secretor blood group phenotypes may influence susceptibility to norovirus infection.

Diagnosis

Cloning and sequencing of the genomes of Norwalk and several other human caliciviruses have allowed the development of assays based on polymerase chain reaction (PCR) for detection of virus in stool and vomitus. Virus-like particles produced by expression of capsid proteins in a recombinant baculovirus vector have been used to develop enzyme immunoassays (EIAs) for detection of virus in stool or a serologic response to a specific viral antigen. These newer diagnostic techniques are considerably more sensitive than previous detection methods, such as electron microscopy, immune electron microscopy, and EIAs based on reagents derived from humans. However, no currently available single assay can detect all human caliciviruses because of their great genetic and antigenic diversity. In addition, the assays are still cumbersome and are available primarily in research

laboratories, although they are increasingly being adopted by public health laboratories for routine screening of fecal specimens from patients affected by outbreaks of gastroenteritis. Commercial EIA kits have been developed but are still being evaluated to determine their optimal use for both outbreak-related and sporadic acute gastroenteritis cases.

Treatment:

Rx INFECTIONS WITH NORWALK AND RELATED HUMAN CALICIVIRUSES

The disease is self-limited, and oral rehydration therapy is generally adequate. If severe dehydration develops, IV fluid therapy is indicated. No specific antiviral therapy is available.

Prevention

Epidemic prevention relies on situation-specific measures, such as control of contamination of food and water, exclusion of ill food handlers, and reduction of person-to-person spread through good personal hygiene and disinfection of contaminated fomites. The role of immunoprophylaxis is not clear, given the lack of long-term immunity from natural disease and the paradoxical inverse association between the level of immune response and protection from disease.

ROTAVIRUS

Etiologic Agent

Rotaviruses are members of the family Reoviridae. The viral genome consists of 11 segments of double-strand RNA that are enclosed in a triple-layered, nonenveloped, icosahedral capsid 75 nm in diameter. Viral protein 6 (VP6), the major structural protein, is the target of commercial immunoassays and determines the group specificity of rotaviruses. There are seven major groups of rotavirus (A through G); human illness is caused primarily by group A and, to a much lesser extent, by groups B and C. Two outer-capsid proteins, VP7 (G-protein) and VP4 (P-protein), determine serotype specificity, induce neutralizing antibodies, and form the basis for binary classification of rotaviruses (G and P types). The segmented genome of rotavirus allows genetic reassortment (i.e., exchange of genome segments between viruses) during co-infection—a property that may play a role in viral evolution and has been utilized in the development of reassortant animal-human rotavirus-based vaccines.

Epidemiology

Worldwide, nearly all children are infected with rotavirus by 3–5 years of age. Neonatal infections are common but are often asymptomatic or mild, presumably because of protection from maternal antibody or breast-feeding. First infections after 3 months of age are likely to be symptomatic, and the incidence of disease peaks among children 4–23 months of age. Reinfections are common, but the severity of disease decreases with

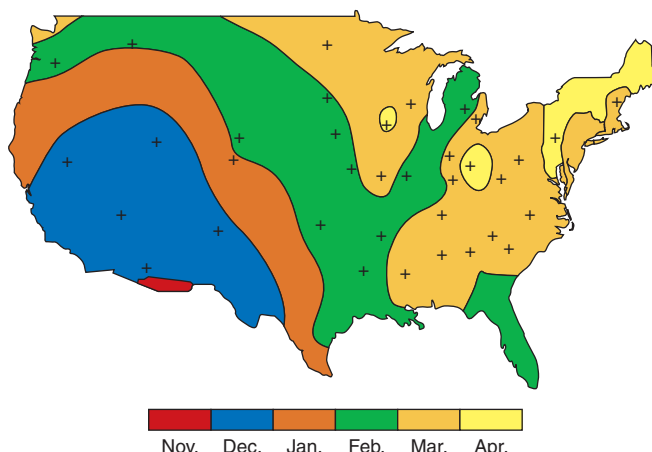

FIGURE 91-2

Time of peak rotavirus activity in the contiguous 48 states: United States, July 1991 to June 1997. Data are from ~90 U.S. laboratories. (Adapted from TJ Torok et al: *Visualizing geographic and temporal trends in rotavirus activity in the United States, 1991 to 1996. National Respiratory and Enteric Virus Surveillance System Collaborating Laboratories. Pediatr Infect Dis J* 16:941, 1997.)

each repeat infection. Therefore, severe rotavirus infections are relatively uncommon among older children and adults. Nevertheless, rotavirus can cause illness in parents and caretakers of children with rotavirus diarrhea, immunocompromised persons, travelers, and elderly individuals and should be considered in the differential diagnosis of gastroenteritis among adults. In temperate climates, rotavirus disease occurs predominantly during the cooler fall and winter months. In the United States, the rotavirus season each year begins in the Southwest during the autumn (October through December) and migrates across the continent, peaking in the Northeast during the spring (March through May) (Fig. 91-2); the reasons for this characteristic pattern are not clear. In tropical settings, rotavirus disease occurs year-round, with less pronounced seasonal peaks.

Rotavirus gastroenteritis is more frequently associated with dehydration than is gastroenteritis caused by other pathogens. Therefore, the proportion of gastroenteritis cases that are attributable to rotavirus increases with increasing severity of illness, ranging from a median of 8% in the community to 18% among outpatients and 40% among hospitalized patients. Each year, rotavirus is estimated to cause ~500,000 childhood deaths worldwide.

During episodes of rotavirus-associated diarrhea, virus is shed in large quantities in stool (10^7 – 10^{12} /g). Viral shedding detectable by EIA usually subsides within 1 week but may persist for >30 days in immunocompromised individuals. Viral shedding may be detected for longer periods by sensitive molecular assays, such as PCR. The virus is transmitted predominantly through the fecal-oral route. Spread through respiratory secretions, person-to-person contact, or contaminated environmental surfaces has also been postulated to explain the rapid acquisition of antibody in the first 3 years of life, regardless of sanitary conditions.

At least 10 different G serotypes of group A rotavirus have been identified in humans, but only five types (G1 through G4 and G9) are common. While human rotavirus strains that possess a high degree of genetic homology with animal strains have been identified, animal-to-human transmission appears to be uncommon.

Group B rotaviruses have been associated with several large epidemics of severe gastroenteritis among adults in China since 1982 and have recently been identified in India but not in other parts of the world. Group C rotaviruses have been associated with a small proportion of pediatric gastroenteritis cases in several countries worldwide.

Pathogenesis

Rotaviruses infect and ultimately destroy mature enterocytes in the villous epithelium of the proximal small intestine. The loss of absorptive villous epithelium, coupled with the proliferation of secretory crypt cells, results in secretory diarrhea. Brush-border enzymes characteristic of differentiated cells are reduced, and this change leads to the accumulation of unmetabolized disaccharides and consequent osmotic diarrhea. Studies in mice indicate that a nonstructural rotavirus protein, NSP4, functions as an enterotoxin and contributes to secretory diarrhea by altering epithelial cell function and permeability. In addition, rotavirus may evoke fluid secretion through activation of the enteric nervous system in the intestinal wall. Recent data indicate that rotavirus antigenemia and viremia are common among children with acute rotavirus infection, although the antigen and RNA levels in serum are substantially lower than those in stool.

Clinical Manifestations

The clinical spectrum of rotavirus infection ranges from subclinical infection to severe gastroenteritis leading to life-threatening dehydration. After an incubation period of 1–3 days, the illness has an abrupt onset, with vomiting frequently preceding the onset of diarrhea. Up to one-third of patients may have a temperature of $>39^{\circ}\text{C}$. The stools are characteristically loose and watery and only infrequently contain red or white cells. Gastrointestinal symptoms generally resolve in 3–7 days.

Respiratory and neurologic features in children with rotavirus infection have been reported, but causal associations have not been proven. Moreover, rotavirus infection has been associated with a variety of other clinical conditions (e.g., sudden infant death syndrome, necrotizing enterocolitis, intussusception, Kawasaki disease, and type 1 diabetes), but no causal relationship has been confirmed with any of these syndromes.

Rotavirus does not appear to be a major opportunistic pathogen in children with HIV infection. In severely immunodeficient children, rotavirus can cause protracted diarrhea with prolonged viral excretion and, in rare instances, can disseminate systemically. Persons who are immunosuppressed for bone marrow transplantation are also at risk for severe or even fatal rotavirus disease.

Immunity

Protection against rotavirus disease is correlated with the presence of virus-specific secretory IgA antibodies in the intestine and, to some extent, the serum. Because virus-specific IgA production at the intestinal surface is short-lived, complete protection against disease is only temporary. However, each infection and subsequent reinfection confers progressively greater immunity; thus severe disease is most common among young children with first or second infections. Immunologic memory is believed to be important in the attenuation of disease severity upon reinfection.

Diagnosis

Illness caused by rotavirus is difficult to distinguish clinically from that caused by other enteric viruses. Because large quantities of virus are shed in feces, the diagnosis can usually be confirmed by a wide variety of commercially available EIAs or by techniques for detecting viral RNA, such as gel electrophoresis, probe hybridization, or PCR.

Treatment: ROTAVIRUS INFECTIONS

Rotavirus gastroenteritis can lead to severe dehydration. Thus appropriate treatment should be instituted early. Standard oral rehydration therapy is successful in most children who can take oral fluids, but IV fluid replacement may be required for patients who are severely dehydrated or are unable to tolerate oral therapy because of frequent vomiting. The therapeutic role of probiotics, bismuth subsalicylate, enkephalinase inhibitors, and nitazoxanide has been evaluated in clinical studies but is not clearly defined. Antibiotics and antimotility agents should be avoided. In immunocompromised children with chronic symptomatic rotavirus disease, orally administered immunoglobulins or colostrum may resolve symptoms, but the choice of agents and their doses have not been well studied and are often empirical.

Prevention

Efforts to develop rotavirus vaccines were pursued because it was apparent—given the similar rates in less developed and industrialized nations—that improvements in hygiene and sanitation were unlikely to reduce disease incidence. The first rotavirus vaccine licensed in the United States in 1998 was withdrawn from the market within 1 year because it was linked with intussusception, a severe bowel obstruction.

In 2006, promising safety and efficacy results for two new rotavirus vaccines were reported from large clinical trials conducted in North America, Europe, and Latin America. One of these vaccines, a multivalent bovine-human reassortant rotavirus-based preparation, was recommended for routine immunization

of all U.S. infants in early 2006. The second vaccine, based on a single attenuated human rotavirus strain, is not licensed in the United States but has been introduced in immunization programs in several countries in Latin America and Europe.

Global Considerations

Rotavirus is ubiquitous and infects nearly all children worldwide by 5 years of age. However, compared with rotavirus disease in industrialized countries, that in developing countries occurs at a younger age, is less seasonal, is more often associated with severe outcomes (including death), and is more frequently caused by uncommon rotavirus strains. The different epidemiology of rotavirus disease and the greater prevalence of co-infection with other enteric pathogens, of comorbidities, and of malnutrition in developing countries may adversely affect the performance of rotavirus vaccines. Therefore, before global recommendations for vaccine use can be issued, it is vital to evaluate the efficacy of rotavirus vaccines in resource-poor settings of Africa and Asia. Trials in these areas are underway.

OTHER VIRAL AGENTS OF GASTROENTERITIS

Enteric *adenoviruses* of serotypes 40 and 41 belonging to subgroup F are 70- to 80-nm viruses with double-strand DNA that cause ~2–12% of all diarrhea episodes in young children. Unlike adenoviruses that cause respiratory illness, enteric adenoviruses are difficult to cultivate in cell lines, but they can be detected with commercially available EIAs.

Astroviruses, 28- to 30-nm viruses with a characteristic icosahedral structure, contain a positive-sense, single-strand RNA. At least seven serotypes have been identified, of which serotype 1 is most common. Astroviruses are primarily pediatric pathogens, causing ~2–10% of cases of mild to moderate gastroenteritis in children. The availability of simple immunoassays to detect virus in fecal specimens and of molecular methods to confirm and characterize strains will permit more comprehensive assessment of the etiologic role of these agents.

Toroviruses are 100- to 140-nm, enveloped, positive-strand RNA viruses that are recognized as causes of gastroenteritis in horses (Berne virus) and cattle (Breda virus). Their role as a cause of diarrhea in humans is still unclear, but studies from Canada have demonstrated associations between torovirus excretion and both nosocomial gastroenteritis and necrotizing enterocolitis in neonates. These associations require further evaluation.

Picobirnaviruses are small, bisegmented, double-strand RNA viruses that cause gastroenteritis in a variety of animals. Their role as primary causes of gastroenteritis in humans remains unclear, but several studies have found an association between picobirnaviruses and gastroenteritis in HIV-infected adults.

Several other viruses (e.g., enteroviruses, reoviruses, pestiviruses, and parvovirus B) have been identified in the feces of patients with diarrhea, but their etiologic role in gastroenteritis has not been proven. Diarrhea has also been noted as a manifestation of infection with two recently recognized viruses that primarily cause severe respiratory illness: the severe acute respiratory syndrome-associated coronavirus (SARS-CoV) and influenza A/H5N1 virus.

CHAPTER 92

ACUTE VIRAL HEPATITIS

Jules L. Dienstag

Acute viral hepatitis is a systemic infection affecting the liver predominantly. Almost all cases of acute viral hepatitis are caused by one of five viral agents: hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), the HBV-associated delta agent or hepatitis D virus (HDV), and hepatitis E virus (HEV). Other transfusion-transmitted agents, e.g., “hepatitis G” virus and “TT” virus, have been identified but do not cause hepatitis. All these human hepatitis viruses are RNA viruses, except for hepatitis B, which is a DNA virus. Although these agents can be distinguished by their molecular and antigenic properties, all types of viral hepatitis produce clinically similar illnesses. These range from asymptomatic and inapparent to fulminant and fatal acute infections common to all types, on the one hand, and from subclinical persistent infections to rapidly progressive chronic liver disease with cirrhosis and even hepatocellular carcinoma, common to the bloodborne types (HBV, HCV, and HDV), on the other.

VIROLOGY AND ETIOLOGY

Hepatitis A

Hepatitis A virus is a nonenveloped 27-nm, heat-, acid-, and ether-resistant RNA virus in the hepatovirus genus of the picornavirus family (**Fig. 92-1**). Its virion contains four capsid polypeptides, designated VP1 to VP4, which are cleaved posttranslationally from the polyprotein product of a 7500-nucleotide genome. Inactivation of viral activity can be achieved by boiling for 1 min, by contact with formaldehyde and chlorine, or by ultraviolet irradiation. Despite nucleotide sequence variation of up to 20% among isolates of HAV, all strains of this virus are immunologically indistinguishable and belong to one serotype. Hepatitis A has an incubation period of ~4 weeks. Its replication is limited to the liver, but the virus is present in the liver, bile, stools, and blood during the late incubation period and acute preicteric phase of illness. Despite persistence of virus in the liver, viral shedding in feces, viremia, and infectivity diminish rapidly once jaundice becomes apparent. HAV can be cultivated reproducibly in vitro.

FIGURE 92-1

Electron micrographs of hepatitis A virus particles and serum from a patient with hepatitis B. A. 27-nm hepatitis A virus particles purified from stool of a patient with acute hepatitis A and aggregated by antibody to hepatitis A virus. **B.** Concentrated serum from a patient with hepatitis B, demonstrating the 42-nm virions, tubular forms, and spherical

22-nm particles of hepatitis B surface antigen. 132,000 \times . (Hepatitis D resembles 42-nm virions of hepatitis B but is smaller, 35–37 nm; hepatitis E resembles hepatitis A virus but is slightly larger, 32–34 nm; hepatitis C has been visualized as a 55-nm particle.)

**FIGURE 92-2**

Scheme of typical clinical and laboratory features of hepatitis A.

Antibodies to HAV (anti-HAV) can be detected during acute illness when serum aminotransferase activity is elevated and fecal HAV shedding is still occurring. This early antibody response is predominantly of the IgM class and persists for several months, rarely for 6–12 months. During convalescence, however, anti-HAV of the IgG class becomes the predominant antibody (Fig. 92-2). Therefore, the diagnosis of hepatitis A is made during acute illness by demonstrating anti-HAV of the IgM class. After acute illness, anti-HAV of the IgG class remains detectable indefinitely, and patients with serum anti-HAV are immune to reinfection. Neutralizing antibody activity parallels the appearance of anti-HAV, and the IgG anti-HAV present in immune globulin accounts for the protection it affords against HAV infection.

Hepatitis B

Hepatitis B virus is a DNA virus with a remarkably compact genomic structure; despite its small, circular, 3200-bp size, HBV DNA codes for four sets of viral products with a complex, multiparticle structure. HBV achieves its genomic economy by relying on an efficient strategy of encoding proteins from four overlapping genes: S, C, P, and X (Fig. 92-3), as detailed below. Once thought to be unique among viruses, HBV is now recognized as one of a family of animal viruses, hepadnaviruses (hepatotropic DNA viruses), and is classified as hepadnavirus type 1. Similar viruses infect certain species of woodchucks, ground and tree squirrels, and Pekin ducks, to mention the most carefully characterized. Like HBV, all have the same distinctive three morphologic forms, have counterparts to the envelope and nucleocapsid virus antigens of HBV, replicate in the liver but exist in extrahepatic sites, contain their own endogenous DNA polymerase, have partially double-strand and partially single-strand genomes, are associated with acute and chronic hepatitis and hepatocellular carcinoma, and rely on a replicative strategy unique among DNA viruses but typical of retroviruses. Instead of DNA replication directly from a DNA template, hepadnaviruses rely on reverse transcription (effected by the DNA polymerase) of minus-strand DNA from a “pregenomic”

**FIGURE 92-3**

Compact genomic structure of HBV. This structure, with overlapping genes, permits HBV to code for multiple proteins. The S gene codes for the “major” envelope protein, HBsAg. Pre-S1 and pre-S2, upstream of S, combine with S to code for two larger proteins, “middle” protein, the product of pre-S2 + S, and “large” protein, the product of pre-S1 + pre-S2 + S. The largest gene, P, codes for DNA polymerase. The C gene codes for two nucleocapsid proteins, HBeAg, a soluble, secreted protein (initiation from the pre-C region of the gene) and HBcAg, the intracellular core protein (initiation after pre-C). The X gene codes for HBxAg, which can transactivate the transcription of cellular and viral genes; its clinical relevance is not known, but it may contribute to carcinogenesis by binding to p53.

RNA intermediate. Then plus-strand DNA is transcribed from the minus-strand DNA template by the DNA-dependent DNA polymerase and converted in the hepatocyte nucleus to a covalently closed circular DNA, which serves as a template for messenger RNA and pregenomic RNA. Viral proteins are translated by the messenger RNA, and the proteins and genome are packaged into virions and secreted from the hepatocyte. Although HBV is difficult to cultivate in vitro in the conventional sense from clinical material, several cell lines have been transfected with HBV DNA. Such transfected cells support in vitro replication of the intact virus and its component proteins.

Viral Proteins and Particles

Of the three particulate forms of HBV (Table 92-1), the most numerous are the 22-nm particles, which appear as spherical or long filamentous forms; these are antigenically indistinguishable from the outer surface or envelope protein of HBV and are thought to represent excess viral envelope protein. Outnumbered in serum by a factor of 100 or 1000 to 1 compared with the spheres and tubules are large, 42-nm, double-shelled spherical particles, which represent the intact hepatitis B virion (Fig. 92-1). The envelope protein expressed on the outer surface of the virion and on the smaller spherical and tubular structures is referred to as *hepatitis B surface antigen* (HBsAg). The concentration of HBsAg and virus particles in the blood may reach 500 $\mu\text{g/mL}$ and 10 trillion

TABLE 92-1

NOMENCLATURE AND FEATURES OF HEPATITIS VIRUSES

| HEPATITIS TYPE | VIRUS PARTICLE, nm | MORPHOLOGY | GENOME ^a | CLASSIFICATION | ANTIGEN(S) | ANTIBODIES | REMARKS |
|----------------|--------------------|--|-----------------------------|---|---------------------------------------|----------------------------------|---|
| HAV | 27 | Icosahedral nonenveloped | 7.5-kb RNA, linear, ss, + | Hepatovirus | HAV | Anti-HAV | Early fecal shedding Diagnosis: IgM anti-HAV Previous infection: IgG anti-HAV |
| HBV | 42 | Double-shelled virion (surface and core) spherical | 3.2-kb DNA, circular, ss/ds | Hepadnavirus | HBsAg HBcAg HBeAg | Anti-HBs Anti-HBc Anti-HBe | Bloodborne virus; carrier state Acute diagnosis: HBsAg, IgM anti-HBc Chronic diagnosis: IgG anti-HBc, HBsAg Markers of replication: HBeAg, HBV DNA Liver, lymphocytes, other organs |
| | 27 | Nucleocapsid core | | | HBcAg HBeAg | Anti-HBc Anti-HBe | Nucleocapsid contains DNA and DNA polymerase; present in hepatocyte nucleus; HBcAg does not circulate; HBeAg (soluble, nonparticulate) and HBV DNA circulate—correlate with infectivity and complete virions |
| | 22 | Spherical and filamentous; represents excess virus coat material | | | HBsAg | Anti-HBs | HBsAg detectable in >95% of patients with acute hepatitis B; found in serum, body fluids, hepatocyte cytoplasm; anti-HBs appears following infection—protective antibody |
| HCV | Approx. 40–60 | Enveloped | 9.4-kb RNA, linear, ss, + | Hepacivirus | HCV C100-3 C33c C22-3 NS5 | Anti-HCV | Bloodborne agent, formerly labeled non-A, non-B hepatitis Acute diagnosis: anti-HCV (C33c, C22-3, NS5), HCV RNA Chronic diagnosis: anti-HCV (C100-3, C33c, C22-3, NS5) and HCV RNA; cytoplasmic location in hepatocytes |
| HDV | 35–37 | Enveloped hybrid particle with HBsAg coat and HDV core | 1.7-kb RNA, circular, ss, – | Resembles viroids and plant satellite viruses | HBsAg HDV antigen | Anti-HBs Anti-HDV | Defective RNA virus, requires helper function of HBV (hepadnaviruses); HDV antigen present in hepatocyte nucleus Diagnosis: anti-HDV, HDV RNA; HBV/HDV coinfection—IgM anti-HBc and anti-HDV; HDV superinfection—IgG anti-HBc and anti-HDV |
| HEV | 32–34 | Nonenveloped icosahedral | 7.6-kb RNA, linear, ss, + | Hepevirus | HEV antigen | Anti-HEV | Agent of enterically transmitted hepatitis; rare in USA; occurs in Asia, Mediterranean countries, Central America Diagnosis: IgM/IgG anti-HEV (assays being developed); virus in stool, bile, hepatocyte cytoplasm |

^ass, single-strand; ss/ds, partially single-strand, partially double-strand; –, minus-strand; +, plus-strand.

particles per milliliter, respectively. The envelope protein, HBsAg, is the product of the S gene of HBV.

A number of different HBsAg subdeterminants have been identified. There is a common group-reactive antigen, *a*, shared by all HBsAg isolates. In addition, HBsAg may contain one of several subtype-specific antigens, namely, *d* or *y*, *w* or *r*, as well as other more recently characterized specificities. Hepatitis B isolates fall into one of at least eight subtypes and eight genotypes (A–H). Geographic distribution of genotypes and subtypes varies; genotypes A (corresponding to subtype *adu*) and D (*ayw*) predominate in the United States and Europe, while genotypes B (*adu*) and C (*adr*) predominate in Asia. Clinical course and outcome are independent of subtype, but preliminary reports suggest that genotype B is associated with less rapidly progressive liver disease and a lower likelihood, or delayed appearance, of hepatocellular carcinoma than genotype C. Patients with genotype A appear to be more likely to clear circulating viremia and to achieve HBsAg seroconversion, both spontaneously and in response to antiviral therapy. In addition, “precore” mutations are favored by certain genotypes (see below).

Upstream of the S gene are the pre-S genes (Fig. 92-3), which code for pre-S gene products, including receptors on the HBV surface for polymerized human serum albumin and for hepatocyte membrane proteins. The pre-S region actually consists of both pre-S1 and pre-S2. Depending on where translation is initiated, three potential HBsAg gene products are synthesized. The protein product of the S gene is HBsAg (*major protein*), the product of the S region plus the adjacent pre-S2 region is the *middle protein*, and the product of the pre-S1 plus pre-S2 plus S regions is the *large protein*. Compared with the smaller spherical and tubular particles of HBV, complete 42-nm virions are enriched in the large protein. Both pre-S proteins and their respective antibodies can be detected during HBV infection, and the period of pre-S antigenemia appears to coincide with other markers of virus replication, as detailed below.

The intact 42-nm virion contains a 27-nm nucleocapsid core particle. Nucleocapsid proteins are coded for by the C gene. The antigen expressed on the surface of the nucleocapsid core is referred to as *hepatitis B core antigen* (HBcAg), and its corresponding antibody is anti-HBc. A third HBV antigen is *hepatitis B e antigen* (HBeAg), a soluble, nonparticulate, nucleocapsid protein that is immunologically distinct from intact HBcAg but is a product of the same C gene. The C gene has two initiation codons, a precore and a core region (Fig. 92-3). If translation is initiated at the precore region, the protein product is HBeAg, which has a signal peptide that binds it to the smooth endoplasmic reticulum and leads to its secretion into the circulation. If translation begins with the core region, HBcAg is the protein product; it has no signal peptide, it is not secreted, but it assembles into nucleocapsid particles, which bind to and incorporate RNA and which, ultimately, contain HBV DNA. Also packaged within the nucleocapsid core is a DNA polymerase, which directs replication and repair of HBV DNA. When packaging within viral proteins is complete, synthesis of the incomplete plus strand stops; this accounts for the single-strand

gap and for differences in the size of the gap. HBcAg particles remain in the hepatocyte, where they are readily detectable by immunohistochemical staining, and are exported after encapsidation by an envelope of HBsAg. Therefore, naked core particles do not circulate in the serum. The secreted nucleocapsid protein, HBeAg, provides a convenient, readily detectable, qualitative marker of HBV replication and relative infectivity.

HBsAg-positive serum containing HBeAg is more likely to be highly infectious and to be associated with the presence of hepatitis B virions (and detectable HBV DNA, see below) than HBeAg-negative or anti-HBe-positive serum. For example, HBsAg carrier mothers who are HBeAg-positive almost invariably (>90%) transmit hepatitis B infection to their offspring, whereas HBsAg carrier mothers with anti-HBe rarely (10–15%) infect their offspring.

Early during the course of acute hepatitis B, HBeAg appears transiently; its disappearance may be a harbinger of clinical improvement and resolution of infection. Persistence of HBeAg in serum beyond the first 3 months of acute infection may be predictive of the development of chronic infection, and the presence of HBeAg during chronic hepatitis B is associated with ongoing viral replication, infectivity, and inflammatory liver injury.

The third of the HBV genes is the largest, the P gene (Fig. 92-3), which codes for the DNA polymerase; as noted above, this enzyme has both DNA-dependent DNA polymerase and RNA-dependent reverse transcriptase activities. The fourth gene, X, codes for a small, nonparticulate protein, *hepatitis B x antigen* (HBxAg), that is capable of transactivating the transcription of both viral and cellular genes (Fig. 92-3). In the cytoplasm, HBxAg effects calcium release (possibly from mitochondria), which activates signal-transduction pathways that lead to stimulation of HBV reverse transcription and HBV DNA replication. Such transactivation may enhance the replication of HBV, leading to the clinical association observed between the expression of HBxAg and antibodies to it in patients with severe chronic hepatitis and hepatocellular carcinoma. The transactivating activity can enhance the transcription and replication of other viruses besides HBV, such as HIV. Cellular processes transactivated by X include the human interferon γ gene and class I major histocompatibility genes; potentially, these effects could contribute to enhanced susceptibility of HBV-infected hepatocytes to cytolytic T cells. The expression of X can also induce programmed cell death (apoptosis).

Serologic and Virologic Markers

After a person is infected with HBV, the first virologic marker detectable in serum within 1–12 weeks, usually between 8–12 weeks, is HBsAg (Fig. 92-4). Circulating HBsAg precedes elevations of serum aminotransferase activity and clinical symptoms by 2–6 weeks and remains detectable during the entire icteric or symptomatic phase of acute hepatitis B and beyond. In typical cases, HBsAg becomes undetectable 1–2 months after the onset of jaundice and rarely persists beyond 6 months. After HBsAg disappears, antibody to HBsAg (anti-HBs) becomes detectable in serum and remains

FIGURE 92-4

Scheme of typical clinical and laboratory features of acute hepatitis B.

detectable indefinitely thereafter. Because HBcAg is intracellular and, when in the serum, sequestered within an HBsAg coat, naked core particles do not circulate in serum and, therefore, HBcAg is not detectable routinely in the serum of patients with HBV infection. By contrast, anti-HBc is readily demonstrable in serum, beginning within the first 1–2 weeks after the appearance of HBsAg and preceding detectable levels of anti-HBs by weeks to months. Because variability exists in the time of appearance of anti-HBs after HBV infection, occasionally a gap of several weeks or longer may separate the disappearance of HBsAg and the appearance of anti-HBs. During this “gap” or “window” period, anti-HBc may represent the only serologic evidence of current or recent HBV infection, and blood containing anti-HBc in the absence of HBsAg and anti-HBs has been implicated in the development of transfusion-associated hepatitis B. In part because the sensitivity of immunoassays for HBsAg and anti-HBs has increased, however, this window period is rarely encountered. In some persons, years after HBV infection, anti-HBc may persist in the circulation longer than anti-HBs. Therefore, isolated anti-HBc does not necessarily indicate active virus replication; most instances of isolated anti-HBc represent hepatitis B infection in the remote past. Rarely, however, isolated anti-HBc represents low-level hepatitis B viremia, with HBsAg below the detection threshold; occasionally, isolated anti-HBc represents a cross-reacting or false-positive immunologic specificity. Recent and remote HBV infections can be distinguished by determination of the immunoglobulin class of anti-HBc. Anti-HBc of the IgM class (IgM anti-HBc) predominates during the first 6 months after acute infection, whereas IgG anti-HBc is the predominant class of anti-HBc beyond 6 months. Therefore, patients with current or recent acute hepatitis B, including those in the anti-HBc window, have IgM anti-HBc in their serum. In patients who have recovered from hepatitis B in the remote past as well as those with chronic HBV infection, anti-HBc is predominantly of the IgG class. Infrequently, in ≤ 1 –5% of

patients with acute HBV infection, levels of HBsAg are too low to be detected; in such cases, the presence of IgM anti-HBc establishes the diagnosis of acute hepatitis B. When isolated anti-HBc occurs in the rare patient with chronic hepatitis B whose HBsAg level is below the sensitivity threshold of contemporary immunoassays (a low-level carrier), the anti-HBc is of the IgG class. Generally, in persons who have recovered from hepatitis B, anti-HBs and anti-HBc persist indefinitely.

The temporal association between the appearance of anti-HBs and resolution of HBV infection as well as the observation that persons with anti-HBs in serum are protected against reinfection with HBV suggests that *anti-HBs are the protective antibody*. Therefore, strategies for prevention of HBV infection are based on providing susceptible persons with circulating anti-HBs (see below). Occasionally, in 10–20% of patients with chronic hepatitis B, low-level, low-affinity anti-HBs can be detected. This antibody is directed against a subtype determinant different from that represented by the patient’s HBsAg; its presence is thought to reflect the stimulation of a related clone of antibody-forming cells, but it has no clinical relevance and does not signal imminent clearance of hepatitis B. These patients with HBsAg and such nonneutralizing anti-HBs should be categorized as having chronic HBV infection.

The other readily detectable serologic marker of HBV infection, HBeAg, appears concurrently with or shortly after HBsAg. Its appearance coincides temporally with high levels of virus replication and reflects the presence of circulating intact virions and detectable HBV DNA (with the notable exception of patients with precore mutations who cannot synthesize HBeAg—see the next section, “Molecular Variants”). Pre-S1 and pre-S2 proteins are also expressed during periods of peak replication, but assays for these gene products are not routinely available. In self-limited HBV infections, HBeAg becomes undetectable shortly after peak elevations in aminotransferase activity, before the disappearance of HBsAg, and anti-HBe then becomes detectable, coinciding with a period of relatively lower infectivity (Fig. 92-4). Because markers of HBV replication appear transiently during acute infection, testing for such markers is of little clinical utility in typical cases of acute HBV infection. In contrast, markers of HBV replication provide valuable information in patients with protracted infections.

Departing from the pattern typical of acute HBV infections, in chronic HBV infection, HBsAg remains detectable beyond 6 months, anti-HBc is primarily of the IgG class, and anti-HBs is either undetectable or detectable at low levels (see “Laboratory Features” later in the chapter) (Fig. 92-5). During early chronic HBV infection, HBV DNA can be detected both in serum and in hepatocyte nuclei, where it is present in free or episomal form. This *replicative stage* of HBV infection is the time of maximal infectivity and liver injury; HBeAg is a qualitative marker and HBV DNA a quantitative marker of this replicative phase, during which all three forms of HBV circulate, including intact virions. Over time, the replicative phase of chronic HBV infection gives way to a relatively *nonreplicative phase*. This occurs at

FIGURE 92-5

Scheme of typical laboratory features of wild-type chronic hepatitis B. HBeAg and HBV DNA can be detected in serum during the *replicative phase* of chronic infection, which is associated with infectivity and liver injury. Seroconversion from the replicative phase to the *nonreplicative phase* occurs at a rate of ~10% per year and is heralded by an acute hepatitis-like elevation of ALT activity; during the nonreplicative phase, infectivity and liver injury are limited. In HBeAg-negative chronic hepatitis B associated with mutations in the precore region of the HBV genome, replicative chronic hepatitis B occurs in the absence of HBeAg.

a rate of ~10% per year and is accompanied by seroconversion from HBeAg-positive to anti-HBe-positive. In most cases, this seroconversion coincides with a transient, acute hepatitis-like elevation in aminotransferase activity, believed to reflect cell-mediated immune clearance of virus-infected hepatocytes. In the nonreplicative phase of chronic infection, when HBV DNA is demonstrable in hepatocyte nuclei, it tends to be integrated into the host genome. In this phase, only spherical and tubular forms of HBV, *not intact virions*, circulate, and liver injury tends to subside. Most such patients would be characterized as *inactive HBV carriers*. In reality, the designations *replicative* and *nonreplicative* are only relative; even in the so-called nonreplicative phase, HBV replication can be detected at levels of $\sim 10^3$ virions with highly sensitive amplification probes such as the polymerase chain reaction (PCR); below this replication threshold, liver injury and infectivity of HBV are limited to negligible. Still, the distinctions are pathophysiologically and clinically meaningful. Occasionally, nonreplicative HBV infection converts back to replicative infection. Such spontaneous reactivations are accompanied by reexpression of HBeAg and HBV DNA, and sometimes of IgM anti-HBc, as well as by exacerbations of liver injury. Because high-titer IgM anti-HBc can reappear during acute exacerbations of chronic hepatitis B, relying on IgM anti-HBc versus IgG anti-HBc to distinguish between acute and chronic hepatitis B infection, respectively, may not always be reliable; in such cases, patient history is invaluable in helping to distinguish *de novo* acute hepatitis B infection from acute exacerbation of chronic hepatitis B infection.

Molecular Variants

Variation occurs throughout the HBV genome, and clinical isolates of HBV that do not express typical viral proteins have been attributed to mutations in individual or even multiple gene locations. For example, variants have been described that lack nucleocapsid proteins, envelope proteins, or both. Two categories of naturally occurring HBV variants have attracted the most attention. One of these was identified initially in Mediterranean countries among patients with an unusual serologic-clinical profile. They have severe chronic HBV infection and detectable HBV DNA but with anti-HBe instead of HBeAg. These patients were found to be infected with an HBV mutant that contained an alteration in the precore region rendering the virus incapable of encoding HBeAg. Although several potential mutation sites exist in the pre-C region, the region of the C gene necessary for the expression of HBeAg (see “Virology and Etiology” earlier in the chapter), the most commonly encountered in such patients is a single base substitution, from G to A, which occurs in the second to last codon of the pre-C gene at nucleotide 1896. This substitution results in the replacement of the TGG tryptophan codon by a stop codon (TAG), which prevents the translation of HBeAg. Another mutation, in the core-promoter region, prevents transcription of the coding region for HBeAg and yields an HBeAg-negative phenotype. Patients with such mutations in the precore region and who are unable to secrete HBeAg tend to have severe liver disease that progresses more rapidly to cirrhosis. Both “wild-type” HBV and precore-mutant HBV can coexist in the same patient, or mutant HBV may arise late during wild-type HBV infection. In addition, clusters of fulminant hepatitis B in Israel and Japan have been attributed to common-source infection with a precore mutant. Fulminant hepatitis B in North America and western Europe, however, occurs in patients infected with wild-type HBV, in the absence of precore mutants, and both precore mutants and other mutations throughout the HBV genome occur commonly even in patients with typical, self-limited, milder forms of HBV infection. HBeAg-negative chronic hepatitis with mutations in the precore region is now the most frequently encountered form of hepatitis B in Mediterranean countries and in Europe. In the United States, where HBV genotype A (less prone to G1896A mutation) is prevalent, precore-mutant HBV is much less common; however, as a result of immigration from Asia and Europe, the proportion of HBeAg-negative hepatitis B-infected individuals has increased in the United States, and they now represent approximately a third of patients with chronic hepatitis B. Characteristic of such HBeAg-negative chronic hepatitis B are lower levels of HBV DNA (usually $\leq 10^5$ copies/mL) and one of several patterns of aminotransferase activity—persistent elevations, periodic fluctuations above the normal range, and periodic fluctuations between the normal and elevated range.

The second important category of HBV mutants consists of *escape mutants*, in which a single amino acid substitution, from glycine to arginine, occurs at position 145 of the immunodominant *a* determinant common to

all subtypes of HBsAg. This change in HBsAg leads to a critical conformational change that results in a loss of neutralizing activity by anti-HBs. This specific HBV/a mutant has been observed in two situations, active and passive immunization, in which humoral immunologic pressure may favor evolutionary change (“escape”) in the virus—in a small number of hepatitis B vaccine recipients who acquired HBV infection despite the prior appearance of neutralizing anti-HBs and in liver transplant recipients who underwent the procedure for hepatitis B and who were treated with a high-potency human monoclonal anti-HBs preparation. Although such mutants have not been recognized frequently, their existence raises a concern that may complicate vaccination strategies and serologic diagnosis. Different types of mutations emerge during antiviral therapy of chronic hepatitis B with nucleoside analogues; such “YMDD” and similar mutations in the polymerase motif of HBV are described in Chap. 93.

Extrahepatic Sites

Hepatitis B antigens and HBV DNA have been identified in extrahepatic sites, including lymph nodes, bone marrow, circulating lymphocytes, spleen, and pancreas. Although the virus does not appear to be associated with tissue injury in any of these extrahepatic sites, its presence in these “remote” reservoirs has been invoked to explain the recurrence of HBV infection after orthotopic liver transplantation. A more complete understanding of the clinical relevance of extrahepatic HBV remains to be defined.

Hepatitis D

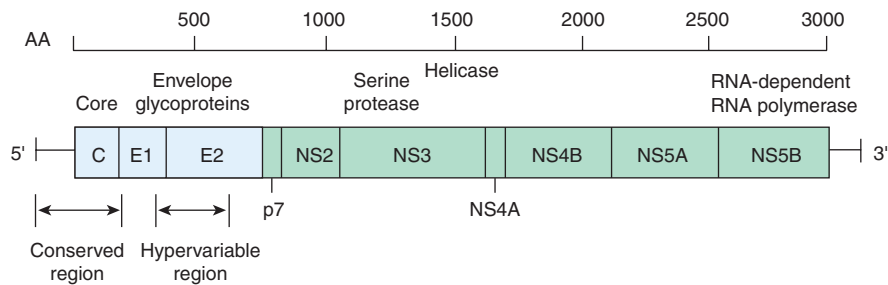

The delta hepatitis agent, or HDV, is a defective RNA virus that coinfects with and requires the helper function of HBV (or other hepadnaviruses) for its replication and expression. Slightly smaller than HBV, delta is a formalin-sensitive, 35- to 37-nm virus with a hybrid structure. Its nucleocapsid expresses delta antigen, which bears no antigenic homology with any of the HBV antigens, and contains the virus genome. The delta core is “encapsidated” by an outer envelope of HBsAg, indistinguishable from that of HBV except in its relative compositions of major, middle, and large HBsAg component proteins. The genome is a small, 1700-nucleotide, circular, single-strand RNA (minus strand) that is nonhomologous with HBV DNA (except for a small area of the polymerase gene) but that has features and the rolling circle model of replication common to genomes of plant satellite viruses or viroids. HDV RNA contains many areas of internal complementarity; therefore, it can fold on itself by internal base pairing to form an unusual, very stable, rodlike structure. HDV RNA requires host RNA polymerase II for its replication via RNA-directed RNA synthesis by transcription of genomic RNA to a complementary antigenomic (plus strand) RNA; the antigenomic RNA, in turn, serves as a template for subsequent genomic RNA synthesis. Between the genomic and antigenomic RNAs of HDV, there are coding regions for nine proteins. Delta antigen, which is a product of the antigenomic strand,

exists in two forms, a small, 195-amino-acid species, which plays a role in facilitating HDV RNA replication, and a large, 214-amino-acid species, which appears to suppress replication but is required for assembly of the antigen into virions. Delta antigens have been shown to bind directly to RNA polymerase II, resulting in stimulation of transcription. Although complete hepatitis D virions and liver injury require the cooperative helper function of HBV, intracellular replication of HDV RNA can occur without HBV. Genomic heterogeneity among HDV isolates has been described; however, pathophysiologic and clinical consequences of this genetic diversity have not been recognized.

HDV can either infect a person simultaneously with HBV (*co-infection*) or superinfect a person already infected with HBV (*superinfection*); when HDV infection is transmitted from a donor with one HBsAg subtype to an HBsAg-positive recipient with a different subtype, the HDV agent assumes the HBsAg subtype of the recipient, rather than the donor. Because HDV relies absolutely on HBV, the duration of HDV infection is determined by the duration of (and cannot outlast) HBV infection. HDV antigen is expressed primarily in hepatocyte nuclei and is occasionally detectable in serum. During acute HDV infection, anti-HDV of the IgM class predominates, and 30–40 days may elapse after symptoms appear before anti-HDV can be detected. In self-limited infection, anti-HDV is low titer and transient, rarely remaining detectable beyond the clearance of HBsAg and HDV antigen. In chronic HDV infection, anti-HDV circulates in high titer, and both IgM and IgG anti-HDV can be detected. HDV antigen in the liver and HDV RNA in serum and liver can be detected during HDV replication.

Hepatitis C

Hepatitis C virus, which, before its identification was labeled “non-A, non-B hepatitis,” is a linear, single-strand, positive-sense, 9600-nucleotide RNA virus, the genome of which is similar in organization to that of flaviviruses and pestiviruses; HCV is the only member of the genus *Hepacivirus* in the family Flaviviridae. The HCV genome contains a single large open reading frame (gene) that codes for a virus polyprotein of ~3000 amino acids, which is cleaved after translation to yield 10 viral proteins. The 5′ end of the genome consists of an untranslated region (containing an internal ribosomal entry site) adjacent to the genes for four structural proteins; the nucleocapsid core protein, C; two envelope glycoproteins, E1 and E2; and a membrane protein p7. The 5′ untranslated region and core gene are highly conserved among genotypes, but the envelope proteins are coded for by the hypervariable region, which varies from isolate to isolate and may allow the virus to evade host immunologic containment directed at accessible virus-envelope proteins. The 3′ end of the genome also includes an untranslated region and contains the genes for six nonstructural (NS) proteins NS2, NS3, NS4A, NS4B, NS5A, and NS5B. The NS2 cysteine protease cleaves NS3 from NS2, and the NS3-4A serine protease cleaves all the downstream proteins from the polyprotein. Important NS proteins

**FIGURE 92-6**

Organization of the hepatitis C virus genome and its associated, 3000-amino-acid (AA) proteins. The three structural genes at the 5' end are the core region, C, which codes for the nucleocapsid, and the envelope regions, E1 and E2, which code for envelope glycoproteins. The 5' untranslated region and the C region are highly conserved among isolates, while the envelope domain E2 contains the hypervariable region. Adjacent to the structural proteins is p7, a membrane protein

that appears to function as an ion channel. At the 3' end are six nonstructural (NS) regions, NS2, which codes for a cysteine protease; NS3, which codes for a serine protease and an RNA helicase; NS4 and NS4B; NS5A; and NS5B, which codes for an RNA-dependent RNA polymerase. After translation of the entire polyprotein, individual proteins are cleaved by both host and viral proteases.

involved in virus replication include the NS3 helicase, NS3-NS4A serine protease, and the NS5B RNA-dependent RNA polymerase (Fig. 92-6). Because HCV does not replicate via a DNA intermediate, it does not integrate into the host genome. Because HCV tends to circulate in relatively low titer, 10^3 – 10^7 virions/mL, visualization of virus particles, estimated to be 40–60 nm in diameter, remains difficult. Still, the replication rate of HCV is very high, 10^{12} virions per day; its half-life is 2.7 h. The chimpanzee is a helpful but cumbersome animal model. Although a robust, reproducible, small-animal model is lacking, HCV replication has been documented in an immunodeficient-mouse model containing explants of human liver and in transgenic mouse and rat models. Although in vitro replication has been difficult, hepatocellular carcinoma-derived cell lines have been described (replicon systems) that support replication of genetically manipulated, truncated or full-length HCV RNA (but not intact virions). Recently, complete replication of HCV and intact 55-nm virions has been described in cell culture systems. Preliminary data suggest that HCV gains entry into the hepatocyte via the CD81 receptor.

At least six distinct genotypes, as well as >50 subtypes within genotypes, of HCV have been identified by nucleotide sequencing. Genotypes differ one from another in sequence homology by $\geq 30\%$. Because divergence of HCV isolates within a genotype or subtype, and within the same host, may vary insufficiently to define a distinct genotype, these intragenotypic differences are referred to as *quasispecies* and differ in sequence homology by only a few percent. The genotypic and quasispecies diversity of HCV, resulting from its high mutation rate, interferes with effective humoral immunity. Neutralizing antibodies to HCV have been demonstrated, but they tend to be short-lived, and HCV infection does not induce lasting immunity against reinfection with different virus isolates or even the same virus isolate. Thus, neither *heterologous* nor *homologous* immunity appears to develop commonly after acute HCV infection. Some HCV genotypes are distributed

worldwide, while others are more geographically confined (see “Epidemiology and Global Features” later in the chapter). In addition, differences exist among genotypes in responsiveness to antiviral therapy; however, early reports of differences in pathogenicity among genotypes have not been corroborated.

Currently available, third-generation immunoassays, which incorporate proteins from the core, NS3, and NS5 regions, detect anti-HCV antibodies during acute infection. The most sensitive indicator of HCV infection is the presence of HCV RNA, which requires molecular amplification by PCR or transcription-mediated amplification (TMA) (Fig. 92-7). To allow standardization of the quantification of HCV RNA among laboratories and commercial assays, HCV RNA is reported as international units (IU) per milliliter; quantitative assays are available that allow detection of HCV RNA with a sensitivity as low as 5 IU/mL. HCV RNA can be detected within a few days of exposure to HCV, well before the appearance of anti-HCV, and tends to persist for the duration of HCV infection; however, occasionally in patients with chronic HCV infection, HCV RNA may

**FIGURE 92-7**

Scheme of typical laboratory features during acute hepatitis C progressing to chronicity. HCV RNA is the first detectable event, preceding ALT elevation and the appearance of anti-HCV.

be detectable only intermittently. Application of sensitive molecular probes for HCV RNA has revealed the presence of replicative HCV in peripheral blood lymphocytes of infected persons; however, as is the case for HBV in lymphocytes, the clinical relevance of HCV lymphocyte infection is not known.

Hepatitis E

Previously labeled *epidemic* or *enterically transmitted non-A, non-B hepatitis*, HEV is an enterically transmitted virus that occurs primarily in India, Asia, Africa, and Central America; in those geographic areas, HEV is the most common cause of acute hepatitis. This agent, with epidemiologic features resembling those of hepatitis A, is a 32- to 34-nm, nonenveloped, HAV-like virus with a 7600-nucleotide, single-strand, positive-sense RNA genome. HEV has three open reading frames (ORF) (genes), the largest of which, *ORF1*, encodes nonstructural proteins involved in virus replication. A middle-sized gene, *ORF2*, encodes the nucleocapsid protein, and the smallest, *ORF3*, encodes a structural protein whose function remains undetermined. All HEV isolates appear to belong to a single serotype, despite genomic heterogeneity of up to 25% and the existence of five genotypes, only four of which have been detected in humans; genotypes 1 and 2 appear to be more virulent, while genotypes 3 and 4 are more attenuated and account for subclinical infections. Contributing to the perpetuation of this virus are animal reservoirs, most notably in swine. There is no genomic or antigenic homology, however, between HEV and HAV or other picornaviruses; and HEV, although resembling caliciviruses, is sufficiently distinct from any known agent to merit a new classification of its own as a unique genus, *Hepevirus*, within the *Hepeviridae* family. The virus has been detected in stool, bile, and liver and is excreted in the stool during the late incubation period; immune responses to viral antigens occur very early during the course of acute infection. Both IgM anti-HEV and IgG anti-HEV can be detected, but both fall rapidly after acute infection, reaching low levels within 9–12 months. Currently, serologic testing for HEV infection is not available routinely.

PATHOGENESIS

Under ordinary circumstances, none of the hepatitis viruses is known to be directly cytopathic to hepatocytes. Evidence suggests that the clinical manifestations and outcomes after acute liver injury associated with viral hepatitis are determined by the immunologic responses of the host. Among the viral hepatitises, the immunopathogenesis of hepatitis B and C have been studied most extensively.

Hepatitis B

For HBV, the existence of inactive hepatitis B carriers with normal liver histology and function suggests that the virus is not directly cytopathic. The fact that patients with defects in cellular immune competence are more likely to

remain chronically infected rather than to clear HBV is cited to support the role of cellular immune responses in the pathogenesis of hepatitis B–related liver injury. The model that has the most experimental support involves cytolytic T cells sensitized specifically to recognize host and hepatitis B viral antigens on the liver cell surface. Laboratory observations suggest that nucleocapsid proteins (HBcAg and possibly HBeAg), present on the cell membrane in minute quantities, are the viral target antigens that, with host antigens, invite cytolytic T cells to destroy HBV-infected hepatocytes. Differences in the robustness of CD8+ cytolytic T-cell responsiveness and in the elaboration of antiviral cytokines by T cells have been invoked to explain differences in outcomes between those who recover after acute hepatitis and those who progress to chronic hepatitis or between those with mild and those with severe (fulminant) acute HBV infection.

Although a robust cytolytic T-cell response occurs and eliminates virus-infected liver cells during acute hepatitis B, >90% of HBV DNA has been found in experimentally infected chimpanzees to disappear from the liver and blood before maximal T-cell infiltration of the liver and before most of the biochemical and histologic evidence of liver injury. This observation suggests that components of the innate immune system and inflammatory cytokines, independent of cytopathic antiviral mechanisms, participate in the early immune response to HBV infection; this effect has been shown to represent elimination of HBV replicative intermediates from the cytoplasm and covalently closed circular viral DNA from the nucleus of infected hepatocytes. Ultimately, HBV-HLA-specific cytolytic T-cell responses of the adaptive immune system are felt to be responsible for recovery from HBV infection.

Debate continues over the relative importance of viral and host factors in the pathogenesis of HBV-associated liver injury and its outcome. As noted above, precore genetic mutants of HBV have been associated with the more severe outcomes of HBV infection (severe chronic and fulminant hepatitis), suggesting that, under certain circumstances, relative pathogenicity is a property of the virus, not the host. The fact that concomitant HDV and HBV infections are associated with more severe liver injury than HBV infection alone and the fact that cells transfected in vitro with the gene for HDV (delta) antigen express HDV antigen and then become necrotic in the absence of any immunologic influences are also consistent with a viral effect on pathogenicity. Similarly, in patients who undergo liver transplantation for end-stage chronic hepatitis B, occasionally, rapidly progressive liver injury appears in the new liver. This clinical pattern is associated with an unusual histologic pattern in the new liver, *fibrosing cholestatic hepatitis*, which, ultrastructurally, appears to represent a choking of the cell with overwhelming quantities of HBsAg. This observation suggests that under the influence of the potent immunosuppressive agents required to prevent allograft rejection, HBV may have a direct cytopathic effect on liver cells, independent of the immune system.

Although the precise mechanism of liver injury in HBV infection remains elusive, studies of nucleocapsid

proteins have shed light on the profound immunologic tolerance to HBV of babies born to mothers with highly replicative (HBeAg-positive), chronic HBV infection. In HBeAg-expressing transgenic mice, in utero exposure to HBeAg, which is sufficiently small to traverse the placenta, induces T cell tolerance to both nucleocapsid proteins. This, in turn, may explain why, when infection occurs so early in life, immunologic clearance does not occur, and protracted, lifelong infection ensues.

An important distinction should be drawn between HBV infection acquired at birth, common in endemic areas, such as the Far East, and infection acquired in adulthood, common in the west. Infection in the neonatal period is associated with the acquisition of immunologic tolerance to HBV, absence of an acute-hepatitis illness, but the almost invariable establishment of chronic, often lifelong infection. Neonatally acquired HBV infection can culminate decades later in cirrhosis and hepatocellular carcinoma (see “Complications and Sequelae” later in the chapter). In contrast, when HBV infection is acquired during adolescence or early adulthood, the host-immune response to HBV-infected hepatocytes tends to be robust, an acute hepatitis-like illness is the rule, and failure to recover is the exception. After adulthood-acquired infection, chronicity is uncommon, and the risk of hepatocellular carcinoma is very low. Based on these observations, some authorities categorize HBV infection into an “immunotolerant” phase, an “immunoreactive” phase, and an inactive phase. This somewhat simplistic formulation does not apply at all to the typical adult in the west with self-limited acute hepatitis B, in whom no period of immunologic tolerance occurs. Even among those with neonatally acquired HBV infection, in whom immunologic tolerance is established definitively, intermittent bursts of hepatic necroinflammatory activity punctuate the period during the early decades of life during which liver injury appears to be quiescent (labeled by some as the “immunotolerant” phase). In addition, even when clinically apparent liver injury and progressive fibrosis emerge during later decades (the so-called immunoreactive, or immunointolerant, phase), the level of immunologic tolerance to HBV remains substantial. More accurately, in patients with neonatally acquired HBV infection, a dynamic equilibrium exists between tolerance and intolerance, the outcome of which determines the clinical expression of chronic infection.

Hepatitis C

Cell-mediated immune responses and elaboration by T cells of antiviral cytokines contribute to the containment of infection and pathogenesis of liver injury associated with hepatitis C. Perhaps HCV infection of lymphoid cells plays a role in moderating immune responsiveness to the virus, as well. Intrahepatic HLA class I-restricted cytolytic T cells directed at nucleocapsid, envelope, and nonstructural viral protein antigens have been demonstrated in patients with chronic hepatitis C; however, such virus-specific cytolytic T cell responses do not correlate adequately with the degree of liver injury or with recovery. Yet, a consensus has emerged supporting a role in the

pathogenesis of HCV-associated liver injury of virus-activated CD4 helper T cells that stimulate, via the cytokines they elaborate, HCV-specific CD8 cytotoxic T cells. These responses appear to be more robust (higher in number, more diverse in viral antigen specificity, more functionally effective, and more long-lasting) in those who recover from HCV than in those who have chronic infection. Several HLA alleles have been linked with self-limited hepatitis C, but such associations do not apply universally. Attention has been focused as well on adaptive immunity; the establishment of persistent infection correlates with failure of adaptive immune responses to HCV. Furthermore, HCV proteins have been shown to interfere with innate immunity by resulting in blocking of type 1 interferon responses and inhibition of interferon signaling and effector molecules in the interferon signaling cascade. Also shown to contribute to limiting HCV infection are natural killer cells of the innate immune system, which function when HLA class 1 molecules required for successful adaptive immunity are underexpressed. Of note, the emergence of substantial viral quasispecies diversity allows the virus to evade attempts by the host to contain HCV infection immunologically.

Finally, cross-reactivity between viral antigens (HCV NS3 and NS5A) and host autoantigens (cytochrome P450 2D6) has been invoked to explain the association between hepatitis C and a subset of patients with autoimmune hepatitis and antibodies to liver-kidney microsomal (LKM) antigen (anti-LKM) (Chap. 93).

EXTRAHEPATIC MANIFESTATIONS

Immune complex-mediated tissue damage appears to play a pathogenetic role in the extrahepatic manifestations of acute hepatitis B. The occasional prodromal serum sickness-like syndrome observed in acute hepatitis B appears to be related to the deposition in tissue blood vessel walls of HBsAg-anti-HBs circulating immune complexes, leading to activation of the complement system and depressed serum complement levels.

In patients with chronic hepatitis B, other types of immune-complex disease may be seen. Glomerulonephritis with the nephritic syndrome is occasionally observed; HBsAg, immunoglobulin, and C3 deposition has been found in the glomerular basement membrane. While polyarteritis nodosa develops in considerably fewer than 1% of patients with chronic HBV infection, 20–30% of patients with polyarteritis nodosa have HBsAg in serum. In these patients, the affected small and medium-size arterioles have been shown to contain HBsAg, immunoglobulins, and complement components. Another extrahepatic manifestation of viral hepatitis, essential mixed cryoglobulinemia (EMC), was reported initially to be associated with hepatitis B. The disorder is characterized clinically by arthritis, cutaneous vasculitis (palpable purpura), and occasionally with glomerulonephritis and serologically by the presence of circulating cryoprecipitable immune complexes of more than one immunoglobulin class. Many patients with this syndrome have chronic liver disease, but the association with HBV infection is limited; instead, a substantial proportion has chronic HCV infection, with

circulating immune complexes containing HCV RNA. Immune-complex glomerulonephritis is another recognized extrahepatic manifestation of chronic hepatitis C.

PATHOLOGY

The typical morphologic lesions of all types of viral hepatitis are similar and consist of panlobular infiltration with mononuclear cells, hepatic cell necrosis, hyperplasia of Kupffer cells, and variable degrees of cholestasis. Hepatic cell regeneration is present, as evidenced by numerous mitotic figures, multinucleated cells, and “rosette” or “pseudocinar” formation. The mononuclear infiltration consists primarily of small lymphocytes, although plasma cells and eosinophils occasionally are present. Liver cell damage consists of hepatic cell degeneration and necrosis, cell dropout, ballooning of cells, and acidophilic degeneration of hepatocytes (forming so-called Councilman or apoptotic bodies). Large hepatocytes with a ground-glass appearance of the cytoplasm may be seen in chronic but not in acute HBV infection; these cells contain HBsAg and can be identified histochemically with orcein or aldehyde fuchsin. In uncomplicated viral hepatitis, the reticulin framework is preserved.

In hepatitis C, the histologic lesion is often remarkable for a relative paucity of inflammation, a marked increase in activation of sinusoidal lining cells, lymphoid aggregates, the presence of fat (more frequent in genotype 3 and linked to increased fibrosis), and, occasionally, bile duct lesions in which biliary epithelial cells appear to be piled up without interruption of the basement membrane. Occasionally, microvesicular steatosis occurs in hepatitis D. In hepatitis E, a common histologic feature is marked cholestasis. A cholestatic variant of slowly resolving acute hepatitis A also has been described.

A more severe histologic lesion, *bridging hepatic necrosis*, also termed *subacute* or *confluent necrosis* or *interface hepatitis*, is occasionally observed in some patients with acute hepatitis. “Bridging” between lobules results from large areas of hepatic cell dropout, with collapse of the reticulin framework. Characteristically, the bridge consists of condensed reticulum, inflammatory debris, and degenerating liver cells that span adjacent portal areas, portal to central veins, or central vein to central vein. This lesion had been thought to have prognostic significance; in many of the originally described patients with this lesion, a subacute course terminated in death within several weeks to months, or severe chronic hepatitis and postnecrotic cirrhosis developed. Subsequent investigations have failed to uphold the association between bridging necrosis and such a poor prognosis in patients with acute hepatitis. Therefore, although demonstration of this lesion in patients with chronic hepatitis has prognostic significance (Chap. 93), its demonstration during acute hepatitis is less meaningful, and liver biopsies to identify this lesion are no longer undertaken routinely in patients with acute hepatitis. In *massive hepatic necrosis* (fulminant hepatitis, “acute yellow atrophy”), the striking feature at post-mortem examination is the finding of a small, shrunken, soft liver. Histologic examination reveals massive necrosis and dropout of liver cells of most lobules with extensive

collapse and condensation of the reticulin framework. When histologic documentation is required in the management of fulminant or very severe hepatitis, a biopsy can be done by the angiographically guided transjugular route, which permits the performance of this invasive procedure in the presence of severe coagulopathy.

Immunohistochemical and electron-microscopic studies have localized HBsAg to the cytoplasm and plasma membrane of infected liver cells. In contrast, HBcAg predominates in the nucleus, but occasionally, scant amounts are also seen in the cytoplasm and on the cell membrane. HDV antigen is localized to the hepatocyte nucleus, while HAV, HCV, and HEV antigens are localized to the cytoplasm.

EPIDEMIOLOGY AND GLOBAL FEATURES

Before the availability of serologic tests for hepatitis viruses, all viral hepatitis cases were labeled either as “infectious” or “serum” hepatitis. Modes of transmission overlap, however, and *a clear distinction among the different types of viral hepatitis cannot be made solely on the basis of clinical or epidemiologic features (Table 92-2)*. The most accurate means to distinguish the various types of viral hepatitis involves specific serologic testing.

Hepatitis A

This agent is transmitted almost exclusively by the fecal-oral route. Person-to-person spread of HAV is enhanced by poor personal hygiene and overcrowding; large outbreaks as well as sporadic cases have been traced to contaminated food, water, milk, frozen raspberries and strawberries, green onions imported from Mexico, and shellfish. Intrafamily and intrainstitutional spread are also common. Early epidemiologic observations supported a predilection for hepatitis A to occur in late fall and early winter. In temperate zones, epidemic waves have been recorded every 5–20 years as new segments of nonimmune population appeared; however, in developed countries, the incidence of hepatitis A has been declining, presumably as a function of improved sanitation, and these cyclic patterns are no longer observed. No HAV carrier state has been identified after acute hepatitis A; perpetuation of the virus in nature depends presumably on nonepidemic, inapparent subclinical infection and/or contamination linked to environmental reservoirs.

In the general population, anti-HAV, a marker for previous HAV infection, increases in prevalence as a function of increasing age and of decreasing socioeconomic status. In the 1970s, serologic evidence of prior hepatitis A infection occurred in ~40% of urban populations in the United States, most of whose members never recalled having had a symptomatic case of hepatitis. In subsequent decades, however, the prevalence of anti-HAV has been declining in the United States. In developing countries, exposure, infection, and subsequent immunity are almost universal in childhood. As the frequency of subclinical childhood infections declines in developed countries, a susceptible cohort of adults emerges. Hepatitis A tends to

TABLE 92-2

CLINICAL AND EPIDEMIOLOGIC FEATURES OF VIRAL HEPATITIS

| FEATURE | HAV | HBV | HCV | HDV | HEV |
|---------------------------|---------------------------|--|-------------------------------------|-------------------------------------|----------------------------|
| Incubation (days) | 15–45, mean 30 | 30–180, mean 60–90 | 15–160, mean 50 | 30–180, mean 60–90 | 14–60, mean 40 |
| Onset | Acute | Insidious or acute | Insidious | Insidious or acute | Acute |
| Age preference | Children, young adults | Young adults (sexual and percutaneous), babies, toddlers | Any age, but more common in adults | Any age (similar to HBV) | Young adults (20–40 years) |
| Transmission | | | | | |
| Fecal-oral | +++ | – | – | – | +++ |
| Percutaneous | Unusual | +++ | +++ | +++ | – |
| Perinatal | – | +++ | ± ^a | + | – |
| Sexual | ± | ++ | ± ^a | ++ | – |
| Clinical | | | | | |
| Severity | Mild | Occasionally severe | Moderate | Occasionally severe | Mild |
| Fulminant | 0.1% | 0.1–1% | 0.1% | 5–20% ^b | 1–2% ^e |
| Progression to chronicity | None | Occasional (1–10%) (90% of neonates) | Common (85%) | Common ^d | None |
| Carrier | None | 0.1–30% ^c | 1.5–3.2% | Variable ^f | None |
| Cancer | None | + (neonatal infection) | + | ± | None |
| Prognosis | Excellent | Worse with age, debility | Moderate | Acute, good Chronic, poor | Good |

| Therapy | None | Interferon Lamivudine Adefovir Pegylated interferon Entecavir Telbivudine | Pegylated interferon plus ribavirin | Interferon ± | None |

^aPrimarily with HIV co-infection and high-level viremia in index case; risk 5%.

^bUp to 5% in acute HBV/HDV co-infection; up to 20% in HDV superinfection of chronic HBV infection.

^cVaries considerably throughout the world and in subpopulations within countries; see text.

^dIn acute HBV/HDV co-infection, the frequency of chronicity is the same as that for HBV; in HDV superinfection, chronicity is invariable.

^e10–20% in pregnant women.

^fCommon in Mediterranean countries, rare in North America and western Europe.

be more symptomatic in adults; therefore, paradoxically, as the frequency of HAV infection declines, the likelihood of clinically apparent, even severe, HAV illnesses increases in the susceptible adult population. Travel to endemic areas is a common source of infection for adults from nonendemic areas. More recently recognized epidemiologic foci of HAV infection include child-care centers, neonatal intensive care units, promiscuous men who have sex with men, and injection drug users. Although hepatitis A is rarely bloodborne, several outbreaks have been recognized in recipients of clotting factor concentrates. In the United States, the introduction of hepatitis A vaccination programs among children from high-incidence states has resulted in a >70% reduction in the annual incidence of new HAV infections and has shifted the burden of new infections from children to young adults.

Hepatitis B

Percutaneous inoculation has long been recognized as a major route of hepatitis B transmission, but the outmoded

designation “serum hepatitis” is an inaccurate label for the epidemiologic spectrum of HBV infection recognized today. As detailed below, most of the hepatitis transmitted by blood transfusion is not caused by HBV; moreover, in approximately two-thirds of patients with acute type B hepatitis, no history of an identifiable percutaneous exposure can be elicited. We now recognize that many cases of hepatitis B result from less obvious modes of nonpercutaneous or covert percutaneous transmission. HBsAg has been identified in almost every body fluid from infected persons, and at least some of these body fluids—most notably semen and saliva—are infectious, albeit less so than serum, when administered percutaneously or nonpercutaneously to experimental animals. Among the nonpercutaneous modes of HBV transmission, oral ingestion has been documented as a potential but inefficient route of exposure. By contrast, the two nonpercutaneous routes considered to have the greatest impact are intimate (especially sexual) contact and perinatal transmission.

In Sub-Saharan Africa, intimate contact among toddlers is considered instrumental in contributing to the

maintenance of the high frequency of hepatitis B in the population. Perinatal transmission occurs primarily in infants born to HBsAg carrier mothers or mothers with acute hepatitis B during the third trimester of pregnancy or during the early postpartum period. Perinatal transmission is uncommon in North America and western Europe but occurs with great frequency and is the most important mode of HBV perpetuation in the Far East and developing countries. Although the precise mode of perinatal transmission is unknown, and although ~10% of infections may be acquired in utero, epidemiologic evidence suggests that most infections occur approximately at the time of delivery and are not related to breast feeding. The likelihood of perinatal transmission of HBV correlates with the presence of HBeAg; 90% of HBeAg-positive mothers but only 10–15% of anti-HBe-positive mothers transmit HBV infection to their offspring. In most cases, acute infection in the neonate is clinically asymptomatic, but the child is very likely to become an HBsAg carrier.

The >350 million HBsAg carriers in the world constitute the main reservoir of hepatitis B in human beings. Serum HBsAg is infrequent (0.1–0.5%) in normal populations in the United States and western Europe. However, a prevalence of up to 5–20% has been found in the Far East and in some tropical countries; in persons with Down's syndrome, lepromatous leprosy, leukemia, Hodgkin's disease, polyarteritis nodosa; in patients with chronic renal disease on hemodialysis; and in injection drug users.

Other groups with high rates of HBV infection include spouses of acutely infected persons, sexually promiscuous persons (especially promiscuous men who have sex with men), health care workers exposed to blood, persons who require repeated transfusions especially with pooled blood product concentrates (e.g., hemophiliacs), residents and staff of custodial institutions for the developmentally handicapped, prisoners, and, to a lesser extent, family members of chronically infected patients. In volunteer blood donors, the prevalence of anti-HBs, a reflection of previous HBV infection, ranges from 5–10%, but the prevalence is higher in lower socioeconomic strata, older age groups, and persons—including those mentioned above—exposed to blood products. Because of highly sensitive virologic screening of donor blood, the risk of acquiring HBV infection from a blood transfusion is 1 in 230,000.

Prevalence of infection, modes of transmission, and human behavior conspire to mold geographically different epidemiologic patterns of HBV infection. In the Far East and Africa, hepatitis B, a disease of the newborn and young children, is perpetuated by a cycle of maternal-neonatal spread. In North America and western Europe, hepatitis B is primarily a disease of adolescence and early adulthood, the time of life when intimate sexual contact as well as recreational and occupational percutaneous exposures tend to occur. The introduction of hepatitis B vaccine in the early 1980s and adoption of universal childhood vaccination policies in many countries resulted in a dramatic, ~90%, decline in the incidence of new HBV infections in those countries as well as in the dire consequences of chronic infection.

Hepatitis D

Infection with HDV has a worldwide distribution, but two epidemiologic patterns exist. In Mediterranean countries (northern Africa, southern Europe, the Middle East), HDV infection is endemic among those with hepatitis B, and the disease is transmitted predominantly by nonpercutaneous means, especially close personal contact. In nonendemic areas, such as the United States and northern Europe, HDV infection is confined to persons exposed frequently to blood and blood products, primarily injection drug users and hemophiliacs. HDV infection can be introduced into a population through drug users or by migration of persons from endemic to nonendemic areas. Thus, patterns of population migration and human behavior facilitating percutaneous contact play important roles in the introduction and amplification of HDV infection. Occasionally, the migrating epidemiology of hepatitis D is expressed in explosive outbreaks of severe hepatitis, such as those that have occurred in remote South American villages as well as in urban centers in the United States. Ultimately, such outbreaks of hepatitis D—either of co-infections with acute hepatitis B or of superinfections in those already infected with HBV—may blur the distinctions between endemic and nonendemic areas. On a global scale, HDV infection is declining. Even in Italy, an HDV-endemic area, public health measures introduced to control HBV infection resulted during the 1990s in a 1.5%/year reduction in the prevalence of HDV infection.

Hepatitis C

Routine screening of blood donors for HBsAg and the elimination of commercial blood sources in the early 1970s reduced the frequency of, but did not eliminate, transfusion-associated hepatitis. During the 1970s, the likelihood of acquiring hepatitis after transfusion of voluntarily donated, HBsAg-screened blood was ~10% per patient (up to 0.9% per unit transfused); 90–95% of these cases were classified, based on serologic exclusion of hepatitis A and B, as “non-A, non-B” hepatitis. For patients requiring transfusion of pooled products, such as clotting factor concentrates, the risk was even higher, up to 20–30%.

During the 1980s, voluntary self-exclusion of blood donors with risk factors for AIDS and then the introduction of donor screening for anti-HIV reduced further the likelihood of transfusion-associated hepatitis to <5%. During the late 1980s and early 1990s, the introduction first of “surrogate” screening tests for non-A, non-B hepatitis [alanine aminotransferase (ALT) and anti-HBc, both shown to identify blood donors with a higher likelihood of transmitting non-A, non-B hepatitis to recipients] and, subsequently, after the discovery of HCV, first-generation immunoassays for anti-HCV reduced the frequency of transfusion-associated hepatitis even further. A prospective analysis of transfusion-associated hepatitis conducted between 1986 and 1990 showed that the incidence of transfusion-associated hepatitis at one urban university hospital fell from a baseline of 3.8% per patient (0.45% per unit transfused) to 1.5% per patient (0.19% per unit) after the introduction of surrogate testing and

to 0.6% per patient (0.03% per unit) after the introduction of first-generation anti-HCV assays. The introduction of second-generation anti-HCV assays reduced the frequency of transfusion-associated hepatitis C to almost imperceptible levels, 1 in 100,000, and these gains were reinforced by the application of automated PCR testing of donated blood for HCV RNA, which has resulted in a reduction in the risk of transfusion-associated HCV infection to 1 in 2.3 million transfusions.

In addition to being transmitted by transfusion, hepatitis C can be transmitted by other percutaneous routes, such as injection drug use. In addition, this virus can be transmitted by occupational exposure to blood, and the likelihood of infection is increased in hemodialysis units. Although the frequency of transfusion-associated hepatitis C fell as a result of blood donor screening, the overall frequency of hepatitis C remained the same until the early 1990s, when the overall frequency fell by 80%, in parallel with a reduction in the number of new cases in injection drug users. After the exclusion of anti-HCV-positive plasma units from the donor pool, rare, sporadic instances have occurred of hepatitis C among recipients of immunoglobulin (IG) preparations for intravenous (but not intramuscular) use.

Serologic evidence for HCV infection occurs in 90% of patients with a history of transfusion-associated hepatitis (almost all occurring before 1992, when second-generation HCV-screening tests were introduced); hemophiliacs and others treated with clotting factors; injection drug users; 60–70% of patients with sporadic “non-A, non-B” hepatitis who lack identifiable risk factors; 0.5% of volunteer blood donors; and, in the most recent survey conducted in the United States between 1999 and 2000, 1.6% of the general population in the United States, which translates into 4.1 million persons (3.2 million with viremia). Comparable frequencies of HCV infection occur in most countries around the world, with 170 million persons infected worldwide, but extraordinarily high prevalences of HCV infection occur in certain countries, such as Egypt, where >20% of the population in some cities is infected. The high frequency in Egypt is attributable to contaminated equipment used for medical procedures and unsafe injection practices. In the United States, African Americans and Mexican Americans have higher frequencies of HCV infection than whites. Between 1988 and 1994, 30- to 40-year-old adult males had the highest prevalence of HCV infection; however, in a survey conducted between 1999 and 2000, the peak age decile had shifted to those age 40–49 years. Thus, despite an 80% reduction in new HCV infections during the 1990s, the prevalence of HCV infection in the population was sustained by an aging cohort that had acquired their infections two to three decades earlier, during the 1960s and 1970s, as a result predominantly of self inoculation with recreational drugs. Hepatitis C accounts for 40% of chronic liver disease, is the most frequent indication for liver transplantation, and is estimated to account for 8000–10,000 deaths per year in the United States.

The distribution of HCV genotypes varies in different parts of the world. Worldwide, genotype 1 is the most

common. In the United States, genotype 1 accounts for 70% of HCV infections, while genotypes 2 and 3 account for the remaining 30%; among African Americans, the frequency of genotype 1 is even higher, i.e., 90%. Genotype 4 predominates in Egypt; genotype 5 is localized to South Africa and genotype 6 to Hong Kong.

Most asymptomatic blood donors found to have anti-HCV and ~20–30% of persons with reported cases of acute hepatitis C do not fall into a recognized risk group; however, many such blood donors do recall risk-associated behaviors when questioned carefully.

As a bloodborne infection, HCV potentially can be transmitted sexually and perinatally; however, both of these modes of transmission are inefficient for hepatitis C. Although 10–15% of patients with acute hepatitis C report having potential sexual sources of infection, most studies have failed to identify sexual transmission of this agent. The chances of sexual and perinatal transmission have been estimated to be ~5%, well below comparable rates for HIV and HBV infections. Moreover, sexual transmission appears to be confined to such subgroups as persons with multiple sexual partners and sexually transmitted diseases; transmission of HCV infection is rare between stable, monogamous sexual partners. Breast feeding does not increase the risk of HCV infection between an infected mother and her infant. Infection of health workers is not dramatically higher than among the general population; however, health workers are more likely to acquire HCV infection through accidental needle punctures, the efficiency of which is ~3%. Infection of household contacts is rare as well.

Other groups with an increased frequency of HCV infection include patients who require hemodialysis and organ transplantation and those who require transfusions in the setting of cancer chemotherapy. In immunosuppressed individuals, levels of anti-HCV may be undetectable, and a diagnosis may require testing for HCV RNA. Although new acute cases of hepatitis C are rare, newly diagnosed cases are common among otherwise healthy persons who experimented briefly with injection drugs, as noted above, two or three decades earlier. Such instances usually remain unrecognized for years, until unearthed by laboratory screening for routine medical examinations, insurance applications, and attempted blood donation.

Hepatitis E

This type of hepatitis, identified in India, Asia, Africa, the Middle East, and Central America, resembles hepatitis A in its primarily enteric mode of spread. The commonly recognized cases occur after contamination of water supplies such as after monsoon flooding, but sporadic, isolated cases occur. An epidemiologic feature that distinguishes HEV from other enteric agents is the rarity of secondary person-to-person spread from infected persons to their close contacts. Infections arise in populations that are immune to HAV and favor young adults. In endemic areas, the prevalence of antibodies to HEV is ≤40%. In nonendemic areas of the world, such as the United States, clinically apparent acute hepatitis E is extremely rare; however, the prevalence of antibodies to HEV can be as high

as 20% in such areas. In nonendemic areas, HEV does not account for any of the sporadic “non-A, non-B” cases of hepatitis; however, cases imported from endemic areas have been found in the United States. Several reports suggest a zoonotic reservoir for HEV in swine.

CLINICAL AND LABORATORY FEATURES

Symptoms and Signs

Acute viral hepatitis occurs after an incubation period that varies according to the responsible agent. Generally, incubation periods for hepatitis A range from 15–45 days (mean, 4 weeks), for hepatitis B and D from 30–180 days (mean, 8–12 weeks), for hepatitis C from 15–160 days (mean, 7 weeks), and for hepatitis E from 14–60 days (mean, 5–6 weeks). The *prodromal symptoms* of acute viral hepatitis are systemic and quite variable. Constitutional symptoms of anorexia, nausea and vomiting, fatigue, malaise, arthralgias, myalgias, headache, photophobia, pharyngitis, cough, and coryza may precede the onset of jaundice by 1–2 weeks. The nausea, vomiting, and anorexia are frequently associated with alterations in olfaction and taste. A low-grade fever between 38° and 39°C (100°–102°F) is more often present in hepatitis A and E than in hepatitis B or C, except when hepatitis B is heralded by a serum sickness–like syndrome; rarely, a fever of 39.5°–40°C (103°–104°F) may accompany the constitutional symptoms. Dark urine and clay-colored stools may be noticed by the patient from 1–5 days before the onset of clinical jaundice.

With the onset of *clinical jaundice*, the constitutional prodromal symptoms usually diminish, but in some patients mild weight loss (2.5–5 kg) is common and may continue during the entire icteric phase. The liver becomes enlarged and tender and may be associated with right upper quadrant pain and discomfort. Infrequently, patients present with a cholestatic picture, suggesting extrahepatic biliary obstruction. Splenomegaly and cervical adenopathy are present in 10–20% of patients with acute hepatitis. Rarely, a few spider angiomas appear during the icteric phase and disappear during convalescence. During the *recovery phase*, constitutional symptoms disappear, but usually some liver enlargement and abnormalities in liver biochemical tests are still evident. The duration of the posticteric phase is variable, ranging 2–12 weeks, and is usually more prolonged in acute hepatitis B and C. Complete clinical and biochemical recovery is to be expected 1–2 months after all cases of hepatitis A and E and 3–4 months after the onset of jaundice in three-quarters of uncomplicated, self-limited cases of hepatitis B and C (among healthy adults, acute hepatitis B is self-limited in 95–99% while hepatitis C is self-limited in only ~15%). In the remainder, biochemical recovery may be delayed. A substantial proportion of patients with viral hepatitis never become icteric.

Infection with HDV can occur in the presence of acute or chronic HBV infection; the duration of HBV infection determines the duration of HDV infection. When acute HDV and HBV infection occur simultaneously, clinical and biochemical features may be indistinguishable from those of HBV infection alone, although occasionally they are more severe. As opposed to patients with *acute* HBV

infection, patients with *chronic* HBV infection can support HDV replication indefinitely. This can happen when acute HDV infection occurs in the presence of a nonresolving acute HBV infection. More commonly, acute HDV infection becomes chronic when it is superimposed on an underlying chronic HBV infection. In such cases, the HDV superinfection appears as a clinical exacerbation or an episode resembling acute viral hepatitis in someone already chronically infected with HBV. Superinfection with HDV in a patient with chronic hepatitis B often leads to clinical deterioration (see below).

In addition to superinfections with other hepatitis agents, acute hepatitis–like clinical events in persons with chronic hepatitis B may accompany spontaneous HBeAg–to–anti–HBe seroconversion or spontaneous reactivation, i.e., reversion from nonreplicative to replicative infection. Such reactivations can occur as well in therapeutically immunosuppressed patients with chronic HBV infection when cytotoxic/immunosuppressive drugs are withdrawn; in these cases, restoration of immune competence is thought to allow resumption of previously checked cell-mediated immune cytolysis of HBV-infected hepatocytes. Occasionally, acute clinical exacerbations of chronic hepatitis B may represent the emergence of a pre-core mutant (see “Virology and Etiology” near the start of the chapter), and the subsequent course in such patients may be characterized by periodic exacerbations.

Laboratory Features

The serum aminotransferases aspartate aminotransferase (AST) and ALT (previously designated SGOT and SGPT) show a variable increase during the prodromal phase of acute viral hepatitis and precede the rise in bilirubin level (Figs. 92–2 and 92–4). The acute level of these enzymes, however, does not correlate well with the degree of liver cell damage. Peak levels vary from 400–4000 IU or more; these levels are usually reached at the time the patient is clinically icteric and diminish progressively during the recovery phase of acute hepatitis. The diagnosis of anicteric hepatitis is based on clinical features and on aminotransferase elevations.

Jaundice is usually visible in the sclera or skin when the serum bilirubin value is >43 μmol/L (2.5 mg/dL). When jaundice appears, the serum bilirubin typically rises to levels ranging from 85–340 μmol/L (5–20 mg/dL). The serum bilirubin may continue to rise despite falling serum aminotransferase levels. In most instances, the total bilirubin is equally divided between the conjugated and unconjugated fractions. Bilirubin levels >340 μmol/L (20 mg/dL) extending and persisting late into the course of viral hepatitis are more likely to be associated with severe disease. In certain patients with underlying hemolytic anemia, however, such as glucose-6-phosphate dehydrogenase deficiency and sickle cell anemia, a high serum bilirubin level is common, resulting from superimposed hemolysis. In such patients, bilirubin levels >513 μmol/L (30 mg/dL) have been observed and are not necessarily associated with a poor prognosis.

Neutropenia and lymphopenia are transient and are followed by a relative lymphocytosis. Atypical lymphocytes

(varying between 2 and 20%) are common during the acute phase. Measurement of the prothrombin time (PT) is important in patients with acute viral hepatitis, for a prolonged value may reflect a severe hepatic synthetic defect, signify extensive hepatocellular necrosis, and indicate a worse prognosis. Occasionally, a prolonged PT may occur with only mild increases in the serum bilirubin and aminotransferase levels. Prolonged nausea and vomiting, inadequate carbohydrate intake, and poor hepatic glycogen reserves may contribute to hypoglycemia noted occasionally in patients with severe viral hepatitis. Serum alkaline phosphatase may be normal or only mildly elevated, while a fall in serum albumin is uncommon in uncomplicated acute viral hepatitis. In some patients, mild and transient steatorrhea has been noted as well as slight microscopic hematuria and minimal proteinuria.

A diffuse but mild elevation of the γ globulin fraction is common during acute viral hepatitis. Serum IgG and IgM levels are elevated in about one-third of patients during the acute phase of viral hepatitis, but the serum IgM level is elevated more characteristically during acute hepatitis A. During the acute phase of viral hepatitis, antibodies to smooth muscle and other cell constituents may be present, and low titers of rheumatoid factor, nuclear antibody, and heterophil antibody can also be found occasionally. In hepatitis C and D, antibodies to LKM may occur; however, the species of LKM antibodies in the two types of hepatitis are different from each other as well as from the LKM antibody species characteristic of autoimmune hepatitis type 2 (Chap. 93). The autoantibodies in viral hepatitis are nonspecific and can also be associated with other viral and systemic diseases. In contrast, virus-specific antibodies, which appear during and after hepatitis virus infection, are serologic markers of diagnostic importance.

As described above, serologic tests are available with which to establish a diagnosis of hepatitis A, B, D, and C. Tests for fecal or serum HAV are not routinely available. Therefore, a diagnosis of hepatitis A is based on detection of IgM anti-HAV during acute illness (Fig. 92-2). Rheumatoid factor can give rise to false-positive results in this test.

A diagnosis of HBV infection can usually be made by detection of HBsAg in serum. Infrequently, levels of HBsAg are too low to be detected during acute HBV infection, even with contemporary, highly sensitive immunoassays. In such cases, the diagnosis can be established by the presence of IgM anti-HBc.

The titer of HBsAg bears little relation to the severity of clinical disease. Indeed, an inverse correlation exists between the serum concentration of HBsAg and the degree of liver cell damage. For example, titers are highest in immunosuppressed patients, lower in patients with chronic liver disease (but higher in mild chronic than in severe chronic hepatitis), and very low in patients with acute fulminant hepatitis. These observations suggest that, in hepatitis B, the degree of liver cell damage and the clinical course are related to variations in the patient's immune response to HBV rather than to the amount of circulating HBsAg. In immunocompetent persons, however, there is a correlation between markers of HBV replication and liver injury (see below).

Another serologic marker that may be of value in patients with hepatitis B is HBeAg. Its principal clinical usefulness is as an indicator of relative infectivity. Because HBeAg is invariably present during early acute hepatitis B, HBeAg testing is indicated primarily during follow-up of chronic infection.

In patients with hepatitis B surface antigenemia of unknown duration, e.g., blood donors found to be HBsAg-positive and referred to a physician for evaluation, testing for IgM anti-HBc may be useful to distinguish between acute or recent infection (IgM anti-HBc-positive) and chronic HBV infection (IgM anti-HBc-negative, IgG anti-HBc-positive). A false-positive test for IgM anti-HBc may be encountered in patients with high-titer rheumatoid factor.

Anti-HBs is rarely detectable in the presence of HBsAg in patients with *acute* hepatitis B, but 10–20% of persons with *chronic* HBV infection may harbor low-level anti-HBs. This antibody is directed not against the common group determinant, *a*, but against the heterotypic subtype determinant (e.g., HBsAg of subtype *ad* with anti-HBs of subtype γ). In most cases, this serologic pattern cannot be attributed to infection with two different HBV subtypes, and the presence of this antibody is not a harbinger of imminent HBsAg clearance. When such antibody is detected, its presence is of no recognized clinical significance (see “Virology and Etiology” earlier in the chapter).

After immunization with hepatitis B vaccine, which consists of HBsAg alone, anti-HBs is the only serologic marker to appear. The commonly encountered serologic patterns of hepatitis B and their interpretations are summarized in Table 92-3. Tests for the detection of HBV DNA in liver and serum are now available. Like HBeAg, serum HBV DNA is an indicator of HBV replication, but tests for HBV DNA are more sensitive and quantitative. First-generation hybridization assays for HBV DNA had a sensitivity of 10^5 – 10^6 virions/mL, a relative threshold below which infectivity and liver injury are limited and HBeAg is usually undetectable. Currently, testing for HBV DNA has shifted from insensitive hybridization assays to amplification assays, e.g., the PCR-based assay, which can detect as few as 10 or 100 virions/mL; among the commercially available PCR assays, the most useful are those with the highest sensitivity (5–10 IU/mL) and the largest dynamic range (10^0 – 10^9 IU/mL). With increased sensitivity, amplification assays remain reactive well below the threshold for infectivity and liver injury. These markers are useful in following the course of HBV replication in patients with chronic hepatitis B receiving antiviral chemotherapy, e.g., with interferon or nucleoside analogues (Chap. 93). In immunocompetent persons, a general correlation does appear to exist between the level of HBV replication, as reflected by the level of HBV DNA in serum, and the degree of liver injury. High serum HBV DNA levels, increased expression of viral antigens, and necroinflammatory activity in the liver go hand in hand unless immunosuppression interferes with cytolytic T cell responses to virus-infected cells; reduction of HBV replication with antiviral drugs tends to be

TABLE 92-3

COMMONLY ENCOUNTERED SEROLOGIC PATTERNS OF HEPATITIS B INFECTION

| HBsAg | ANTI-HBs | ANTI-HBc | HBeAg | ANTI-HBe | INTERPRETATION |
|-------|----------|----------|-------|----------|---|
| + | — | IgM | + | — | Acute hepatitis B, high infectivity |
| + | — | IgG | + | — | Chronic hepatitis B, high infectivity |
| + | — | IgG | — | + | 1. Late acute or chronic hepatitis B, low infectivity 2. HBeAg-negative (“precore-mutant”) hepatitis B (chronic or, rarely, acute) |
| + | + | + | +/- | +/- | 1. HBsAg of one subtype and heterotypic anti-HBs (common) 2. Process of seroconversion from HBsAg to anti-HBs (rare) |
| — | — | IgM | +/- | +/- | 1. Acute hepatitis B 2. Anti-HBc “window” |
| — | — | IgG | — | +/- | 1. Low-level hepatitis B carrier 2. Hepatitis B in remote past |
| — | + | IgG | — | +/- | Recovery from hepatitis B |
| — | + | — | — | — | 1. Immunization with HBsAg (after vaccination) 2. Hepatitis B in the remote past (?) 3. False-positive |

accompanied by an improvement in liver histology. Among patients with chronic hepatitis B, high levels of HBV DNA increase the risk of cirrhosis, hepatic decompensation, and hepatocellular carcinoma (see “Complications and Sequelae” later in the chapter).

In patients with hepatitis C, an episodic pattern of aminotransferase elevation is common. A specific serologic diagnosis of hepatitis C can be made by demonstrating the presence in serum of anti-HCV. When contemporary immunoassays are used, anti-HCV can be detected in acute hepatitis C during the initial phase of elevated aminotransferase activity. This antibody may never become detectable in 5–10% of patients with acute hepatitis C, and levels of anti-HCV may become undetectable after recovery (albeit rare) from acute hepatitis C. In patients with chronic hepatitis C, anti-HCV is detectable in >95% of cases. Nonspecificity can confound immunoassays for anti-HCV, especially in persons with a low prior probability of infection, such as volunteer blood donors, or in persons with circulating rheumatoid factor, which can bind nonspecifically to assay reagents; testing for HCV RNA can be used in such settings to distinguish between true-positive and false-positive anti-HCV determinations. Assays for HCV RNA are the most sensitive tests for HCV infection and represent the “gold standard” in establishing a diagnosis of hepatitis C. HCV RNA can be detected even before acute elevation of aminotransferase activity and before the appearance of anti-HCV in patients with acute hepatitis C. In addition, HCV RNA remains detectable indefinitely, continuously in most but intermittently in some, in patients with chronic hepatitis C (detectable as well in some persons with normal liver tests, i.e., inactive carriers). In the small minority of patients with hepatitis C who lack anti-HCV, a diagnosis can be supported by detection of HCV RNA. If all these tests are negative and the patient has a well-characterized case of

hepatitis after percutaneous exposure to blood or blood products, a diagnosis of hepatitis caused by another agent, as yet unidentified, can be entertained.

Amplification techniques are required to detect HCV RNA, and two types are available. One is a branched-chain complementary DNA (bDNA) assay, in which the detection signal (a colorimetrically detectable enzyme bound to a complementary DNA probe) is amplified. The other involves target amplification, i.e., synthesis of multiple copies of the viral genome. This can be done by PCR or TMA, in which the viral RNA is reverse transcribed to complementary DNA and then amplified by repeated cycles of DNA synthesis. Both can be used as quantitative assays and a measurement of relative “viral load”; PCR and TMA, with a sensitivity of 10–10² IU/mL, are more sensitive than bDNA, with a sensitivity of 10³ IU/mL; assays are available with a wide dynamic range (10–10⁷ IU/mL). Determination of HCV RNA level is not a reliable marker of disease severity or prognosis but is helpful in predicting relative responsiveness to antiviral therapy. The same is true for determinations of HCV genotype (Chap. 93).

A proportion of patients with hepatitis C have isolated anti-HBc in their blood, a reflection of a common risk in certain populations of exposure to multiple bloodborne hepatitis agents. The anti-HBc in such cases is almost invariably of the IgG class and usually represents HBV infection in the remote past (HBV DNA undetectable), rarely current HBV infection with low-level virus carriage.

The presence of HDV infection can be identified by demonstrating intrahepatic HDV antigen or, more practically, an anti-HDV seroconversion (a rise in titer of anti-HDV or de novo appearance of anti-HDV). Circulating HDV antigen, also diagnostic of acute infection, is detectable only briefly, if at all. Because anti-HDV is often undetectable once HBsAg disappears, retrospective

serodiagnosis of acute self-limited, simultaneous HBV and HDV infection is difficult. Early diagnosis of acute infection may be hampered by a delay of up to 30–40 days in the appearance of anti-HDV.

When a patient presents with acute hepatitis and has HBsAg and anti-HDV in serum, determination of the class of anti-HBc is helpful in establishing the relationship between infection with HBV and HDV. Although IgM anti-HBc does not distinguish *absolutely* between acute and chronic HBV infection, its presence is a reliable indicator of recent infection and its absence a reliable indicator of infection in the remote past. In simultaneous acute HBV and HDV infections, IgM anti-HBc will be detectable, while in acute HDV infection superimposed on chronic HBV infection, anti-HBc will be of the IgG class.

Tests for the presence of HDV RNA are useful for determining the presence of ongoing HDV replication and relative infectivity. Diagnostic tests for hepatitis E are commercially available in several countries outside the United States; in the United States, diagnostic assays can be performed at the Centers for Disease Control and Prevention.

Liver biopsy is rarely necessary or indicated in acute viral hepatitis, except when the diagnosis is questionable or when clinical evidence suggests a diagnosis of chronic hepatitis.

A diagnostic algorithm can be applied in the evaluation of cases of acute viral hepatitis. A patient with acute hepatitis should undergo four serologic tests: HBsAg, IgM anti-HAV, IgM anti-HBc, and anti-HCV (Table 92-4). The presence of HBsAg, with or without IgM anti-HBc, represents HBV infection. If IgM anti-HBc is present, the HBV infection is considered acute; if IgM anti-HBc is absent, the HBV infection is considered chronic. A diagnosis

of acute hepatitis B can be made in the absence of HBsAg when IgM anti-HBc is detectable. A diagnosis of acute hepatitis A is based on the presence of IgM anti-HAV. If IgM anti-HAV coexists with HBsAg, a diagnosis of simultaneous HAV and HBV infections can be made; if IgM anti-HBc (with or without HBsAg) is detectable, the patient has simultaneous acute hepatitis A and B, and if IgM anti-HBc is undetectable, the patient has acute hepatitis A superimposed on chronic HBV infection. The presence of anti-HCV supports a diagnosis of acute hepatitis C. Occasionally, testing for HCV RNA or repeat anti-HCV testing later during the illness is necessary to establish the diagnosis. Absence of all serologic markers is consistent with a diagnosis of “non-A, non-B, non-C” hepatitis, if the epidemiologic setting is appropriate.

In patients with chronic hepatitis, initial testing should consist of HBsAg and anti-HCV. Anti-HCV supports and HCV RNA testing establishes the diagnosis of chronic hepatitis C. If a serologic diagnosis of chronic hepatitis B is made, testing for HBeAg and anti-HBe is indicated to evaluate relative infectivity. Testing for HBV DNA in such patients provides a more quantitative and sensitive measure of the level of virus replication and, therefore, is very helpful during antiviral therapy (Chap. 93). In patients with chronic hepatitis B and normal aminotransferase activity in the absence of HBeAg, serial testing over time is often required to distinguish between inactive carriage and HBeAg-negative chronic hepatitis B with fluctuating virologic and necroinflammatory activity. In patients with hepatitis B, testing for anti-HDV is useful under the following circumstances: patients with severe and fulminant disease, patients with severe chronic disease, patients with chronic hepatitis B who have acute hepatitis-like exacerbations, persons with frequent percutaneous exposures, and persons from areas where HDV infection is endemic.

TABLE 92-4

SIMPLIFIED DIAGNOSTIC APPROACH IN PATIENTS PRESENTING WITH ACUTE HEPATITIS

SEROLOGIC TESTS OF PATIENT'S SERUM

| + | – | – | – | Chronic hepatitis B |
| + | + | – | – | Acute hepatitis A superimposed on chronic hepatitis B |
| + | + | + | – | Acute hepatitis A and B |
| – | + | – | – | Acute hepatitis A |
| – | + | + | – | Acute hepatitis A and B (HBsAg below detection threshold) |
| – | – | + | – | Acute hepatitis B (HBsAg below detection threshold) |
| – | – | – | + | Acute hepatitis C |

PROGNOSIS

Virtually all previously healthy patients with hepatitis A recover completely from their illness with no clinical sequelae. Similarly, in acute hepatitis B, 95–99% of previously healthy adults have a favorable course and recover completely. Certain clinical and laboratory features, however, suggest a more complicated and protracted course. Patients of advanced age and with serious underlying medical disorders may have a prolonged course and are more likely to experience severe hepatitis. Initial presenting features such as ascites, peripheral edema, and symptoms of hepatic encephalopathy suggest a poorer prognosis. In addition, a prolonged PT, low serum albumin level, hypoglycemia, and very high serum bilirubin values suggest severe hepatocellular disease. Patients with these clinical and laboratory features deserve prompt hospital admission. The case-fatality rate in hepatitis A and B is very low (~0.1%) but is increased by advanced age and underlying debilitating disorders. Among patients ill enough to be hospitalized for acute hepatitis B, the fatality rate is 1%. Hepatitis C is less severe during the acute phase than hepatitis B and is more likely to be anicteric; fatalities are rare, but the precise case-fatality rate is not

known. In outbreaks of waterborne hepatitis E in India and Asia, the case-fatality rate is 1–2% and up to 10–20% in pregnant women. Patients with simultaneous acute hepatitis B and hepatitis D do not necessarily experience a higher mortality rate than do patients with acute hepatitis B alone; however, in several recent outbreaks of acute simultaneous HBV and HDV infection among injection drug users, the case-fatality rate has been ~5%. In the case of HDV superinfection of a person with chronic hepatitis B, the likelihood of fulminant hepatitis and death is increased substantially. Although the case-fatality rate for hepatitis D has not been defined adequately, in outbreaks of severe HDV superinfection in isolated populations with a high hepatitis B carrier rate, the mortality rate has been recorded in excess of 20%.

Complications and Sequelae

A small proportion of patients with hepatitis A experience *relapsing hepatitis* weeks to months after apparent recovery from acute hepatitis. Relapses are characterized by recurrence of symptoms, aminotransferase elevations, occasionally jaundice, and fecal excretion of HAV. Another unusual variant of acute hepatitis A is *cholestatic hepatitis*, characterized by protracted cholestatic jaundice and pruritus. Rarely, liver test abnormalities persist for many months, even up to a year. Even when these complications occur, hepatitis A remains self-limited and does not progress to chronic liver disease. During the prodromal phase of acute hepatitis B, a serum sickness-like syndrome characterized by arthralgia or arthritis, rash, angioedema, and rarely hematuria and proteinuria may develop in 5–10% of patients. This syndrome occurs before the onset of clinical jaundice, and these patients are often diagnosed erroneously as having rheumatologic diseases. The diagnosis can be established by measuring serum aminotransferase levels, which are almost invariably elevated, and serum HBsAg. As noted above, EMC is an immune-complex disease that can complicate chronic hepatitis C and is part of a spectrum of B cell lymphoproliferative disorders, which, in rare instances, can evolve to B cell lymphoma. Attention has been drawn as well to associations between hepatitis C and such cutaneous disorders as porphyria cutanea tarda and lichen planus. A mechanism for these associations is unknown.

The most feared complication of viral hepatitis is *fulminant hepatitis* (massive hepatic necrosis); fortunately, this is a rare event. Fulminant hepatitis is primarily seen in hepatitis B and D, as well as hepatitis E, but rare fulminant cases of hepatitis A occur primarily in older adults and in persons with underlying chronic liver disease, including, according to some reports, chronic hepatitis B and C. Hepatitis B accounts for >50% of fulminant cases of viral hepatitis, a sizable proportion of which are associated with HDV infection and another proportion with underlying chronic hepatitis C. Fulminant hepatitis is hardly ever seen in hepatitis C, but hepatitis E, as noted above, can be complicated by fatal fulminant hepatitis in 1–2% of all cases and in up to 20% of cases occurring in pregnant women. Patients usually present with signs and symptoms of encephalopathy that may evolve to deep coma. The liver is usually small and the PT excessively

prolonged. The combination of rapidly shrinking liver size, rapidly rising bilirubin level, and marked prolongation of the PT, even as aminotransferase levels fall, together with clinical signs of confusion, disorientation, somnolence, ascites, and edema, indicates that the patient has hepatic failure with encephalopathy. Cerebral edema is common; brainstem compression, gastrointestinal bleeding, sepsis, respiratory failure, cardiovascular collapse, and renal failure are terminal events. The mortality rate is exceedingly high (>80% in patients with deep coma), but patients who survive may have a complete biochemical and histologic recovery. If a donor liver can be located in time, liver transplantation may be life-saving in patients with fulminant hepatitis.

Documenting the disappearance of HBsAg after apparent clinical recovery from acute hepatitis B is particularly important. Before laboratory methods were available to distinguish between acute hepatitis and acute hepatitis-like exacerbations (*spontaneous reactivations*) of chronic hepatitis B, observations suggested that ~10% of previously healthy patients remained HBsAg-positive for >6 months after the onset of clinically apparent acute hepatitis B. Half of these persons cleared the antigen from their circulations during the next several years, but the other 5% remained chronically HBsAg-positive. More recent observations suggest that the true rate of chronic infection after clinically apparent acute hepatitis B is as low as 1% in normal, immunocompetent, young adults. Earlier, higher estimates may have been confounded by inadvertent inclusion of acute exacerbations in chronically infected patients; these patients, chronically HBsAg-positive before exacerbation, were unlikely to seroconvert to HBsAg-negative thereafter. Whether the rate of chronicity is 10 or 1%, such patients have anti-HBc in serum; anti-HBs is either undetected or detected at low titer against the opposite subtype specificity of the antigen (see “Laboratory Features” earlier in the chapter). These patients may (1) be inactive carriers; (2) have low-grade, mild chronic hepatitis; or (3) have moderate to severe chronic hepatitis with or without cirrhosis. The likelihood of remaining chronically infected after acute HBV infection is especially high among neonates, persons with Down’s syndrome, chronically hemodialyzed patients, and immunosuppressed patients, including persons with HIV infection.

Chronic hepatitis is an important late complication of acute hepatitis B occurring in a small proportion of patients with acute disease but more common in those who present with chronic infection without having experienced an acute illness, as occurs typically after neonatal infection or after infection in an immunosuppressed host (Chap. 93). Certain clinical and laboratory features suggest progression of acute hepatitis to chronic hepatitis: (1) lack of complete resolution of clinical symptoms of anorexia, weight loss, and fatigue and the persistence of hepatomegaly; (2) the presence of bridging/interface or multilobular hepatic necrosis on liver biopsy during protracted, severe acute viral hepatitis; (3) failure of the serum aminotransferase, bilirubin, and globulin levels to return to normal within 6–12 months after the acute illness; and (4) the persistence of HBeAg for >3 months or HBsAg for >6 months after acute hepatitis.

Although acute hepatitis D infection does not increase the likelihood of chronicity of simultaneous acute hepatitis B, hepatitis D has the potential for contributing to the severity of chronic hepatitis B. Hepatitis D superinfection can transform inactive or mild chronic hepatitis B into severe, progressive chronic hepatitis and cirrhosis; it also can accelerate the course of chronic hepatitis B. Some HDV superinfections in patients with chronic hepatitis B lead to fulminant hepatitis. Although HDV and HBV infections are associated with severe liver disease, mild hepatitis and even inactive carriage have been identified in some patients, and the disease may become indolent beyond the early years of infection. After acute HCV infection, the likelihood of remaining chronically infected approaches 85–90%. Although many patients with chronic hepatitis C have no symptoms, cirrhosis may develop in as many as 20% within 10–20 years of acute illness; in some series of cases reported by referral centers, cirrhosis has been reported in as many as 50% of patients with chronic hepatitis C. Although chronic hepatitis C accounts for at least 40% of cases of chronic liver disease and of patients undergoing liver transplantation for end-stage liver disease in the United States and Europe, in the majority of patients with chronic hepatitis C, morbidity and mortality are limited during the initial 20 years after the onset of infection. Progression of chronic hepatitis C may be influenced by age of acquisition, duration of infection, immunosuppression, coexisting excessive alcohol use, concomitant hepatic steatosis, other hepatitis virus infection, or HIV co-infection. In fact, instances of severe and rapidly progressive chronic hepatitis B and C are being recognized with increasing frequency in patients with HIV infection (Chap. 90). In contrast, neither HAV nor HEV causes chronic liver disease.

Rare complications of viral hepatitis include pancreatitis, myocarditis, atypical pneumonia, aplastic anemia, transverse myelitis, and peripheral neuropathy. Persons with chronic hepatitis B, particularly those infected in infancy or early childhood and especially those with HBeAg and/or high-level HBV DNA, have an enhanced risk of hepatocellular carcinoma. The risk of hepatocellular carcinoma is increased as well in patients with chronic hepatitis C, almost exclusively in patients with cirrhosis, and almost always after at least several decades, usually after three decades of disease. In children, hepatitis B may present rarely with anicteric hepatitis, a nonpruritic papular rash of the face, buttocks, and limbs, and lymphadenopathy (papular acrodermatitis of childhood, or Gianotti-Crosti syndrome).

Rarely, autoimmune hepatitis (Chap. 93) can be triggered by a bout of otherwise self-limited acute hepatitis, as reported after acute hepatitis A, B, and C.

DIFFERENTIAL DIAGNOSIS

Viral diseases such as infectious mononucleosis; those due to cytomegalovirus, herpes simplex, and coxsackieviruses; and toxoplasmosis may share certain clinical features with viral hepatitis and cause elevations in serum aminotransferase and less commonly in serum bilirubin levels. Tests such as the differential heterophile and serologic tests for

these agents may be helpful in the differential diagnosis if HBsAg, anti-HBc, IgM anti-HAV, and anti-HCV determinations are negative. Aminotransferase elevations can accompany almost any systemic viral infection; other rare causes of liver injury confused with viral hepatitis are infections with *Leptospira*, *Candida*, *Brucella*, *Mycobacterium*, and *Pneumocystis*. A complete drug history is particularly important, for many drugs and certain anesthetic agents can produce a picture of either acute hepatitis or cholestasis. Equally important is a past history of unexplained “repeated episodes” of acute hepatitis. This history should alert the physician to the possibility that the underlying disorder is chronic hepatitis. Alcoholic hepatitis must also be considered, but usually the serum aminotransferase levels are not as markedly elevated and other stigmata of alcoholism may be present. The finding on liver biopsy of fatty infiltration, a neutrophilic inflammatory reaction, and “alcoholic hyaline” would be consistent with alcohol-induced rather than viral liver injury. Because acute hepatitis may present with right upper quadrant abdominal pain, nausea and vomiting, fever, and icterus, it is often confused with acute cholecystitis, common duct stone, or ascending cholangitis. Patients with acute viral hepatitis may tolerate surgery poorly; therefore, it is important to exclude this diagnosis, and in confusing cases, a percutaneous liver biopsy may be necessary before laparotomy. Viral hepatitis in the elderly is often misdiagnosed as obstructive jaundice resulting from a common duct stone or carcinoma of the pancreas. Because acute hepatitis in the elderly may be quite severe and the operative mortality high, a thorough evaluation including biochemical tests, radiographic studies of the biliary tree, and even liver biopsy may be necessary to exclude primary parenchymal liver disease. Another clinical constellation that may mimic acute hepatitis is right ventricular failure with passive hepatic congestion or hypoperfusion syndromes, such as those associated with shock, severe hypotension, and severe left ventricular failure. Also included in this general category is any disorder that interferes with venous return to the heart, such as right atrial myxoma, constrictive pericarditis, hepatic vein occlusion (Budd-Chiari syndrome), or venoocclusive disease. Clinical features are usually sufficient to distinguish between these vascular disorders and viral hepatitis. Acute fatty liver of pregnancy, cholestasis of pregnancy, eclampsia, and the HELLP syndrome (hemolysis, elevated liver tests, and low platelets) can be confused with viral hepatitis during pregnancy. Very rarely, malignancies metastatic to the liver can mimic acute or even fulminant viral hepatitis. Occasionally, genetic or metabolic liver disorders (e.g., Wilson’s disease, α_1 -antitrypsin deficiency) as well as nonalcoholic fatty liver disease are confused with viral hepatitis.

Treatment:

ACUTE VIRAL HEPATITIS

In hepatitis B, among previously healthy adults who present with clinically apparent acute hepatitis, recovery occurs in ~99%; therefore, antiviral therapy is not likely to

improve the rate of recovery and is not required. In rare instances of severe acute hepatitis B, treatment with a nucleoside analogue, such as lamivudine, at the 100-mg/d oral dose used to treat chronic hepatitis B (Chap. 93), has been attempted successfully. Although clinical trials have not been done to establish the efficacy of this approach, although severe acute hepatitis B is not an approved indication for therapy, and although the duration of therapy has not been determined, nonetheless, most authorities would recommend institution of antiviral therapy for severe, but not mild-moderate, acute hepatitis B. In typical cases of acute hepatitis C, recovery is rare, progression to chronic hepatitis is the rule, and meta-analyses of small clinical trials suggest that antiviral therapy with interferon α monotherapy (3 million units SC three times a week) is beneficial, reducing the rate of chronicity considerably by inducing sustained responses in 30–70% of patients. In a German multicenter study of 44 patients with acute symptomatic hepatitis C, initiation of intensive interferon α therapy (5 million units SC daily for 4 weeks, then three times a week for another 20 weeks) within an average of 3 months after infection resulted in a sustained virologic response rate of 98%. Although treatment of acute hepatitis C is recommended, the optimum regimen, duration of therapy, and time to initiate therapy remain to be determined. Many authorities now opt for a 24-week course (beginning within 2–3 months after onset) of the best regimen identified for the treatment of chronic hepatitis C, long-acting pegylated interferon plus the nucleoside analogue ribavirin, the efficacy of which is superior to that of standard interferon monotherapy regimens (see Chap. 93 for doses). Because of the marked reduction over the past two decades in the frequency of acute hepatitis C, opportunities to identify and treat patients with acute hepatitis C are rare indeed, except in injection drug users. Hospital epidemiologists, however, will encounter health workers who sustain hepatitis C–contaminated needle sticks; when monitoring for ALT elevations and HCV RNA after these accidents identifies acute hepatitis C (risk only ~3%), therapy should be initiated.

Notwithstanding these specific therapeutic considerations, in most cases of typical acute viral hepatitis, specific treatment generally is not necessary. Although hospitalization may be required for clinically severe illness, most patients do not require hospital care. Forced and prolonged bed rest is not essential for full recovery, but many patients will feel better with restricted physical activity. A high-calorie diet is desirable, and because many patients may experience nausea late in the day, the major caloric intake is best tolerated in the morning. Intravenous feeding is necessary in the acute stage if the patient has persistent vomiting and cannot maintain oral intake. Drugs capable of producing adverse reactions such as cholestasis and drugs metabolized by the liver should be avoided. If severe pruritus is present, the use of the bile salt–sequestering resin cholestyramine is helpful. Glucocorticoid therapy has no value in acute viral hepatitis,

even in severe cases associated with *bridging necrosis*, and may be deleterious, even increasing the risk of chronicity (e.g., of acute hepatitis B).

Physical isolation of patients with hepatitis to a single room and bathroom is rarely necessary except in the case of fecal incontinence for hepatitis A and E or uncontrolled, voluminous bleeding for hepatitis B (with or without concomitant hepatitis D) and hepatitis C. Because most patients hospitalized with hepatitis A excrete little if any HAV, the likelihood of HAV transmission from these patients during their hospitalization is low. Therefore, burdensome *enteric precautions are no longer recommended*. Although gloves should be worn when the bedpans or fecal material of patients with hepatitis A are handled, these precautions do not represent a departure from sensible procedure and contemporary universal precautions for all hospitalized patients. For patients with hepatitis B and hepatitis C, emphasis should be placed on blood precautions, i.e., avoiding direct, ungloved hand contact with blood and other body fluids. Enteric precautions are unnecessary. The importance of simple hygienic precautions, such as hand washing, cannot be overemphasized. Universal precautions that have been adopted for all patients apply to patients with viral hepatitis.

Hospitalized patients may be discharged following substantial symptomatic improvement, a significant downward trend in the serum aminotransferase and bilirubin values, and a return to normal of the PT. Mild aminotransferase elevations should not be considered contraindications to the gradual resumption of normal activity.

In *fulminant hepatitis*, the goal of therapy is to support the patient by maintenance of fluid balance, support of circulation and respiration, control of bleeding, correction of hypoglycemia, and treatment of other complications of the comatose state in anticipation of liver regeneration and repair. Protein intake should be restricted, and oral lactulose or neomycin administered. Glucocorticoid therapy has been shown in controlled trials to be ineffective. Likewise, exchange transfusion, plasmapheresis, human cross-circulation, porcine liver cross-perfusion, hemoperfusion, and extracorporeal liver-assist devices have not been proved to enhance survival. Meticulous intensive care that includes prophylactic antibiotic coverage is the one factor that does appear to improve survival. Orthotopic liver transplantation is resorted to with increasing frequency, with excellent results, in patients with fulminant hepatitis.

PROPHYLAXIS

Because application of therapy for acute viral hepatitis is limited, and because antiviral therapy for chronic viral hepatitis is cumbersome and costly but effective in only a proportion of patients (Chap. 93), emphasis is placed on prevention through immunization. The prophylactic approach differs for each of the types of

viral hepatitis. In the past, immunoprophylaxis relied exclusively on passive immunization with antibody-containing globulin preparations purified by cold ethanol fractionation from the plasma of hundreds of normal donors. Currently, for hepatitis A and B, active immunization with vaccines is the preferable approach to prevention.

Hepatitis A

Both passive immunization with IG and active immunization with killed vaccines are available. All preparations of IG contain anti-HAV concentrations sufficient to be protective. When administered before exposure or during the early incubation period, IG is effective in preventing clinically apparent hepatitis A. For postexposure prophylaxis of intimate contacts (household, sexual, institutional) of persons with hepatitis A, the administration of 0.02 mL/kg is recommended as early after exposure as possible; it may be effective even when administered as late as 2 weeks after exposure. Prophylaxis is not necessary for those who have already received hepatitis A vaccine, casual contacts (office, factory, school, or hospital), for most elderly persons, who are very likely to be immune, or for those known to have anti-HAV in their serum. In day-care centers, recognition of hepatitis A in children or staff should provide a stimulus for immunoprophylaxis in the center and in the children's family members. By the time most common-source outbreaks of hepatitis A are recognized, it is usually too late in the incubation period for IG to be effective; however, prophylaxis may limit the frequency of secondary cases. For travelers to tropical countries, developing countries, and other areas outside standard tourist routes, IG prophylaxis had been recommended, before a vaccine became available. When such travel lasted <3 months, 0.02 mL/kg was given; for longer travel or residence in these areas, a dose of 0.06 mL/kg every 4–6 months was recommended. Administration of plasma-derived globulin is safe; all contemporary lots of IG are subjected to viral inactivation steps and must be free of HCV RNA as determined by PCR testing. Administration of IM lots of IG has not been associated with transmission of HBV, HCV, or HIV.

Formalin-inactivated vaccines made from strains of HAV attenuated in tissue culture have been shown to be safe, immunogenic, and effective in preventing hepatitis A. Hepatitis A vaccines are approved for use in persons who are at least 1 year old and appear to provide adequate protection beginning 4 weeks after a primary inoculation. If it can be given within 4 weeks of an expected exposure, such as by travel to an endemic area, hepatitis A vaccine is the preferred approach to *preexposure* immunoprophylaxis. If travel is more imminent, IG (0.02 mL/kg) should be administered at a different injection site, along with the first dose of vaccine. Because vaccination provides long-lasting protection (protective levels of anti-HAV should last 20 years after vaccination), persons whose risk will be sustained (e.g., frequent travelers or those remaining in endemic areas for prolonged periods) should be vaccinated, and vaccine should supplant the need for repeated IG injections. Shortly after its introduction, hepatitis A

vaccine was recommended for children living in communities with a high incidence of HAV infection; in 1999, this recommendation was extended to include all children living in states, counties, and communities with high rates of HAV infection. As of 2006, the Advisory Committee on Immunization Practices of the U.S. Public Health Service recommended *routine hepatitis A vaccination of all children*. Other groups considered to be at increased risk for HAV infection and who are candidates for hepatitis A vaccination include military personnel, populations with cyclic outbreaks of hepatitis A (e.g., Alaskan natives), employees of day-care centers, primate handlers, laboratory workers exposed to hepatitis A or fecal specimens, and patients with chronic liver disease. Because of an increased risk of fulminant hepatitis A—observed in some experiences but not confirmed in others—among patients with chronic hepatitis C, patients with chronic hepatitis C have been singled out as candidates for hepatitis A vaccination. Other populations whose recognized risk of hepatitis A is increased should be vaccinated, including men who have sex with men, injection drug users, and persons with clotting disorders who require frequent administration of clotting-factor concentrates. Recommendations for dose and frequency differ for the two approved vaccine preparations (Table 92-5); all injections are IM. Hepatitis A vaccine has been reported to be effective in preventing secondary household cases of acute hepatitis A, but its role in other instances of postexposure prophylaxis remains to be demonstrated.

Hepatitis B

Until 1982, prevention of hepatitis B was based on *passive* immunoprophylaxis either with standard IG, containing

TABLE 92-5

HEPATITIS A VACCINATION SCHEDULES

| AGE, YEARS | NO. OF DOSES | DOSE | SCHEDULE, MONTHS |
|---|--------------|----------------------------------|------------------|
| HAVRIX (GlaxoSmithKline)^a | | | |
| 1–18 | 2 | 720 ELU ^b (0.5 mL) | 0, 6–12 |
| ≥19 | 2 | 1440 ELU (1.0 mL) | 0, 6–12 |
| VAQTA (Merck) | | | |
| 1–18 | 2 | 25 units (0.5 mL) | 0, 6–18 |
| ≥19 | 2 | 50 units (1.0 mL) | 0, 6–18 |

^aA combination of this hepatitis A vaccine and hepatitis B vaccine, TWINRIX, is licensed for simultaneous protection against both of these viruses among adults (age ≥18 years). Each 1.0-mL dose contains 720 ELU of hepatitis A vaccine and 20 µg of hepatitis B vaccine. These doses are recommended at months 0, 1, and 6.

^bEnzyme-linked immunoassay units.

modest levels of anti-HBs, or hepatitis B immune globulin (HBIG), containing high-titer anti-HBs. The efficacy of standard IG has never been established and remains questionable; even the efficacy of HBIG, demonstrated in several clinical trials, has been challenged, and its contribution appears to be in reducing the frequency of clinical *illness*, not in preventing *infection*. The first vaccine for *active* immunization, introduced in 1982, was prepared from purified, noninfectious 22-nm spherical forms of HBsAg derived from the plasma of healthy HBsAg carriers. In 1987, the plasma-derived vaccine was supplanted by a genetically engineered vaccine derived from recombinant yeast. The latter vaccine consists of HBsAg particles that are nonglycosylated but are otherwise indistinguishable from natural HBsAg; two recombinant vaccines are licensed for use in the United States. Current recommendations can be divided into those for preexposure and postexposure prophylaxis.

For *preexposure* prophylaxis against hepatitis B in settings of frequent exposure (health workers exposed to blood; hemodialysis patients and staff; residents and staff of custodial institutions for the developmentally handicapped; injection drug users; inmates of long-term correctional facilities; persons with multiple sexual partners; persons such as hemophiliacs who require long-term, high-volume therapy with blood derivatives; household and sexual contacts of HBsAg carriers; persons living in or traveling extensively in endemic areas; unvaccinated children under the age of 18; and unvaccinated children who are Alaskan natives, Pacific Islanders, or residents in households of first-generation immigrants from endemic countries), three IM (deltoid, not gluteal) injections of hepatitis B vaccine are recommended at 0, 1, and 6 months (other, optional schedules are summarized in [Table 92-6](#)). Pregnancy is *not* a contraindication to vaccination. In areas of low HBV endemicity such as the United States, despite the availability of safe and effective hepatitis B vaccines, a strategy of vaccinating persons in high-risk groups has not been effective. The incidence of new hepatitis B cases continued to increase in the United States after introduction of vaccines; <10% of all targeted persons in high-risk groups have actually been vaccinated, and ~30% of persons with sporadic acute hepatitis B do not fall into any high-risk-group category. Therefore, to have an impact on the frequency of HBV infection in an area of low endemicity such as the United States, universal hepatitis B vaccination in childhood has been recommended. For unvaccinated children born after the implementation of universal infant vaccination, vaccination during early adolescence, at age 11–12 years, was recommended, and this recommendation has been extended to include all unvaccinated children age 0–19 years. In HBV-hyperendemic areas, e.g., Asia, universal vaccination of children has resulted in a marked 10- to 15-year decline in hepatitis B and its complications.

The two available recombinant hepatitis B vaccines are comparable, one containing 10 µg of HBsAg (Recombivax-HB) and the other containing 20 µg of HBsAg (Engerix-B), and recommended doses for each injection vary for the two preparations (Table 92-6).

TABLE 92-6

PREEXPOSURE HEPATITIS B VACCINATION SCHEDULES

| TARGET GROUP | NO. OF DOSES | DOSE | SCHEDULE, MONTHS |
|---|--------------|----------------|---|
| RECOMBIVAX-HB (Merck)^a | | | |
| Infants, children (<1–10 years) | 3 | 5 µg (0.5 mL) | 0, 1–2, 4–6 |
| Adolescents (11–19 years) | 3 or 4 | 5 µg (0.5 mL) | 0–2, 1–4, 4–6 or 0, 12, 24 or 0, 1, 2, 12 |
| | | or | |
| | 2 | 10 µg (1.0 mL) | 0, 4–6 (age 11–15) |
| Adults (≥20 years) | 3 | 10 µg (1.0 mL) | 0–2, 1–4, 4–6 |
| HEMODYALYSIS PATIENTS^b | | | |
| <20 years | 3 | 5 µg (0.5 mL) | 0, 1, 6 |
| ≥20 years | 3 | 40 µg (4.0 mL) | 0, 1, 6 |
| ENGRIX-B (GlaxoSmithKline)^c | | | |
| Infants, children (<1–10 years) | 3 or 4 | 10 µg (0.5 mL) | 0, 1–2, 4–6 or 0, 1, 2, 12 |
| Adolescents (10–19 years) | 3 or 4 | 10 µg (0.5 mL) | 0, 1–2, 4–6 or 0, 12, 24 or 0, 1, 2, 12 |
| Adults (≥20 years) | 3 or 4 | 20 µg (1.0 mL) | 0–2, 1–4, 4–6 or 0, 1, 2, 12 |
| HEMODYALYSIS PATIENTS^b | | | |
| <20 years | 4 | 10 µg (0.5 mL) | 0, 1, 2, 6 |
| ≥20 years | 4 | 40 µg (2.0 mL) | 0, 1, 2, 6 |

^aThis manufacturer produces a licensed combination of hepatitis B vaccine and vaccines against *Haemophilus influenzae* type b and *Neisseria meningitidis*, Comvax, for use in infants and young children. Please consult product insert for dose and schedule.

^bThis group also includes other immunocompromised persons.

^cThis manufacturer produces two licensed combination hepatitis B vaccines: (1) Twinrix, recombinant hepatitis B vaccine plus inactivated hepatitis A vaccine, is licensed for simultaneous protection against both of these viruses among adults (age ≥ 18 years). Each 1.0-mL dose contains 720 enzyme-linked immunoassay units of hepatitis A vaccine and 20 µg of hepatitis B vaccine. These doses are recommended at months 0, 1, and 6. (2) Pediarix, recombinant hepatitis B vaccine plus diphtheria and tetanus toxoid, pertussis, and inactivated poliovirus, is licensed for use in infants and young children. Please consult product insert for doses and schedules.

Combinations of hepatitis B vaccine with other childhood vaccines are available as well (Table 92-6).

For unvaccinated persons sustaining an exposure to HBV, *postexposure* prophylaxis with a combination of HBIG (for rapid achievement of high-titer circulating

anti-HBs) and hepatitis B vaccine (for achievement of long-lasting immunity as well as its apparent efficacy in attenuating clinical illness after exposure) is recommended. For *perinatal* exposure of infants born to HBsAg-positive mothers, a single dose of HBIG, 0.5 mL, should be administered IM in the thigh *immediately after birth*, followed by a complete course of three injections of recombinant hepatitis B vaccine (see doses above) to be started within the first 12 h of life. For those experiencing a direct percutaneous inoculation or transmucosal exposure to HBsAg-positive blood or body fluids (e.g., accidental *needle stick*, other mucosal penetration, or ingestion), a single IM dose of HBIG, 0.06 mL/kg, administered as soon after exposure as possible, is followed by a complete course of hepatitis B vaccine to begin within the first week. For those exposed by *sexual* contact to a patient with acute hepatitis B, a single IM dose of HBIG, 0.06 mL/kg, should be given within 14 days of exposure, to be followed by a complete course of hepatitis B vaccine. When both HBIG and hepatitis B vaccine are recommended, they may be given at the same time but at separate sites.

The precise duration of protection afforded by hepatitis B vaccine is unknown; however, ~80–90% of immunocompetent vaccinees retain protective levels of anti-HBs for at least 5 years, and 60–80% for 10 years. Thereafter and even after anti-HBs becomes undetectable, protection persists against clinical hepatitis B, hepatitis B surface antigenemia, and chronic HBV infection. Currently, *booster* immunizations are not recommended routinely, except in immunosuppressed persons who have lost detectable anti-HBs or immunocompetent persons who sustain percutaneous HBsAg-positive inoculations after losing detectable antibody. Specifically, for hemodialysis patients, annual anti-HBs testing is recommended after vaccination; booster doses are recommended when anti-HBs levels fall to <10 mIU/mL. As noted above, for persons at risk of both hepatitis A and B, a combined vaccine is available containing 720 enzyme-linked immunoassay units of inactivated HAV and 20 µg of recombinant HBsAg (at 0, 1, and 6 months).

Hepatitis D

Infection with hepatitis D can be prevented by vaccinating susceptible persons with hepatitis B vaccine. No product is available for immunoprophylaxis to prevent HDV superinfection in HBsAg carriers; for them, avoidance of percutaneous exposures and limitation of intimate contact with persons who have HDV infection are recommended.

Hepatitis C

IG is ineffective in preventing hepatitis C and is no longer recommended for postexposure prophylaxis in cases of perinatal, needle stick, or sexual exposure. Although prototype vaccines that induce antibodies to HCV envelope proteins have been developed, currently, hepatitis C vaccination is not feasible practically. Genotype and quasispecies viral heterogeneity, as well as rapid evasion of neutralizing antibodies by this rapidly mutating

virus, conspire to render HCV a difficult target for immunoprophylaxis with a vaccine. Prevention of transfusion-associated hepatitis C has been accomplished by the following successively introduced measures: Exclusion of commercial blood donors and reliance on a volunteer blood supply; screening donor blood with surrogate markers such as ALT (no longer recommended) and anti-HBc, markers that identify segments of the blood donor population with an increased risk of bloodborne infections; exclusion of blood donors in high-risk groups for AIDS and the introduction of anti-HIV screening tests; and progressively sensitive serologic and virologic screening tests for HCV infection.

In the absence of active or passive immunization, prevention of hepatitis C includes behavior changes and precautions to limit exposures to infected persons. Recommendations designed to identify patients with clinically inapparent hepatitis as candidates for medical management have as a secondary benefit the identification of persons whose contacts could be at risk of becoming infected. A so-called look-back program has been recommended to identify persons who were transfused before 1992 with blood from a donor found subsequently to have hepatitis C. In addition, anti-HCV testing is recommended for anyone who received a blood transfusion or a transplanted organ before the introduction of second-generation screening tests in 1992, those who ever used injection drugs, chronically hemodialyzed patients, persons with clotting disorders who received clotting factors made before 1987 from pooled blood products, persons with elevated aminotransferase levels, health workers exposed to HCV-positive blood or contaminated needles, and children born to HCV-positive mothers.

For stable, monogamous sexual partners, sexual transmission of hepatitis C is unlikely, and sexual barrier precautions are not recommended. For persons with multiple sexual partners or with sexually transmitted diseases, the risk of sexual transmission of hepatitis C is increased, and barrier precautions (latex condoms) are recommended. A person with hepatitis C should avoid sharing such items as razors, toothbrushes, and nail clippers with sexual partners and family members. No special precautions are recommended for babies born to mothers with hepatitis C, and breast feeding does not have to be restricted.

Hepatitis E

Whether IG prevents hepatitis E remains undetermined. A recombinant vaccine has been developed and is undergoing clinical testing.

CHAPTER 93

CHRONIC HEPATITIS

Jules L. Dienstag

Chronic hepatitis represents a series of liver disorders of varying causes and severity in which hepatic inflammation and necrosis continue for at least 6 months. Milder forms are nonprogressive or only slowly progressive, while more severe forms may be associated with scarring and architectural reorganization, which, when advanced, lead ultimately to cirrhosis. Several categories of chronic hepatitis have been recognized. These include chronic viral hepatitis, drug-induced chronic hepatitis, and autoimmune chronic hepatitis. In many cases, clinical and laboratory features are insufficient to allow assignment into one of these three categories; these “idiopathic” cases are also believed to represent autoimmune chronic hepatitis. Finally, clinical and laboratory features of chronic hepatitis are observed occasionally in patients with such hereditary/metabolic disorders as Wilson’s disease (copper overload) and even occasionally in patients with alcoholic liver injury. Although all types of chronic hepatitis share certain clinical, laboratory, and histopathologic features, chronic viral and chronic autoimmune hepatitis are sufficiently distinct to merit separate discussions. For discussion of acute hepatitis, see Chap. 92.

CLASSIFICATION OF CHRONIC HEPATITIS

Common to all forms of chronic hepatitis are histopathologic distinctions based on localization and extent of liver injury. These vary from the milder forms, previously labeled *chronic persistent hepatitis* and *chronic lobular hepatitis*, to the more severe form, formerly called *chronic active hepatitis*. When first defined, these designations were felt to have prognostic implications, which have been challenged by more recent observations. Categorization of chronic hepatitis based primarily on histopathologic features has been replaced by a more informative classification based on a combination of clinical, serologic, and histologic variables. Classification of chronic hepatitis is based on (1) its *cause*; (2) its histologic activity, or *grade*; and (3) its degree of progression, or *stage*. Thus, neither clinical features alone nor histologic features—requiring liver biopsy—alone are sufficient to characterize and distinguish among the several categories of chronic hepatitis.

TABLE 93-1

CLINICAL AND LABORATORY FEATURES OF CHRONIC HEPATITIS

| TYPE OF HEPATITIS | DIAGNOSTIC TEST(S) | AUTOANTIBODIES | THERAPY |
|----------------------|---|---------------------------------------|---|
| Chronic hepatitis B | HBsAg, IgG anti-HBc, HBeAg, HBV DNA | Uncommon | IFN- α , PEG IFN- α , lamivudine, adefovir, entecavir |
| Chronic hepatitis C | Anti-HCV, HCV RNA | Anti-LKM1 ^a | PEG IFN- α plus ribavirin |
| Chronic hepatitis D | Anti-HDV, HDV RNA, HBsAg, IgG anti-HBc | Anti-LKM3 | IFN- α , PEG IFN- α ^b |
| Autoimmune hepatitis | ANA ^c (homogeneous), anti-LKM1(\pm), hyperglobulinemia | ANA, anti-LKM1, anti-SLA ^d | Prednisone, azathioprine |
| Drug-associated | — | Uncommon | Withdraw drug |
| Cryptogenic | All negative | None | Prednisone (?), azathioprine (?) |

^aAntibodies to liver-kidney microsomes type 1 (autoimmune hepatitis type II and some cases of hepatitis C).

^bClinical trials suggest benefit of IFN- α therapy or PEG IFN- α .

^cAntinuclear antibody (autoimmune hepatitis type I).

^dAntibodies to soluble liver antigen (autoimmune hepatitis type III).

Note: HBc, hepatitis B core; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; IFN- α , interferon α ; IgG, immunoglobulin G; LKM, liver-kidney microsome; PEG-IFN- α , pegylated interferon α ; SLA, soluble liver antigen.

CLASSIFICATION BY CAUSE

Clinical and serologic features allow the establishment of a diagnosis of *chronic viral hepatitis*, caused by hepatitis B, hepatitis B plus D, or hepatitis C; *autoimmune hepatitis*, including several subcategories, I and II (perhaps III), based on serologic distinctions; *drug-associated chronic hepatitis*; and a category of unknown cause, or *cryptogenic chronic hepatitis* (Table 93-1). These are addressed in more detail below.

CLASSIFICATION BY GRADE

Grade, a histologic assessment of necroinflammatory activity, is based on examination of the liver biopsy. An assessment of important histologic features includes the degree of *periportal necrosis* and the disruption of the limiting plate of periportal hepatocytes by inflammatory cells (so-called *piecemeal necrosis* or *interface hepatitis*); the degree of confluent necrosis that links or forms bridges between vascular structures—between portal tract and portal tract or even more important bridges between portal tract and central vein—referred to as *bridging necrosis*; the degree of hepatocyte degeneration and focal necrosis within the lobule; and the degree of *portal inflammation*. Several scoring systems that take these histologic features into account have been devised, and the most popular are the histologic activity index (HAI) and the METAVIR score (Table 93-2). Based on the presence and degree of these features of histologic activity, chronic hepatitis can be graded as mild, moderate, or severe.

CLASSIFICATION BY STAGE

The stage of chronic hepatitis, which reflects the level of progression of the disease, is based on the degree of hepatic fibrosis. When fibrosis is so extensive that fibrous

septa surround parenchymal nodules and alter the normal architecture of the liver lobule, the histologic lesion is defined as *cirrhosis*. Staging is based on the degree of fibrosis as categorized on a numerical scale from 0–6 (HAI) or 0–4 (METAVIR) (Table 93-2).

CHRONIC VIRAL HEPATITIS

Both the enterically transmitted forms of viral hepatitis, hepatitis A and E, are self-limited and do not cause chronic hepatitis (rare reports notwithstanding in which acute hepatitis A serves as a trigger for the onset of autoimmune hepatitis in genetically susceptible patients). In contrast, the entire clinicopathologic spectrum of chronic hepatitis occurs in patients with chronic viral hepatitis B and C as well as in patients with chronic hepatitis D superimposed on chronic hepatitis B.

CHRONIC HEPATITIS B

The likelihood of chronicity after acute hepatitis B varies as a function of age. Infection at birth is associated with clinically silent acute infection but a 90% chance of chronic infection, while infection in young adulthood in immunocompetent persons is typically associated with clinically apparent acute hepatitis but a risk of chronicity of only approximately 1%. Most cases of chronic hepatitis B among adults, however, occur in patients who never had a recognized episode of clinically apparent acute viral hepatitis. The degree of liver injury (grade) in patients with chronic hepatitis B is variable, ranging from none in inactive carriers to mild to moderate to severe. Among adults with chronic hepatitis B, histologic features are of prognostic importance. In one long-term study of patients with chronic hepatitis B, investigators

^aJ Hepatol 22:696, 1995.^bHepatology 24:289, 1996.^cNecroinflammatory grade: A0 = none; A1 = mild; A2 = moderate; A3 = severe.

found a 5-year survival rate of 97% for patients with mild chronic hepatitis, 86% for patients with moderate to severe chronic hepatitis, and only 55% for patients with chronic hepatitis and postnecrotic cirrhosis. The 15-year survival in these cohorts was 77, 66, and 40%, respectively. On the other hand, more recent observations do not allow us to be so sanguine about the prognosis in patients with mild chronic hepatitis; among such patients followed for 1–13 years, progression to more severe chronic hepatitis and cirrhosis has been observed in more than a quarter of cases.

More important to consider than histology alone in patients with chronic hepatitis B is the degree of hepatitis

B virus (HBV) replication. As reviewed in Chap. 92, chronic HBV infection can occur in the presence or absence of serum hepatitis B e antigen (HBeAg), and generally, for both HBeAg-reactive and HBeAg-negative chronic hepatitis B, the level of HBV DNA correlates with the level of liver injury and risk of progression. In *HBeAg-reactive chronic hepatitis B*, two phases have been recognized based on the relative level of HBV replication. The relatively *replicative phase* is characterized by the presence in the serum of HBeAg and HBV DNA levels well in excess of 10^5 – 10^6 virions/mL, by the presence in the liver of detectable intrahepatocyte nucleocapsid antigens [primarily hepatitis B core antigen (HBcAg)],

by high infectivity, and by accompanying liver injury. In contrast, the relatively *nonreplicative phase* is characterized by the absence of the conventional serum marker of HBV replication (HBeAg), the appearance of anti-HBe, levels of HBV DNA below a threshold of $\sim 10^3$ virions/mL, the absence of intrahepatocytic HBcAg, limited infectivity, and minimal liver injury. Those patients in the replicative phase tend to have more severe chronic hepatitis, while those in the nonreplicative phase tend to have minimal or mild chronic hepatitis or to be inactive hepatitis B carriers; however, distinctions in HBV replication and in histologic category do not always coincide. The likelihood in a patient with HBeAg-reactive chronic hepatitis B of converting spontaneously from relatively replicative to nonreplicative infection is approximately 10–15% per year. In patients with HBeAg-reactive chronic HBV infection, especially when acquired at birth or in early childhood, as recognized commonly in Asian countries, a dichotomy is common between very high levels of HBV replication and negligible levels of liver injury. Yet despite the relatively immediate, apparently benign nature of liver disease for many decades in this population, patients with childhood-acquired HBV infection are the ones at ultimately increased risk later in life of cirrhosis and hepatocellular carcinoma (HCC). A discussion of the pathogenesis of liver injury in patients with chronic hepatitis B appears in Chap. 92.

HBeAg-negative chronic hepatitis B, i.e., chronic HBV infection with active virus replication, readily detectable HBV DNA but without HBeAg (anti-HBe-reactive), is more common than HBeAg-reactive chronic hepatitis B in Mediterranean and European countries and in Asia (and, correspondingly, in HBV genotypes other than A). Compared to patients with HBeAg-reactive chronic hepatitis B, patients with HBeAg-negative chronic hepatitis B have levels of HBV DNA that are several orders of magnitude lower (no more than 10^5 – 10^6 virions/mL) than those observed in the HBeAg-reactive subset. Most such cases represent precore or core-promoter mutations acquired late in the natural history of the disease (mostly early-life onset; age range 40–55 years, older than that for HBeAg-reactive chronic hepatitis B); these mutations prevent translation of HBeAg from the precore component of the HBV genome (precore mutants) or are characterized by down-regulated transcription of precore mRNA (core-promoter mutants; Chap. 92). Although their levels of HBV DNA tend to be lower than among patients with HBeAg-reactive chronic hepatitis B, patients with HBeAg-negative chronic hepatitis B can have progressive liver injury (complicated by cirrhosis and HCC) and experience episodic reactivation of liver disease reflected in fluctuating levels of aminotransferase activity (“flares”). The biochemical and histologic activity of HBeAg-negative disease tends to correlate closely with levels of HBV replication, unlike the case mentioned above of Asian patients with HBeAg-reactive chronic hepatitis B during the early decades of their HBV infection. An important point worth reiterating is the observation that the level of HBV replication is the

most important risk factor for the ultimate development of cirrhosis and HCC in both HBeAg-reactive and HBeAg-negative patients. Although levels of HBV DNA are lower and more readily suppressed to undetectable levels in HBeAg-negative (compared to HBeAg-reactive) chronic hepatitis B, achieving sustained responses that permit discontinuation of antiviral therapy is less likely in HBeAg-negative patients (see below). Inactive carriers are patients with circulating hepatitis B surface antigen (HBsAg), normal serum aminotransferase levels, undetectable HBeAg, and levels of HBV DNA that are either undetectable or present at levels $\leq 10^3$ virions/mL. This serologic profile can occur not only in inactive carriers but also in patients with HBeAg-negative chronic hepatitis B during periods of relative inactivity; distinguishing between the two requires sequential biochemical and virologic monitoring over many months.

The spectrum of *clinical features* of chronic hepatitis B is broad, ranging from asymptomatic infection to debilitating disease or even end-stage, fatal hepatic failure. As noted above, the onset of the disease tends to be insidious in most patients, with the exception of the very few in whom chronic disease follows failure of resolution of clinically apparent acute hepatitis B. The clinical and laboratory features associated with progression from acute to chronic hepatitis B are discussed in Chap. 92.

Fatigue is a common symptom, and persistent or intermittent *jaundice* is a common feature in severe or advanced cases. Intermittent deepening of jaundice and recurrence of malaise and anorexia, as well as worsening fatigue, are reminiscent of acute hepatitis; such exacerbations may occur spontaneously, often coinciding with evidence of virologic reactivation; may lead to progressive liver injury; and, when superimposed on well-established cirrhosis, may cause hepatic decompensation. Complications of cirrhosis occur in end-stage chronic hepatitis and include ascites, edema, bleeding gastroesophageal varices, hepatic encephalopathy, coagulopathy, or hypersplenism. Occasionally these complications bring the patient to initial clinical attention. Extrahepatic complications of chronic hepatitis B, similar to those seen during the prodromal phase of acute hepatitis B, are associated with deposition of circulating hepatitis B antigen–antibody immune complexes. These include arthralgias and arthritis, which are common, and the more rare purpuric cutaneous lesions (leukocytoclastic vasculitis), immune-complex glomerulonephritis, and generalized vasculitis (polyarteritis nodosa) (Chap. 92).

Laboratory features of chronic hepatitis B do not distinguish adequately between histologically mild and severe hepatitis. Aminotransferase elevations tend to be modest for chronic hepatitis B but may fluctuate in the range of 100–1000 units. As is true for acute viral hepatitis B, alanine aminotransferase (ALT) tends to be more elevated than aspartate aminotransferase (AST); however, once cirrhosis is established, AST tends to exceed ALT. Levels of alkaline phosphatase activity tend to be normal or only marginally elevated. In severe cases, moderate elevations

in serum bilirubin [51.3–171 $\mu\text{mol/L}$ (3–10 mg/dL)] occur. Hypoalbuminemia and prolongation of the prothrombin time occur in severe or end-stage cases. Hyperglobulinemia and detectable circulating autoantibodies are distinctly absent in chronic hepatitis B (in contrast to autoimmune hepatitis). Viral markers of chronic HBV infection are discussed in Chap. 92.

Rx Treatment: **CHRONIC HEPATITIS B**

Although progression to cirrhosis is more likely in severe than in mild or moderate chronic hepatitis B, all forms of chronic hepatitis B can be progressive, and progression occurs primarily in patients with active HBV replication. Moreover, in populations of patients with chronic hepatitis B who are at risk for HCC, the risk is highest for those with continued, high-level HBV replication. Therefore, management of chronic hepatitis B is directed at suppressing the level of virus replication. To date, five drugs have been approved for treatment of chronic hepatitis B: injectable interferon (IFN) α ; pegylated interferon [long-acting IFN bound to polyethylene glycol (PEG), known as *PEG IFN*]; and the oral agents lamivudine, adefovir dipivoxil, and entecavir. Several other drugs, including emtricitabine, tenofovir, telbivudine, pradevovir, and clevudine, are in the process of efficacy testing in clinical trials.

Antiviral therapy for hepatitis B has evolved rapidly since the mid-1990s, as has the sensitivity of tests for HBV DNA. When IFN and lamivudine were evaluated in clinical trials, HBV DNA was measured by insensitive hybridization assays with detection thresholds of 10^5 – 10^6 virions/mL; when adefovir, entecavir, and PEG IFN were studied in clinical trials, HBV DNA was measured by sensitive amplification assays [polymerase chain reaction (PCR)] with detection thresholds of 10^2 – 10^3 virions/mL. Recognition of these distinctions is helpful when comparing results of clinical trials that established the efficacy of these therapies (reviewed below in chronological order of publication of these efficacy trials).

INTERFERON IFN- α was the first approved therapy for chronic hepatitis B. For immunocompetent adults with HBeAg-reactive chronic hepatitis B [who tend to have high-level HBV DNA ($>10^5$ – 10^6 virions/mL) and histologic evidence of chronic hepatitis on liver biopsy], a 16-week course of IFN given subcutaneously at a daily dose of 5 million units, or three times a week at a dose of 10 million units, results in a loss of HBeAg and hybridization-detectable HBV DNA (i.e., a reduction to levels below 10^5 – 10^6 virions/mL) in ~30% of patients, with a concomitant improvement in liver histology. Seroconversion from HBeAg to anti-HBe occurs in approximately 20%, and, in early trials, approximately 8% lost HBsAg. Successful IFN therapy and seroconversion are often accompanied by an acute hepatitis-like elevation in aminotransferase activity, which has been postulated to result from enhanced cytolytic T cell clearance of HBV-infected hepatocytes.

Relapse after successful therapy is rare (1 or 2%). The likelihood of responding to IFN is higher in patients with lower levels of HBV DNA and substantial elevations of ALT. Although children can respond as well as adults, IFN therapy has not been effective in very young children infected at birth. Similarly, IFN therapy has not been effective in immunosuppressed persons, Asian patients with minimal-to-mild ALT elevations, or patients with decompensated chronic hepatitis B (in whom such therapy can actually be detrimental, sometimes precipitating decompensation, often associated with severe adverse effects). Among patients with HBeAg loss during therapy, long-term follow-up has demonstrated that 80% experience eventual loss of HBsAg, i.e., all serologic markers of infection, and normalization of ALT over a 9-year posttreatment period. In addition, improved long-term and complication-free survival as well as a reduction in the frequency of HCC have been documented among interferon responders, supporting the conclusion that successful interferon therapy improves the natural history of chronic hepatitis B.

Retreatment of IFN nonresponders with another course of IFN may enhance response rates somewhat; currently, however, most would opt to address IFN nonresponders by offering them one of the newer, oral therapies.

Initial trials of brief-duration IFN therapy in patients with *HBeAg-negative chronic hepatitis B* were disappointing, suppressing HBV replication transiently during therapy but almost never resulting in sustained antiviral responses. In subsequent IFN trials among patients with HBeAg-negative chronic hepatitis B, however, more protracted courses, lasting up to a year and a half, have been reported to result in sustained remissions, with suppressed HBV DNA and aminotransferase activity, in ~20%.

Complications of IFN therapy include systemic “flu-like” symptoms; marrow suppression; emotional lability (irritability commonly, depression/anxiety less frequently); autoimmune reactions (especially autoimmune thyroiditis); and miscellaneous side effects such as alopecia, rashes, diarrhea, and numbness and tingling of the extremities. With the possible exception of autoimmune thyroiditis, all these side effects are reversible upon dose lowering or cessation of therapy.

Whether or not IFN remains competitive with the newer generation of antivirals, it did represent the first successful antiviral approach, and it set the standard against which subsequent drugs are measured—the achievement of durable virologic, serologic, biochemical, and histologic responses; consolidation of virologic and biochemical benefit in the ensuing years after therapy; and improvement in the natural history of chronic hepatitis B. For all practical purposes, standard IFN has been supplanted by long-acting PEG IFN (see below).

LAMIVUDINE The first of the nucleoside analogues to be approved, the dideoxynucleoside lamivudine, inhibits reverse transcriptase activity of both HIV and HBV and is a potent and effective agent for patients with chronic hepatitis B. In clinical trials among patients with HBeAg-reactive chronic hepatitis B, lamivudine

therapy at daily doses of 100 mg for 48–52 weeks suppressed HBV DNA by a median of approximately $5.5 \log_{10}$ copies/mL and to undetectable levels, as measured by PCR amplification assays, in approximately 40% of patients. Therapy was associated with HBeAg loss in 32–33%; HBeAg seroconversion (i.e., conversion from HBeAg-reactive to anti-HBe-reactive) in 16–21%; normalization of ALT in 40–75%; improvement in histology in 50–60%; retardation in fibrosis in 20–30%; and prevention of progression to cirrhosis. HBeAg responses can occur even in subgroups who are resistant to IFN (e.g., those with high-level HBV DNA) or who failed in the past to respond to it. As is true for IFN therapy of chronic hepatitis B, patients with near-normal ALT activity tend not to experience HBeAg responses (despite suppression of HBV DNA), and those with ALT levels exceeding five times the upper limit of normal can expect 1-year HBeAg seroconversion rates of 50–60%. Generally, HBeAg seroconversions are confined to patients who achieve suppression of HBV DNA to $<10^4$ genomes/mL. Among patients who undergo HBeAg responses during a year-long course of therapy and in whom the response is sustained for 4–6 months after cessation of therapy, the response is durable thereafter in the vast majority, $>80\%$; therefore, the achievement of an HBeAg response represents a viable stopping point in therapy. Reduced durability has been reported in some Asian experiences; however, in most western and Asian patient study populations, long-term durability of HBeAg responses is the rule, which, at least in Western patients, is accompanied by a posttreatment HBsAg seroconversion rate comparable to that seen after IFN-induced HBeAg responses. If HBeAg is unaffected by lamivudine therapy, the current approach is to continue therapy until an HBeAg response occurs, but long-term therapy may be required to suppress HBV replication and, in turn, limit liver injury; HBeAg seroconversions can increase to a level of 50% after 5 years of therapy. Histologic improvement continues to accrue with therapy beyond the first year; after a cumulative course of 3 years of lamivudine therapy, necroinflammatory activity is reduced in the majority of patients, and even cirrhosis has been shown to regress to precirrhotic stages.

Losses of HBsAg have been few during the first year of lamivudine therapy, and this observation had been cited as an advantage of IFN over lamivudine; however, in head-to-head comparisons between standard IFN and lamivudine monotherapy, HBsAg losses were rare in both groups. Trials in which lamivudine and interferon were administered in combination failed to show a benefit of combination therapy over lamivudine monotherapy for either treatment-naïve patients or prior interferon nonresponders.

In patients with *HBeAg-negative chronic hepatitis B*, i.e., in those with precore and core-promoter HBV mutations, 1 year of lamivudine therapy results in HBV DNA suppression and normalization of ALT in three-quarters of patients and in histologic improvement in approximately two-thirds. Therapy has been shown to suppress

HBV DNA by approximately $4.5 \log_{10}$ copies/mL (baseline HBV DNA levels are lower than in patients with HBeAg-reactive hepatitis B) and to undetectable levels in 70%, as measured by sensitive PCR amplification assays. Lacking HBeAg at the outset, patients with HBeAg-negative chronic hepatitis B cannot achieve an HBeAg response—a stopping point in HBeAg-reactive patients; invariably, when therapy is discontinued, reactivation is the rule. Therefore, these patients require long-term therapy; with successive years, the proportion with suppressed HBV DNA and normal ALT increases.

Clinical and laboratory side effects of lamivudine are negligible, indistinguishable from those observed in placebo recipients. During lamivudine therapy, transient ALT elevations, resembling those seen during IFN therapy and during spontaneous HBeAg-to-anti-HBe seroconversions, occur in a quarter of patients. These ALT elevations may result from restored cytolytic T cell activation permitted by suppression of HBV replication. Similar ALT elevations, however, occur at an identical frequency in placebo recipients, but ALT elevations associated with HBeAg seroconversion are confined to lamivudine-treated patients. When therapy is stopped after a year of therapy, two- to threefold ALT elevations occur in 20–30% of lamivudine-treated patients, representing renewed liver-cell injury as HBV replication returns. Although these posttreatment flares are almost always transient and mild, rare severe exacerbations, especially in cirrhotic patients, have been observed, mandating close and careful clinical and virologic monitoring after discontinuation of treatment. Many authorities caution against discontinuing therapy in patients with cirrhosis, in whom posttreatment flares could precipitate decompensation.

Long-term monotherapy with lamivudine is associated with methionine-to-valine (M204V) or methionine-to-isoleucine (M204I) mutations, primarily at amino acid 204 in the tyrosine-methionine-aspartate-aspartate (YMDD) motif of HBV DNA polymerase, analogous to mutations that occur in HIV-infected patients treated with this drug. During a year of therapy, YMDD mutations occur in 15–30% of patients; the frequency increases with each year of therapy, reaching 70% at year 5. Although resistance to lamivudine may not lead to immediate loss of antiviral effect, patients with YMDD mutants ultimately experience degradation of clinical, biochemical, and histologic responses. Therefore, if treatment is begun with lamivudine monotherapy, the emergence of lamivudine resistance, reflected clinically by a breakthrough from suppressed levels of HBV DNA and ALT, is managed by adding another antiviral to which YMDD variants are sensitive (e.g., adefovir; see below).

Currently, although lamivudine is very safe and still used widely in other parts of the world, in the United States and Europe lamivudine has been eclipsed by more potent antivirals that have superior resistance profiles (see below). Still, as the first successful oral antiviral agent for use in hepatitis B, lamivudine has provided proof of the concept that polymerase inhibitors can achieve both virologic, serologic, biochemical, and

histologic benefit. In addition, lamivudine has been shown to be effective in the treatment of patients with decompensated hepatitis B (for whom IFN is contraindicated), in some of whom decompensation can be reversed. Moreover, among patients with cirrhosis or advanced fibrosis, lamivudine has been shown to be effective in reducing the risk of progression to hepatic decompensation and, marginally, the risk of HCC.

Because lamivudine monotherapy can result universally in the rapid emergence of YMDD variants in persons with HIV infection, patients with chronic hepatitis B should be tested for anti-HIV prior to therapy; if HIV infection is identified, lamivudine monotherapy at the HBV daily dose of 100 mg is contraindicated. These patients should be treated with triple-drug antiretroviral therapy, including a lamivudine daily dose of 300 mg (Chap. 90). The safety of lamivudine during pregnancy has not been established; however, the drug is not teratogenic in rodents and has been used safely in pregnant women with HIV infection and with HBV infection. Limited data even suggest that administration of lamivudine during the last month of pregnancy to mothers with high-level hepatitis B viremia can reduce the likelihood of perinatal transmission of hepatitis B.

ADEFOVIR DIPIVOXIL The acyclic nucleotide analogue adefovir dipivoxil, the prodrug of adefovir, is a potent antiviral that, at an oral daily dose of 10 mg, reduces HBV DNA by approximately 3.5–4 log₁₀ copies/mL and is equally effective in treatment-naïve patients and IFN nonresponders. In HBeAg-reactive chronic hepatitis B, a 48-week course of adefovir dipivoxil was shown to achieve histologic improvement (and reduce the progression of fibrosis) and normalization of ALT in half of patients, HBeAg seroconversion in 12%, HBeAg loss in 23%, and suppression to an undetectable level of HBV DNA in 20–30%, as measured by PCR. Similar to IFN and lamivudine, adefovir dipivoxil is more likely to achieve an HBeAg response in patients with high baseline ALT; for example, among adefovir-treated patients with ALT level >5 times the upper limit of normal, HBeAg seroconversions occurred in 25%. The durability of adefovir-induced HBeAg responses is high (91% in one study); therefore, HBeAg response can be relied upon as a stopping point for adefovir therapy. Although data on the impact of additional therapy beyond one year are limited, biochemical, serologic, and virologic outcomes improve progressively as therapy is continued.

In patients with *HBeAg-negative chronic hepatitis B*, a 48-week course of 10 mg/d of adefovir dipivoxil resulted in histologic improvement in two-thirds, normalization of ALT in three-quarters, and suppression of HBV DNA to PCR-undetectable levels in half. As was true for lamivudine, because HBeAg responses—a potential stopping point—cannot be achieved in this group, reactivation is the rule when adefovir therapy is discontinued, and indefinite, long-term therapy is required. Treatment beyond the first year consolidates the gain of the first year; after 5 years of therapy, improvement in hepatic inflammation and regression of fibrosis was observed in

three-quarters of patients, ALT was normal in 70%, and HBV DNA was undetectable in almost 70%.

Adefovir contains a flexible acyclic linker instead of the L-nucleoside ring of lamivudine, avoiding steric hindrance by mutated amino acids. In addition, the molecular structure of phosphorylated adefovir is very similar to that of its natural substrate; therefore mutations to adefovir would also affect binding of the natural substrate, dATP. Hypothetically, these are among the reasons that resistance to adefovir dipivoxil is much less likely than resistance to lamivudine; no resistance was encountered in 1 year of clinical-trial therapy. In subsequent years, however, adefovir resistance begins to emerge [asparagine to threonine at amino acid 236 (N236T) and alanine to valine or threonine at amino acid 181 (A181V/T) primarily], occurring in 2.5% after 2 years, but in 29% after 5 years of therapy. Among patients co-infected with HBV and HIV and who have normal CD4+ T cell counts, adefovir dipivoxil is effective in suppressing HBV dramatically (by 5 logs₁₀ in one study). Moreover, adefovir dipivoxil is effective in lamivudine-resistant, YMDD-mutant HBV and can be used when such lamivudine-induced variants emerge. When lamivudine resistance occurs, authorities have debated whether to add adefovir or switch to adefovir; however, adding adefovir, i.e., maintaining lamivudine to preempt the emergence of adefovir resistance, appears to be the favored approach. In this vein, almost invariably, patients with adefovir-mutant HBV respond to lamivudine. When, in the past, adefovir had been evaluated as therapy for HIV infection, doses of 60–120 mg were required to suppress HIV, and at these doses the drug was nephrotoxic. Even at 30 mg/d, creatinine elevations of 44 µmol/L (0.5 mg/dL) occur in 10% of patients; however, at the HBV-effective dose of 10 mg, such elevations of creatinine are rarely encountered. If any nephrotoxicity does occur, it rarely appears before 6–8 months of therapy. Although renal tubular injury is a rare potential side effect, and although creatinine monitoring is recommended during treatment, the therapeutic index of adefovir dipivoxil is high, and the nephrotoxicity observed in clinical trials at higher doses was reversible. For patients with underlying renal disease, adefovir dipivoxil dose reductions are recommended: administration reduced to every 48 h for creatinine clearances of 20–49 mL/min, to every 72 h for creatinine clearances of 10–19 mL/min, and once a week, following dialysis, for patients undergoing hemodialysis. Adefovir dipivoxil is very well tolerated, and ALT elevations during and after withdrawal of therapy are similar to those observed and described above in clinical trials of lamivudine. An advantage of adefovir is its relatively favorable resistance profile; however, it is not as potent as the other approved oral agents, it does not suppress HBV DNA as rapidly or as uniformly as the others, and a small proportion of patients have no demonstrable response to the drug (“primary nonresponders”).

PEGYLATED INTERFERON After long-acting PEG IFN was shown to be effective in the treatment of hepatitis C (see below), this more convenient drug was

evaluated in the treatment of chronic hepatitis B. Preliminary trials documented that once-a-week PEG IFN was more effective than the more frequently administered, standard IFN, following which several large-scale trials were conducted among patients with HBeAg-reactive and HBeAg-negative chronic hepatitis B.

In HBeAg-reactive chronic hepatitis B, two large-scale studies were done, one with PEG IFN- α 2b (100 μ g weekly for 32 weeks, then 50 μ g weekly for another 20 weeks for a total of 52 weeks, with a comparison arm of combination PEG IFN with oral lamivudine) in 307 subjects; the other involved PEG IFN- α 2a (180 μ g weekly for 48 weeks) in 814 primarily Asian patients confined to those with ALT $\geq 2 \times$ the upper limit of normal, with comparison arms of lamivudine monotherapy and combination PEG IFN plus lamivudine. At the end of therapy (48–52 weeks) in the PEG IFN monotherapy arms, HBeAg loss occurred in approximately 30%, HBeAg seroconversion in 22–27%, undetectable HBV DNA (<400 copies/mL by PCR) in 10–25%, normal ALT in 34–39%, and a mean reduction in HBV DNA of 2 log₁₀ copies/mL (PEG IFN- α 2b) to 4.5 log₁₀ copies/mL (PEG IFN- α 2a). Six months after completing PEG IFN monotherapy in these trials, HBeAg losses were present in approximately 35%, HBeAg seroconversion in approximately 30%, undetectable HBV DNA in 7–14%, normal ALT in 32–41%, and a mean reduction in HBV DNA of 2–2.4 log₁₀ copies/mL. Although the combination of PEG IFN and lamivudine was superior at the end of therapy in one or more serologic, virologic, or biochemical outcomes, neither the combination arm (in both studies) nor the lamivudine monotherapy arm (in the PEG IFN- α 2a trial) demonstrated any benefit compared to the PEG IFN monotherapy arms 6 months after therapy. Moreover, HBsAg seroconversion occurred in 3–7% of PEG IFN recipients (with or without lamivudine); some of these seroconversions were identified by the end of therapy, but many were identified during the posttreatment follow-up period. The likelihood of HBeAg loss in PEG IFN-treated HBeAg-reactive patients is associated with HBV genotype A > B > C > D.

Based on these results, some authorities concluded that PEG IFN monotherapy should be the first-line therapy of choice in HBeAg-reactive chronic hepatitis B; however, this conclusion has been challenged. Although a finite, 1-year course of PEG IFN results in a higher rate of sustained response (6 months after treatment) than is achieved with oral nucleoside/nucleotide analogue therapy, the comparison is confounded by the fact that oral agents are not discontinued at the end of a year. Instead, taken orally and free of side effects, therapy with oral agents is extended indefinitely or until after the occurrence of an HBeAg response. The rate of HBeAg responses after 2 years of oral-agent therapy is at least as high as, if not higher than, that achieved with PEG IFN after 1 year; favoring oral agents is the absence of injections and difficult-to-tolerate side effects as well as lower direct and indirect medical costs and inconvenience. The association of HBsAg responses with PEG

IFN therapy occurs in such a small proportion of patients that subjecting everyone to PEG IFN for the marginal gain of HBsAg responses during or immediately after therapy in such a very small minority is questionable. Moreover, HBsAg responses occur in a comparable proportion of nucleoside/nucleotide-treated patients in the years after therapy. Of course, resistance is not an issue during PEG IFN therapy, but the risk of resistance is much lower with new agents (none recorded after 2 years in previously treatment-naïve entecavir-treated patients; see below). Finally, the level of HBV DNA inhibition that can be achieved with the newer agents, and even with lamivudine, exceeds that which can be achieved with PEG IFN, in some cases by several orders of magnitude.

In HBeAg-negative chronic hepatitis B, a trial of PEG IFN- α 2a (180 μ g weekly for 48 weeks versus comparison arms of lamivudine monotherapy and of combination therapy) in 564 patients showed that PEG IFN monotherapy resulted at the end of therapy in suppression of HBV DNA by a mean of 4.1 log₁₀ copies/mL, undetectable HBV DNA (<400 copies/mL by PCR) in 63%, and normal ALT in 38%. Although lamivudine monotherapy and combination lamivudine-PEG IFN therapy were both superior to PEG IFN at the end of therapy, no advantage of lamivudine monotherapy or combination therapy was apparent over PEG IFN monotherapy 6 months after therapy—suppression of HBV DNA by a mean of 2.3 log₁₀ copies/mL, undetectable HBV DNA in 19%, and normal ALT in 59%. As was the case for standard IFN therapy in HBeAg-negative patients, after longer periods of post-PEG IFN treatment observation, sustained response rates fell substantially, raising questions about the value of a finite period of PEG IFN in these patients.

ENTECAVIR Entecavir, an oral guanosine analogue polymerase inhibitor, appears to be the most potent of the HBV antivirals and is just as well tolerated as lamivudine. In a 709-subject clinical trial among HBeAg-reactive patients, oral entecavir, 0.5 mg daily, was compared to lamivudine, 100 mg daily. At 48 weeks, entecavir was superior to lamivudine in suppression of HBV DNA, mean 6.9 versus 5.5 log₁₀ copies/mL and in percent with undetectable HBV DNA (<300 copies/mL by PCR), 67% versus 36%; histologic improvement (≥ 2 -point improvement in necroinflammatory HAI score), 72% versus 62%; and normal ALT (68% versus 60%). The two treatments were indistinguishable in percent with HBeAg loss (22% versus 20%) and seroconversion (21% versus 18%). Among patients treated with entecavir for 96 weeks, HBV DNA was undetectable cumulatively in 80% (versus 39% for lamivudine), and HBeAg seroconversions had occurred in 31% (versus 26% for lamivudine). Similarly, in a 638-subject clinical trial among HBeAg-negative patients, at week 48, oral entecavir, 0.5 mg daily, was superior to lamivudine, 100 mg daily, in suppression of HBV DNA, mean 5.0 versus 4.5 log₁₀ copies/mL and in percent with undetectable HBV DNA, 90% versus 72%; histologic improvement, 78% versus 71% and normal

ALT, 68% versus 60%. No resistance mutations were encountered in previously treatment-naïve entecavir-treated patients during 96 weeks of therapy.

Entecavir is also effective against lamivudine-resistant HBV infection. In a trial of 286 lamivudine-resistant patients, entecavir, at a higher daily dose of 1.0 mg, was superior to lamivudine, as measured at week 48, in achieving suppression of HBV DNA (mean 5.1 versus 0.48 log₁₀ copies/mL); undetectable HBV DNA, in 72% versus 19%; normal ALT, in 61% versus 15%; HBeAg loss, in 10% versus 3%; and HBeAg seroconversion, in 8% versus 3%. In this population of lamivudine-experienced patients, however, entecavir resistance did emerge in 7% at 48 weeks and in 9% at 96 weeks. Therefore, entecavir is not as attractive a choice as adefovir (or off-label tenofovir) for patients with lamivudine-resistant hepatitis B.

At the end of 2 years of entecavir therapy in clinical trials among HBeAg-reactive patients, HBsAg seroconversion were observed in 5% ($\leq 2\%$ during the first year). In addition, on-treatment and posttreatment ALT flares are relatively uncommon and relatively mild in entecavir-treated patients.

A comparison of the four antiviral therapies in current use appears in **Table 93-3**.

COMBINATION THERAPY Although the combination of lamivudine and PEG IFN suppresses HBV DNA more profoundly during therapy than does monotherapy with either drug alone (and is much less likely to be associated with lamivudine resistance), this combination used for a year is no better than a year of PEG IFN in achieving sustained responses. To date, combinations of oral nucleoside/nucleotide agents have not achieved an enhancement in virologic, serologic, or biochemical efficacy over that achieved by the more potent of the combined drugs given individually. On the other hand, combining agents that are not cross-resistant (e.g., lamivudine and adefovir) has the potential to reduce the risk or perhaps even to preempt entirely the emergence of drug resistance. In the future, the treatment paradigm is likely to shift from the current approach of sequential monotherapy to preemptive combination therapy; clinical trials are warranted.

TREATMENT RECOMMENDATIONS Several learned societies and groups of expert physicians have issued treatment recommendations for patients with chronic hepatitis B. Although the recommendations differ slightly, a consensus has emerged on most of the important points (**Table 93-4**). No treatment is recommended or available for inactive “nonreplicative” hepatitis B carriers (undetectable HBeAg with normal ALT and HBV DNA $<10^4$ copies/mL documented serially over time). In patients with detectable HBeAg and HBV DNA levels $\geq 10^5$ copies/mL, treatment is recommended for those with elevated ALT levels (some authorities require the elevation to be at least twice the upper limit of normal). For those patients with normal ALT (or $\leq 2 \times$ the upper limit of normal), in whom sustained responses are not likely and who would require multiyear therapy,

antiviral therapy is not recommended currently. For patients with HBeAg-negative chronic hepatitis B, elevated ALT ($\geq 2 \times$ the upper limit of normal according to some authorities), and HBV DNA $\geq 10^4$ (or 10^5 according to some authorities) copies/mL, antiviral therapy is recommended. If HBV DNA is $<10^4$ – 10^5 and ALT is normal (or near normal), treatment is not recommended; however, if HBV DNA is $\geq 10^4$ copies/mL but ALT is normal or near normal, some would recommend considering liver biopsy and basing a decision to treat on the presence of substantial liver injury.

For patients with compensated cirrhosis, because antiviral therapy has been shown to retard clinical progression, many authorities would choose to treat regardless of HBeAg status, HBV DNA level and ALT; however, some authorities favor monitoring without therapy for those with HBV DNA levels $<10^4$ copies/mL. For patients with decompensated cirrhosis, treatment is recommended by some authorities regardless of serologic, virologic, and biochemical status; however, other experts do not recommend therapy if HBV DNA is undetectable or low ($<10^5$ copies/mL). At the same time, patients with decompensated cirrhosis should be evaluated as candidates for liver transplantation.

Among the five available drugs for hepatitis B, PEG IFN has supplanted standard IFN. Because entecavir has been proved superior to lamivudine in clinical trials, entecavir has supplanted lamivudine in some countries. PEG IFN, lamivudine, adefovir, and entecavir can each be used as first-line therapy (Table 93-3). PEG IFN requires finite-duration therapy, achieves the highest rate of HBeAg responses after a year of therapy, and does not support viral mutations, but it requires subcutaneous injections and is associated with inconvenience and intolerability. Lamivudine, adefovir, and entecavir require long-term therapy in most patients, and when used alone, lamivudine fosters the emergence of viral mutations, adefovir much less so, and entecavir rarely at all, except in lamivudine-experienced patients. These oral agents do not require injections, are very well tolerated, lead to improved histology in 50–90% of patients, for the most part suppress HBV DNA more profoundly than does PEG IFN, and are effective even in patients who fail to respond to IFN-based therapy. Although these oral agents are less likely to result in HBeAg responses during the first year of therapy, as compared to PEG IFN, treatment with oral agents tends to be extended beyond the first year and, by the end of the second year, yields HBeAg responses (and even HBsAg responses) comparable in frequency to those achieved after 1 year of PEG IFN (and without the associated side effects). Although adefovir is safe, creatinine monitoring is recommended. Substantial experience with lamivudine during pregnancy (see above) has identified no teratogenicity. Standard IFN does not appear to cause congenital anomalies, and data on the safety of PEG IFN during pregnancy are not available. Adefovir during pregnancy has not been associated with birth defects; however, there may be an increased risk of spontaneous abortion.

TABLE 93-3

COMPARISON OF INTERFERON (PEG IFN), LAMIVUDINE, ADEFOVIR, AND ENTECAVIR THERAPY FOR CHRONIC HEPATITIS B^a

| FEATURE | PEG IFN ^b | LAMIVUDINE | ADEFOVIR | ENTECAVIR |
|--|------------------------|----------------------------------|---|-----------------------------|
| Route of administration | Subcutaneous injection | Oral | Oral | Oral |
| Duration of therapy ^c | 48–52 weeks | ≥52 weeks | ≥48 weeks | ≥48 weeks |
| Tolerability | Poorly tolerated | Well tolerated | Well tolerated; creatinine monitoring recommended | Well tolerated |
| HBeAg loss 1 year | 29–30% | 20–33% | 23% | 22% |
| HBeAg seroconversion | | | | |
| 1 year Rx | 18–20% | 16–21% | 12% | 21% |
| >1 year Rx | NA | Up to 50% @ 5 years | 43% @ 3 years ^d | 31% @ 2 years |
| HBeAg seroconversion if ALT >5 × normal | Not reported | >50% | 21% | Not reported |
| Log ₁₀ HBV DNA reduction (mean copies/mL) | | | | |
| HBeAg-reactive | 4.5 | 5.5 | Median 3.5–5 | 6.9 |
| HBeAg-negative | 4.1 | 4.4–4.7 | Median 3.5–3.9 | 5.0 |
| HBV DNA PCR negative (<300–400 copies/mL; <1,000 copies/mL for adefovir) end of year 1 | | | | |
| HBeAg-reactive | 10–25% | 36–40% | 12–21% | 69% (80% @ 2 years) |
| HBeAg-negative | 63% | 39–73% | 51% (79% @ 3 years) | 90% |
| ALT normalization at end of year 1 | | | | |
| HBeAg-reactive | 39% | 41–75% | 58% (81% @ 3 years) | 78% |
| HBeAg-negative | 34–38% | 62–79% | 48% (69% @ 3 years) | 78% |
| HBsAg loss during year 1 | 0–7% | 0–4% | 0% (1–2% @ 2 years) | 2% (5% @ 2 years) |
| HBsAg loss after therapy | 3–7% after 6 months | 23% after 2 years | Not reported | Not reported |
| Histologic improvement (≥2 point reduction in HAI) at year 1 | | | | |
| HBeAg-reactive | 38% 6 months after | 51–62% | 53% | 62% |
| HBeAg-negative | 48% 6 months after | 61–66% | 64% | 70% |
| Viral resistance | None | 15–30% @ 1 year 70% @ 5 years | None @ 1 year 29% @ 5 years | None @ 2 years ^e |
| Durability of response 4–6 months after therapy ^f | | | | |
| HBeAg-reactive | Limited data | 70–80% | 91% | 82% |
| HBeAg-negative | 36% | 23–35% | Low | 48% |
| Cost (U.S. \$) for 1 year | ~\$18,000 | ~\$2,500 | ~\$6,500 | ~\$8,700 ^g |

^aGenerally, these comparisons are based on data on each drug tested individually versus placebo in registration clinical trials. With rare exception, these comparisons are not based on head-to-head testing of these drugs, hence relative advantages and disadvantages should be interpreted cautiously.

^bAlthough standard interferon α administered daily or three times a week is approved as therapy for chronic hepatitis B, it has been supplanted by pegylated interferon (PEG IFN), which is administered once a week and is more effective. Standard interferon has no advantages over PEG IFN.

^cDuration of therapy in clinical efficacy trials; use in clinical practice may vary.

^dBecause of a computer-generated randomization error that resulted in misallocation of drug versus placebo during the second year of clinical treatment, the frequency of HBeAg seroconversion beyond the first year is an estimate (Kaplan-Meier analysis) based on the small subset in whom adefovir was administered correctly.

^e7% during a year of therapy (9% during 2 years) in lamivudine-resistant patients.

^fIn HBeAg-reactive patients, durability of HBeAg seroconversion; in HBeAg-negative patients, durability of virologic (HBV DNA undetectable by PCR) and biochemical (normal ALT) response.

^g~17,400 for lamivudine-refractory patients.

Note: ALT, alanine aminotransferase; HAI, histologic activity index; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; NA, not applicable; Rx, therapy; PCR, polymerase chain reaction.

TABLE 93-4

RECOMMENDATIONS FOR TREATMENT OF CHRONIC HEPATITIS B

| HBeAg STATUS | CLINICAL | HBV DNA (COPIES/ML) | ALT | RECOMMENDATION |
|----------------|-----------------------------------|--|---|--|
| HBeAg-reactive | ^a Chronic hepatitis | <10 ⁵ ≥10 ⁵ | Normal (≤2 × ULN) ^b Normal (≤2 × ULN) ^{b, c} | No treatment; monitor No treatment; current treatment of limited benefit (some suggest liver biopsy and treating if abnormal) |
| | Chronic hepatitis | ≥10 ⁵ | Elevated (>2 × ULN) ^b | Treat ^d |
| | Cirrhosis compensated | + or – ^e | Normal or elevated | Treat ^e with oral agents, ^f not PEG IFN |
| | Cirrhosis decompensated | + or – ^e | Normal or elevated | Treat ^e with oral agents, ^g not PEG IFN; refer for liver transplantation |
| HBeAg-negative | ^a Chronic hepatitis | <10 ⁴ or 10 ^{5h} ≥10 ⁴ or 10 ^{5h} | Normal (≤2 × ULN) ^b Normal | Inactive carrier; treatment not necessary Consider liver biopsy; treat if biopsy abnormal |
| | Chronic hepatitis | ≥10 ⁴ or 10 ^{5h} | Elevated (>2 × ULN) ^b | Treat ⁱ |
| | Cirrhosis compensated | + or – | Elevated or normal | Treat with oral agents, ^j not PEG IFN (some authorities recommend either following or treating for HBV DNA <10 ⁴ copies/mL) |
| | Cirrhosis decompensated | + or – | Elevated or normal | Treat with oral agents, ^j not PEG IFN (some authorities would follow without therapy for undetectable HBV DNA; refer for liver transplantation) |
| | | | | |

^aLiver disease tends to be mild or inactive clinically; most such patients do not undergo liver biopsy.

^bIn some guidelines, ALT categories are normal or elevated; in others, ALT categories are ≤ or > 2 times the upper limit of normal.

^cTypical pattern in childhood-acquired infection, common in Asian populations.

^dAny of the oral drugs (lamivudine, adefovir, entecavir) or PEG IFN can be used as first-line therapy (see text); although still used extensively in some parts of the world, lamivudine has been supplanted in some countries as first-line therapy because of its resistance profile. The oral agents, but not PEG IFN, should be used for interferon-refractory/intolerant and immunocompromised patients. PEG IFN is administered weekly by subcutaneous injection for a year; the oral agents are administered daily for at least a year and continued indefinitely or until at least 6 months after HBeAg seroconversion.

^eTreating or monitoring without therapy are options for patients with HBV DNA <10⁴ or <10⁵ copies/mL.

^fSome authorities would observe without treatment if HBV DNA is undetectable (<10⁴ copies/mL), while others would treat regardless of the HBV DNA status. Lamivudine monotherapy is not an attractive choice because of its resistance profile.

^gSome authorities recommend treating regardless of HBV DNA status, while others suggest referring for liver transplantation, without treatment, for those with undetectable HBV DNA (<10⁵ copies/mL). Lamivudine is a less attractive choice because of its resistance profile. Because the emergence of resistance can lead to loss of antiviral benefit and further deterioration in decompensated cirrhosis, some authorities recommend combination therapy (e.g., lamivudine or entecavir plus adefovir) for patients with decompensated cirrhosis.

^hSome authorities rely on a cutoff of 10⁴ copies/mL, while others choose 10⁵ copies/mL.

ⁱBecause HBeAg seroconversion is not an option, the goal of therapy is to suppress HBV DNA and maintain a normal ALT. Although any of the oral agents or PEG IFN can be used as first-line therapy, lamivudine is less favored because of its resistance profile and the need, in the vast majority of cases, for long-term therapy. PEG IFN is administered by subcutaneous injection weekly for a year (caution is warranted in relying on a 6-month posttreatment interval to define a sustained response; the majority of such responses are lost thereafter). Adefovir and entecavir are administered daily, usually indefinitely or, until, as occurs very rarely, virologic and biochemical responses are accompanied by an HBsAg seroconversion.

^jLow-resistance regimen favored (i.e., adefovir or entecavir, not lamivudine) indefinitely.

Note: ALT, alanine aminotransferase; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; ULN, upper limits of normal; PEG IFN, pegylated interferon.

Data on the safety of entecavir during pregnancy have not been published. In general, except perhaps for lamivudine, and until additional data become available, the other antivirals for hepatitis B should be avoided or used with extreme caution during pregnancy.

As noted above, some physicians prefer to begin with PEG IFN, while other physicians and patients prefer oral

agents as first-line therapy. For patients with decompensated cirrhosis, the emergence of resistance can result in further deterioration and loss of antiviral effectiveness. Therefore, in this patient subset, the threshold for relying on therapy with a very favorable resistance profile (e.g., entecavir) or on combination therapy (e.g., lamivudine or entecavir along with adefovir or the yet-to-be-approved

tenofovir) is low. PEG IFN should not be used in patients with compensated or decompensated cirrhosis.

For patients with end-stage chronic hepatitis B who undergo liver transplantation, reinfection of the new liver is almost universal in the absence of antiviral therapy. The majority of patients become high-level viremic carriers with minimal liver injury. Before the availability of antiviral therapy, an unpredictable proportion experienced severe hepatitis B–related liver injury, sometimes a fulminant-like hepatitis, sometimes a rapid recapitulation of the original severe chronic hepatitis B. Currently, however, prevention of recurrent hepatitis B after liver transplantation has been achieved definitively by *combining* hepatitis B immune globulin with one of the oral nucleoside or nucleotide analogues (lamivudine, adefovir, or entecavir).

Patients with HBV-HIV co-infection can have progressive HBV-associated liver disease and, occasionally, a severe exacerbation of hepatitis B resulting from immunologic reconstitution following highly active antiretroviral therapy. Lamivudine should never be used as monotherapy in patients with HBV-HIV infection, because HIV resistance emerges rapidly to both viruses. Adefovir and entecavir have been used successfully to treat chronic hepatitis B in HBV-HIV co-infected patients. Tenofovir and the combination of tenofovir and emtricitabine in one pill are approved therapies for HIV and represent excellent choices for treating HBV infection in HBV-HIV co-infected patients.

Patients with chronic hepatitis B who undergo cytotoxic chemotherapy for treatment of malignancies experience enhanced HBV replication and viral expression on hepatocyte membranes during chemotherapy coupled with suppression of cellular immunity. When chemotherapy is withdrawn, such patients are at risk for reactivation of hepatitis B, often severe and occasionally fatal. Such rebound reactivation represents restoration of cytolytic T-cell function against a target organ enriched in HBV expression. Preemptive treatment with lamivudine prior to the initiation of chemotherapy has been shown to reduce the risk of such reactivation. In all likelihood, the newer, more potent oral antiviral agents will work as well and with a lower risk of antiviral drug resistance. The optimal duration of antiviral therapy after completion of chemotherapy is not known, but some authorities have suggested 3 months.

NOVEL ANTIVIRALS AND STRATEGIES In addition to the five approved antiviral drugs for hepatitis B, several others are being evaluated in clinical trials, as listed in [Table 93-5](#). Telbivudine, a cytosine analogue, appears to be similar in efficacy to entecavir but slightly less potent in suppressing HBV DNA, and it is associated with low-level resistance (M204I, not M204V mutations). This drug was approved in October 2006. Resistance mutations after 2 years of treatment occur in ~20%. Tenofovir, a nucleotide analogue, is similar to adefovir but more potent in suppressing HBV DNA and inducing HBeAg responses; it is highly active against both wild-type and lamivudine-resistant HBV and active in

TABLE 93-5
NEW ANTIVIRAL DRUGS BEING DEVELOPED FOR THE TREATMENT OF CHRONIC HEPATITIS B

^aApproved in October 2006.

^bActive against lamivudine-associated YMDD-mutant HBV. (YMDD, tyrosine-methionine-aspartate-aspartate.)

patients with primary nonresponse to adefovir. Its safety and resistance profile are very favorable as well; in all likelihood, it will supplant adefovir once comparisons in clinical trials are complete. Emtricitabine is a fluorinated cytosine analogue very similar to lamivudine in structure, efficacy, and resistance profile. A combination of emtricitabine and tenofovir is approved for the treatment of HIV infection and is an appealing combination therapy for hepatitis B; however, neither emtricitabine nor the combination are approved yet for hepatitis B. Clevudine is a pyrimidine nucleoside analogue whose potency in the woodchuck model of hepatitis B is higher than that of any other antiviral agent; however, in human trials, maximal HBV DNA suppression has been 5 log₁₀ copies/mL; after clevudine therapy, HBV DNA is much slower to rebound than after withdrawal of other agents. Because direct-acting antivirals have been so successful in the management of chronic hepatitis B, more unconventional approaches—e.g., immunologic or genetic manipulation—are not likely to be competitive. Finally, initial emphasis in the development of antiviral therapy for hepatitis B was placed on monotherapy; however, in the future, with or without additive or synergistic efficacy, combination therapy regimens that prevent resistance are likely to become the norm.

CHRONIC HEPATITIS D (DELTA HEPATITIS)

Chronic hepatitis D (HDV) may follow acute co-infection with HBV but at a rate no higher than the rate of chronicity of acute hepatitis B. That is, although HDV co-infection can increase the severity of acute hepatitis B, HDV does not increase the likelihood of progression to chronic hepatitis B. When, however, HDV superinfection occurs in a person who is already chronically infected with HBV, long-term HDV infection is the rule and a worsening of the liver disease the expected consequence. Except for severity, chronic hepatitis B plus D has similar clinical and laboratory features to those seen in chronic hepatitis B alone. Relatively severe chronic hepatitis, with or without cirrhosis, is the rule, and mild chronic hepatitis is the exception. Occasionally, mild hepatitis or even, rarely, inactive carriage occurs in patients with chronic hepatitis B plus D, and the disease may become indolent after several years of infection. A distinguishing serologic feature of chronic hepatitis D is the presence in the circulation of antibodies

to liver-kidney microsomes (anti-LKM); however, the anti-LKM seen in hepatitis D, anti-LKM3, are directed against uridine diphosphate glucuronosyltransferase and are distinct from anti-LKM1 seen in patients with autoimmune hepatitis and in a subset of patients with chronic hepatitis C (see below). The clinical and laboratory features of chronic HDV infection are summarized in Chap. 92.

R_x Treatment: **CHRONIC HEPATITIS D**

Management is not well defined. Glucocorticoids are ineffective and are not used. Preliminary experimental trials of IFN- α suggested that conventional doses and durations of therapy lower levels of HDV RNA and aminotransferase activity only transiently during treatment but have no impact on the natural history of the disease. In contrast, high-dose IFN- α (9 million units three times a week) for 12 months may be associated with a sustained loss of HDV replication and clinical improvement in up to 50% of patients. Moreover, the beneficial impact of treatment has been observed to persist for 15 years and to be associated with a reduction in grade of hepatic necrosis and inflammation, reversion of advanced fibrosis (improved stage), and clearance of HDV RNA in some patients. A suggested approach to therapy has been high-dose, long-term IFN for at least a year and, in responders, extension of therapy until HDV RNA and HBsAg clearance. Although experience with PEG IFN in the treatment of chronic hepatitis D is limited, if future studies confirm its equivalence to, or superiority over, standard IFN, PEG IFN is likely to become a more convenient replacement for standard IFN. None of the new antiviral agents for hepatitis B—lamivudine, adefovir, entecavir—are effective in hepatitis D; however, preliminary indications in the woodchuck model of hepatitis B are that clevudine may be. In patients with end-stage liver disease secondary to chronic hepatitis D, liver transplantation has been effective. If hepatitis D recurs in the new liver without the expression of hepatitis B (an unusual serologic profile in immunocompetent persons but common in transplant patients), liver injury is limited. In fact, the outcome of transplantation for chronic hepatitis D is superior to that for chronic hepatitis B.

CHRONIC HEPATITIS C

Regardless of the epidemiologic mode of acquisition of hepatitis C virus (HCV) infection, chronic hepatitis follows acute hepatitis C in 50–70% of cases; chronic infection is common even in those with a return to normal in aminotransferase levels after acute hepatitis C, adding up to an 85% likelihood of chronic HCV infection after acute hepatitis C. Furthermore, in patients with chronic transfusion-associated hepatitis followed for 10–20 years, progression to cirrhosis occurs in about 20%. Such is the case even for patients with relatively

clinically mild chronic hepatitis, including those without symptoms, with only modest elevations of aminotransferase activity and with mild chronic hepatitis on liver biopsy. Even in cohorts of well-compensated patients with chronic hepatitis C referred for clinical research trials (no complications of chronic liver disease and with normal hepatic synthetic function), the prevalence of cirrhosis may be as high as 50%. Most cases of hepatitis C are identified initially in asymptomatic patients who have no history of acute hepatitis C, e.g., those discovered while attempting to donate blood, while undergoing lab testing as part of an application for life insurance, or as a result of routine laboratory tests. The source of HCV infection in many of these cases is not defined, although a long-forgotten percutaneous exposure in the remote past can be elicited in a substantial proportion and probably accounts for most infections; most of these infections were acquired in the 1960s and 1970s, coming to clinical attention decades later.

Approximately a third of patients with chronic hepatitis C have normal or near-normal aminotransferase activity; although a third to a half of these patients have chronic hepatitis on liver biopsy, the grade of liver injury and stage of fibrosis tend to be mild in the vast majority. In some cases, more severe liver injury has been reported—even, rarely, cirrhosis, most likely the result of previous histologic activity. Among patients with persistent normal aminotransferase activity sustained over ≥ 5 –10 years, histologic progression has been shown not to occur; however, approximately a quarter of patients with normal aminotransferase activity experience subsequent aminotransferase elevations, and histologic injury can be progressive once abnormal biochemical activity resumes. Therefore, continued clinical monitoring is indicated, even for patients with normal aminotransferase activity.

Despite this substantial rate of progression of chronic hepatitis C, and despite the fact that liver failure can result from end-stage chronic hepatitis C, the long-term prognosis for chronic hepatitis C in a majority of patients is relatively benign. Mortality over 10–20 years among patients with transfusion-associated chronic hepatitis C has been shown not to differ from mortality in a matched population of transfused patients in whom hepatitis C did not develop. Although death in the hepatitis group is more likely to result from liver failure, and although hepatic decompensation may occur in $\sim 15\%$ of such patients over the course of a decade, the majority (almost 60%) of patients remain asymptomatic and well compensated, with no clinical sequelae of chronic liver disease. Overall, then, chronic hepatitis C tends to be very slowly and insidiously progressive, if at all, in the vast majority of patients, while in approximately a quarter of cases, chronic hepatitis C will progress eventually to end-stage cirrhosis. In fact, because HCV infection is so prevalent, and because a proportion of patients progress inexorably to end-stage liver disease, hepatitis C is the most frequent indication for liver transplantation. Referral bias may account for the more severe outcomes described in cohorts of patients reported from tertiary care centers (20-year progression of 20%) versus the more benign outcomes

in cohorts of patients monitored from initial blood-product-associated acute hepatitis or identified in community settings (20-year progression of only 4–7%). Still unexplained, however, are the wide ranges in reported progression to cirrhosis, from 2% over 17 years in a population of women with hepatitis C infection acquired from contaminated anti-D immune globulin to 30% over ≤11 years in recipients of contaminated intravenous immune globulin.

Progression of liver disease in patients with chronic hepatitis C has been reported to be more likely in patients with older age, longer duration of infection, advanced histologic stage and grade, genotype 1, more complex quasispecies diversity, increased hepatic iron, concomitant other liver disorders (alcoholic liver disease, chronic hepatitis B, hemochromatosis, α_1 -antitrypsin deficiency, and steatohepatitis), HIV infection, and obesity. Among these variables, however, duration of infection appears to be the most important, and some of the others probably reflect disease duration to some extent (e.g., quasispecies diversity, hepatic iron accumulation). No other epidemiologic or clinical features of chronic hepatitis C (e.g., severity of acute hepatitis, level of aminotransferase activity, level of HCV RNA, presence or absence of jaundice during acute hepatitis) are predictive of eventual outcome. Despite the relatively benign nature of chronic hepatitis C over time in many patients, cirrhosis following chronic hepatitis C has been associated with the late development, after several decades, of HCC; the annual rate of HCC in cirrhotic patients with hepatitis C is 1–4%, occurring primarily in patients who have had HCV infection for 30 or more years.

Perhaps the best prognostic indicator in chronic hepatitis C is liver histology; the rate of hepatic fibrosis may be slow, moderate, or rapid. Patients with mild necrosis and inflammation as well as those with limited fibrosis have an excellent prognosis and limited progression to cirrhosis. In contrast, among patients with moderate to severe necroinflammatory activity or fibrosis, including septal or bridging fibrosis, progression to cirrhosis is highly likely over the course of 10–20 years. Among patients with compensated cirrhosis associated with hepatitis C, the 10-year survival is close to 80%; mortality occurs at a rate of 2–6% per year, decompensation at a rate of 4–5% per year, and, as noted above, HCC at a rate of 1–4% per year.

Clinical features of chronic hepatitis C are similar to those described above for chronic hepatitis B. Generally, *fatigue* is the most common symptom; jaundice is rare. Immune complex-mediated extrahepatic complications of chronic hepatitis C are less common than in chronic hepatitis B (despite the fact that assays for immune complexes are often positive in patients with chronic hepatitis C), with the exception of essential mixed cryoglobulinemia (Chap. 92). In addition, chronic hepatitis C has been associated with extrahepatic complications unrelated to immune-complex injury. These include Sjögren's syndrome, lichen planus, and porphyria cutanea tarda.

Laboratory features of chronic hepatitis C are similar to those in patients with chronic hepatitis B, but aminotransferase levels tend to fluctuate more (the characteristic

episodic pattern of aminotransferase activity) and to be lower, especially in patients with long-standing disease. An interesting and occasionally confusing finding in patients with chronic hepatitis C is the presence of autoantibodies. Rarely, patients with autoimmune hepatitis (see below) and hyperglobulinemia have false-positive immunoassays for anti-HCV. On the other hand, some patients with serologically confirmable chronic hepatitis C have circulating anti-LKM. These antibodies are anti-LKM1, as seen in patients with autoimmune hepatitis type 2 (see below), and are directed against a 33-amino-acid sequence of cytochrome P450 IID6. The occurrence of anti-LKM1 in some patients with chronic hepatitis C may result from the partial sequence homology between the epitope recognized by anti-LKM1 and two segments of the HCV polypeptide. In addition, the presence of this autoantibody in some patients with chronic hepatitis C suggests that autoimmunity may be playing a role in the pathogenesis of chronic hepatitis C.

Histopathologic features of chronic hepatitis C, especially those that distinguish hepatitis C from hepatitis B, are described in Chap. 92.

Rx Treatment: **CHRONIC HEPATITIS C**

Therapy for chronic hepatitis C has evolved substantially in the decade and a half since IFN- α was introduced for this indication. When first approved, IFN- α was administered via subcutaneous injection three times a week for 6 months but achieved a sustained virologic response (a reduction of HCV RNA to undetectable levels by PCR when measured ≥ 6 months after completion of therapy) below 10%. Doubling the duration of therapy—but not increasing the dose or changing IFN preparations—increased the sustained virologic response rate to ~20%, and addition to the regimen of daily ribavirin, an oral guanosine nucleoside, increased sustained virologic responses to 40%. When used alone, ribavirin is ineffective and does not reduce HCV RNA levels, but ribavirin enhances the efficacy of IFN by reducing the likelihood of virologic relapse after the achievement of an end-treatment response (response measured during, and maintained to the end of, treatment). Proposed mechanisms to explain the role of ribavirin include subtle direct reduction of HCV replication, inhibition of host inosine monophosphate dehydrogenase activity (and associated depletion of guanosine pools), immune modulation, and induction of virologic mutational catastrophe.

Many important lessons about antiviral therapy for chronic hepatitis C were learned from the experience with IFN monotherapy and combination IFN-ribavirin therapy. Even in the absence of biochemical and virologic responses, histologic improvement occurs in approximately three-quarters of all treated patients. In chronic hepatitis C, unlike the case in hepatitis B, responses to therapy are not accompanied by transient, acute hepatitis-like aminotransferase elevations. Instead, ALT levels fall precipitously during therapy. Up to 90% of virologic responses are achieved within the first 12 weeks of

therapy; responses thereafter are rare. Most relapses occur within the first 12 weeks after treatment. Sustained virologic responses are very durable; normal ALT, improved histology, and absence of HCV RNA in serum and liver have been documented 5–6 years after successful therapy, and “relapses” 2 years after sustained responses are almost unheard of. Thus, sustained virologic responses to antiviral therapy of chronic hepatitis C are tantamount to cures.

Patient variables that tend to correlate with sustained virologic responsiveness to IFN include favorable genotype (genotypes 2 and 3 as opposed to genotypes 1 and 4), low baseline HCV RNA level (<2 million copies/mL, which is equivalent to ~800,000 international units/mL, the current convention of quantitation), histologically mild hepatitis and minimal fibrosis, age <40, absence of obesity, and female gender. Patients with cirrhosis can respond, but they are less likely to do so. Studies of combination IFN-ribavirin therapy showed conclusively that in patients with genotype 1, therapy should last a full year, while in those with genotypes 2 and 3, a 6-month course of therapy suffices. The response rate in African Americans is disappointingly low for reasons that remain obscure. Finally, the likelihood of a sustained response is best if adherence to the treatment regimen is high, i.e., if patients receive ≥80% of the IFN and ribavirin doses and if they continue treatment for ≥80% of the anticipated duration of therapy. Other variables reported to correlate with increased responsiveness include brief duration of infection, low HCV quasispecies diversity, immunocompetence, and low liver iron levels. High levels of HCV RNA, more histologically advanced liver disease, and high quasispecies diversity all go hand in hand with advanced duration of infection, which may be the single most important variable determining IFN responsiveness. The ironic fact, then, is that patients whose disease is least likely to progress are the ones *most* likely to respond to interferon and vice versa. Finally, among patients with genotype 1b, responsiveness to IFN is enhanced in those with amino-acid-substitution mutations in the nonstructural protein 5A gene.

Side effects of IFN therapy are described above in the section on treatment of chronic hepatitis B. The most pronounced side effect of ribavirin therapy is hemolysis; a reduction in hemoglobin of up to 2–3 g or in hematocrit of 5–10% can be anticipated. A small, unpredictable proportion of patients experience profound, brisk hemolysis, resulting in symptomatic anemia; therefore, close monitoring of blood counts is crucial, and ribavirin should be avoided in patients with anemia or hemoglobinopathies and in patients with coronary artery disease or cerebrovascular disease, in whom anemia can precipitate an ischemic event. When symptomatic anemia occurs, ribavirin dose reductions or addition of erythropoietin to boost red blood cell levels may be required. In addition, ribavirin, which is renally excreted, should not be used in patients with renal insufficiency; the drug is teratogenic, precluding its use during pregnancy and mandating the scrupulous use of efficient contraception during therapy.

Ribavirin can also cause nasal and chest congestion, pruritus, and precipitation of gout. Combination

IFN-ribavirin therapy is more difficult to tolerate than IFN monotherapy. In one large clinical trial of combination therapy versus monotherapy, among those in the 1-year treatment group, 21% of the combination group (but only 14% of the monotherapy group) had to discontinue treatment, while 26% of the combination group (but only 9% of the monotherapy group) required dose reductions.

Studies of viral kinetics have shown that despite a virion half-life in serum of only 2–3 h, the level of HCV is maintained by a high replication rate of 10^{12} hepatitis C virions per day. IFN- α blocks virion production or release with an efficacy that increases with increasing drug doses; moreover, the calculated death rate for infected cells during IFN therapy is inversely related to viral load; patients with the most rapid death rate of infected hepatocytes are more likely to achieve undetectable HCV RNA at 3 months; achieving this landmark is predictive of a subsequent sustained response. Therefore, to achieve rapid viral clearance from serum and the liver, *high-dose induction therapy* has been advocated. In practice, however, high-dose induction therapy has not yielded higher sustained response rates.

TREATMENT OF CHOICE For the treatment of chronic hepatitis C, standard IFNs have now been supplanted by PEG IFNs. These have elimination times up to sevenfold longer than standard IFNs, i.e., a substantially longer half-life, and achieve prolonged concentrations, permitting administration once (rather than three times) a week. Instead of the frequent drug peaks (linked to side effects) and troughs (when drug is absent) associated with frequent administration of short-acting IFNs, administration of PEG IFNs results in drug concentrations that are more stable and sustained over time. Once-a-week PEG IFN monotherapy is twice as effective as monotherapy with its standard IFN counterpart, approaches the efficacy of combination standard IFN plus ribavirin, and is as well tolerated as standard IFNs, without more difficult-to-manage thrombocytopenia and leukopenia than standard IFNs. The current standard of care, however, is a combination of PEG IFN plus ribavirin.

Two PEG IFNs are available: PEG IFN- α 2b and α 2a. In the registration trial for PEG IFN- α 2b plus ribavirin, the best regimen was 48 weeks of 1.5 μ g/kg of PEG IFN once a week plus 800 mg of ribavirin daily. A post hoc analysis suggested that weight-based dosing of ribavirin would have been more effective than the fixed 800-mg dose used in the study. In the first registration trial for PEG IFN- α 2a plus ribavirin, the best regimen was 48 weeks of 180 μ g of PEG IFN plus 1000 mg (for patients <75 kg) to 1200 mg (for patients ≥75 kg) of ribavirin. Sustained virologic responses of 54 and 56% were reported in these two studies, respectively. A subsequent study of PEG IFN- α 2a plus ribavirin showed that, for patients with genotypes 2 and 3, a duration of 6 months and a ribavirin dose of 800 mg were sufficient. Among the three studies, for patients in the optimal treatment arm, sustained response rates for patients with genotype 1 were

42–51% and for patients with genotypes 2 and 3 rates were 76–82%. Subsequent studies have shown that, in patients with genotypes 2 and 3, if HCV RNA is undetectable at 4 weeks (“rapid virologic response”), the total duration of therapy required to achieve a sustained virologic response can be as short as 12–16 weeks, especially for patients with genotype 2 (less so for those with genotype 3). These clinical trials of abbreviated treatment, however, were conducted with full, weight-based ribavirin doses rather than the current convention of uniform, 800-mg flat dosing; studies of abbreviated-duration therapy with flat ribavirin dosing in patients with genotypes 2 and 3 are awaited. Between genotypes 2 and 3, genotype 3 is somewhat more refractory, and some authorities would extend therapy for a full 48 weeks in patients with genotype 3, especially if they have advanced hepatic fibrosis or cirrhosis and/or high-level HCV RNA.

In the initial registration trials for combination PEG IFN plus ribavirin, both combination PEG IFN regimens were compared to standard IFN- α 2b plus ribavirin. Side effects of the combination PEG IFN- α 2b regimen were comparable to those for the combination standard IFN regimen; however, when the combination PEG IFN- α 2a regimen was compared to the combination standard IFN- α 2b regimen, flulike symptoms and depression were less common in the combination PEG IFN group. Although the two combination PEG IFN regimens were not tested head-to-head, and although ascertainment of side effects differed between studies of the two drugs, when each was tested against standard IFN- α 2b plus ribavirin, combination PEG IFN- α 2a plus ribavirin appeared to be better tolerated. Recommended doses for the two PEG IFNs plus ribavirin and other comparisons between the two therapies are shown in [Table 93-6](#).

Unless ribavirin is contraindicated (see above), combination PEG IFN plus ribavirin is the recommended course of therapy—24 weeks for genotypes 2 and 3 and 48 weeks for genotype 1. Measurement of quantitative HCV RNA levels at 12 weeks is helpful in guiding therapy; if a 2- \log_{10} drop in HCV RNA has not been achieved by this time, chances for a sustained virologic response are negligible. If the 12-week HCV RNA has fallen by two \log_{10} (“early virologic response”), the chances for a sustained virologic response at the end of therapy are approximately two-thirds; if the 12-week HCV RNA is undetectable, the chances for a sustained virologic response exceed 80%. If the goal of therapy is sustained virologic response, failure to achieve a 12-week 2- \log_{10} drop in HCV RNA may be used as a signal to discontinue therapy, especially in those who do not tolerate the drugs well. Still, conceivably, some may achieve histologic benefit in the absence of a virologic response, and some clinicians choose to continue therapy even in the absence of a 2- \log_{10} HCV RNA reduction at 12 weeks. Studies are underway to determine whether, even in the absence of a virologic response, maintenance therapy with PEG IFN can slow histologic and clinical progression of hepatitis C.

Studies have suggested that the frequency of sustained virologic responses to PEG IFN/ribavirin therapy can be increased by raising the dose of ribavirin

TABLE 93-6**PEGYLATED INTERFERON- α -2a AND α -2b FOR CHRONIC HEPATITIS C**

| | PEG IFN- α 2b | PEG IFN- α 2a |
|---|-------------------------------|---------------------------|
| PEG size | 12 kD linear | 40 kD branched |
| Elimination half-life | 54 h | 65 h |
| Clearance | 725 mL/h | 60 mL/h |
| Best dose monotherapy ^a | 1.0 μ g/kg (weight-based) | 180 μ g |
| Best dose combination therapy | 1.5 μ g/kg (weight-based) | 180 μ g |
| Storage | Room temperature | Refrigerated |
| Ribavirin dose | | |
| Genotype 1 | 800 mg ^b | 1000–1200 mg ^c |
| Genotype 2/3 | 800 mg | 800 mg |
| Duration of therapy | | |
| Genotype 1 | 48 weeks | 48 weeks |
| Genotype 2/3 | 48 weeks ^d | 24 weeks |

| Genotype 2/3 | 82% | 76–78% |

^aReserved for patients in whom ribavirin is contraindicated or not tolerated.

^bIn the registration trial for PEG IFN- α 2b plus ribavirin, the optimal regimen was 1.5 μ g of PEG IFN plus 800 mg of ribavirin; however, a post hoc analysis of this study suggested that higher ribavirin doses are better. In addition, data from the study of PEG IFN- α 2a supported weight-based dosing, 1000 mg (for patients weighing <75 kg) and 1200 mg (for patients weighing \geq 75 kg) for genotype 1. Therefore, the higher ribavirin doses are recommended for both types of PEG IFN in patients with genotype 1.

^c1000 mg for patients weighing <75 kg; 1200 mg for patients weighing \geq 75 kg.

^dIn the registration trial for PEG IFN- α 2b plus ribavirin, all patients were treated for 48 weeks; however, data from other trials of standard interferons and the other PEG IFN demonstrated that 24 weeks suffices for patients with genotypes 2 and 3. For patients with genotype 3 who have advanced fibrosis/cirrhosis and/or high-level HCV RNA, a full 48 weeks is preferable.

^eTo date, direct, head-to-head comparisons of the two PEG IFNs have not been reported. Attempts to compare the two PEG IFN preparations based on the results of registration clinical trials are confounded by differences between trials of the two agents in methodological details (different ribavirin doses, different methods for recording depression and other side effects) and study-population composition (different proportion with bridging fibrosis/cirrhosis, proportion from the United States versus international, mean weight, proportion with genotype 1, and proportion with high-level HCV RNA).

Note: HCV RNA, hepatitis C virus RNA; PEG, polyethylene glycol; PEG IFN, pegylated interferon.

(if tolerated or supplemented by erythropoietin) or by tailoring treatment based on viral response to prolong the duration of viral clearance before discontinuing therapy, i.e., extending therapy from 48 to 72 weeks for patients with genotype 1 and a slow virologic response, i.e., those whose HCV RNA has not fallen rapidly to undetectable levels within 4 weeks (absence of “rapid virologic

TABLE 93-7

INDICATIONS AND RECOMMENDATIONS FOR ANTIVIRAL THERAPY OF CHRONIC HEPATITIS C

Standard Indications for Therapy

Detectable HCV RNA (with or without elevated ALT)
Portal/bridging fibrosis or moderate to severe hepatitis on liver biopsy

Retreatment Recommended

Relapsers after a previous course of standard interferon monotherapy or combination standard interferon/ribavirin therapy

A course of PEG IFN plus ribavirin

Nonresponders to a previous course of standard IFN monotherapy or combination standard IFN/ribavirin therapy

A course of PEG IFN plus ribavirin—more likely to achieve a sustained virologic response in Caucasian patients without previous ribavirin therapy, with low baseline HCV RNA levels, with a 2-log₁₀ reduction in HCV RNA during previous therapy, with genotypes 2 and 3, and without reduction in ribavirin dose

Antiviral Therapy Not Recommended Routinely but Management Decisions Made on an Individual Basis

Children (age <18 years)

Age >60

Mild hepatitis on liver biopsy

Long-Term Maintenance Therapy Recommended

Cutaneous vasculitis and glomerulonephritis associated with chronic hepatitis C

Long-Term Maintenance Therapy being Assessed in Clinical Trials

Relapsers

Nonresponders

Antiviral Therapy Not Recommended

Decompensated cirrhosis

Pregnancy (teratogenicity of ribavirin)

Therapeutic Regimens

First-line treatment: PEG IFN subcutaneously once a week plus daily ribavirin orally

HCV genotypes 1 and 4—48 weeks of therapy

PEG IFN- α 2a 180 μ g weekly plus ribavirin 1000 mg/d (weight <75 kg) to 1200 mg/d (weight \geq 75 kg) or

PEG IFN- α 2b 1.5 μ g/kg weekly plus ribavirin 800 mg/d (the dose used in registration clinical trials, but the higher, weight-based ribavirin doses above are recommended for both types of PEG IFN)

HCV genotypes 2 and 3—24 weeks of therapy

PEG IFN- α 2a 180 μ g weekly plus ribavirin 800 mg/d or

PEG IFN- α 2b 1.5 μ g/kg weekly plus ribavirin 800 mg/d (for patients with genotype 3 who have advanced fibrosis and/or high-level HCV RNA, a full 48 weeks of therapy may be preferable)

Alternative regimen: PEG IFN (α 2a 180 μ g or α 2b 1.0 μ g/kg) subcutaneously once a week (primarily for patients in whom ribavirin is contraindicated or not tolerated) for 24 (genotypes 2 and 3) or 48 (genotypes 1 and 4) weeks

For HCV-HIV co-infected patients: 48 weeks, regardless of genotype, of weekly PEG IFN- α 2a (180 μ g) or PEG IFN- α 2b (1.5 μ g/kg) plus a daily ribavirin dose of at least 600–800 mg, up to full weight-based 1000–1200 mg dosing if tolerated

Features Associated with Reduced Responsiveness

Genotype 1

High-level HCV RNA (>2 million copies/mL or >800,000 IU/mL)

Advanced fibrosis (bridging fibrosis, cirrhosis)

Long-duration disease

Age >40

High HCV quasispecies diversity

Immunosuppression

African American

Obesity

Hepatic steatosis

Reduced adherence (lower drug doses and reduced duration of therapy)

Note: ALT, alanine aminotransferase; HCV, hepatitis C virus; IFN, interferon; PEG IFN, pegylated interferon; IU, international units (1 IU/mL is equivalent to ~2.5 copies/mL).

response"). Confirmatory studies are awaited. Tailoring therapy based on the kinetics of HCV RNA reduction has also been applied to abbreviating the duration of therapy in patients with genotype 1. The results of several clinical trials suggest that, in genotype 1 patients with a 4-week rapid virologic response, but only in the subset with a baseline low level of HCV RNA, 24 weeks of therapy with PEG IFN and weight-based ribavirin suffices, yielding sustained response rates comparable to those achieved with 48 weeks of therapy. Again, although regulatory agencies in Europe have adopted this treatment approach, broad adoption of this approach awaits confirmatory studies.

INDICATIONS FOR ANTIVIRAL THERAPY

Patients with chronic hepatitis C who have detectable HCV RNA in serum and chronic hepatitis of at least moderate grade and stage (portal or bridging fibrosis) are

candidates for antiviral therapy with PEG IFN plus ribavirin. Most authorities recommend 800 mg of ribavirin for patients with genotypes 2 and 3 and weight-based 1000–1200 mg for patients with genotype 1 (and 4) for both types of PEG IFN, unless ribavirin is contraindicated (Table 93-7). Although patients with persistently normal ALT activity tend not to progress histologically, they respond to antiviral therapy just as well as do patients with elevated ALT levels; therefore, while observation without therapy is an option, such patients are potential candidates for antiviral therapy. Therapy with IFN has been shown to improve survival and complication-free survival and to slow progression of fibrosis.

Prior to therapy, HCV genotype should be determined, and the genotype dictates the duration of therapy: 1 year (48 weeks) for patients with genotype 1; 6 months (24 weeks) for those with genotypes 2 and 3;

and potentially only 12–16 weeks for patients with genotype 2 whose HCV RNA becomes undetectable within 4 weeks. As noted above, the absence of a 2-log₁₀ drop in HCV RNA at week 12 (an *early virologic response*) weighs heavily against the likelihood of a sustained virologic response even if therapy is continued for the remainder of the planned full year. Therefore, measuring HCV RNA at baseline and at 12 weeks is recommended routinely, especially for patients with genotype 1. The consensus view is that therapy can be discontinued if an early virologic response is not achieved; however, histologic benefit may occur even in the absence of a virologic response. In addition, if current trials show that maintenance therapy can slow the progression of chronic hepatitis C, early virologic nonresponders may be identified as candidates for maintenance therapy; the results of these trials are awaited. Although response rates are lower in patients with certain pretreatment variables, selection for treatment should not be based on symptoms, genotype, HCV RNA level, mode of acquisition of hepatitis C, or advanced hepatic fibrosis. Patients with cirrhosis can respond and should not be excluded as candidates for therapy.

Patients who have relapsed after a course of IFN monotherapy are candidates for retreatment with PEG IFN plus ribavirin (i.e., a more effective treatment regimen is required). For nonresponders to a prior course of IFN monotherapy, retreatment with IFN monotherapy or combination IFN plus ribavirin therapy is unlikely to achieve a sustained virologic response; however, a trial of combination PEG IFN plus ribavirin may be worthwhile. End-treatment virologic responses as high as 40% can occur in this setting, but a sustained virologic response is the outcome in <15–20% of patients. Sustained virologic responses to retreatment of nonresponders are more frequent in those who had never received ribavirin in the past, those with genotypes 2 and 3, those with low pretreatment HCV RNA levels, and noncirrhotics, but less frequent in African Americans, those who failed to achieve a substantial reduction in HCV RNA during their previous course of therapy, and those who required ribavirin-dose reductions. Potential approaches to improving responsiveness to PEG IFN/ribavirin in prior nonresponders include longer duration of treatment; higher doses of either PEG IFN, ribavirin, or both; and switching to a different IFN preparation. However, none of these approaches is of proven efficacy.

Early treatment is indicated for persons with acute hepatitis C (Chap. 92). In patients with biochemically and histologically mild chronic hepatitis C, the rate of progression is slow, and monitoring without therapy is an option; however, such patients respond just as well to combination PEG IFN plus ribavirin therapy as those with elevated ALT and more histologically severe hepatitis. Therefore, therapy for these patients should be considered and the decision made based on such factors as patient motivation, genotype, stage of fibrosis, age, and comorbid conditions. A pretreatment liver biopsy to assess histologic grade and stage provides substantial information about progression of hepatitis C in the past

and has prognostic value for future progression. As therapy has improved for patients with a broad range of histologic severity, and as noninvasive laboratory markers of fibrosis have gained popularity, some authorities have placed less value on pretreatment liver biopsies. On the other hand, serum markers of fibrosis are not considered sufficiently accurate, and histologic findings provide important prognostic information to physician and patient. Therefore, a pretreatment liver biopsy is still recommended in most cases.

Patients with compensated cirrhosis can respond to therapy, although their likelihood of a sustained response is lower than in noncirrhotics. Whether survival is improved after successful antiviral therapy in cirrhotics is controversial. Similarly, although several retrospective studies have suggested that antiviral therapy in cirrhotics with chronic hepatitis C reduces the frequency of HCC, less advanced disease in the treated cirrhotics, not treatment itself, may have accounted for the reduced frequency of HCC observed in the treated cohort; prospective studies to address this question are in progress. Patients with decompensated cirrhosis are not candidates for IFN-based antiviral therapy but should be referred for liver transplantation. Some liver transplantation centers have evaluated progressively escalated, low-dose antiviral therapy in an attempt to eradicate hepatitis C viremia prior to transplantation; however, data supporting this approach are limited. After liver transplantation, recurrent hepatitis C is the rule, and the pace of disease progression is more accelerated than in immunocompetent patients. Current therapy with PEG IFN and ribavirin is unsatisfactory in most patients, but attempts to minimize immunosuppression are beneficial. The cutaneous and renal vasculitis of HCV-associated essential mixed cryoglobulinemia (Chap. 92) may respond to antiviral therapy, but sustained responses are rare after discontinuation of therapy; therefore, prolonged, perhaps indefinite, therapy is recommended in this group. Anecdotal reports suggest that antiviral therapy may be effective in porphyria cutanea tarda or lichen planus associated with hepatitis C.

In patients with HCV/HIV co-infection, hepatitis C is more progressive and severe than in HCV-monoinfected patients. Although patients with HCV/HIV co-infection respond to antiviral therapy for hepatitis C, they do not respond as well as patients with HCV infection alone. Four large national and international trials of antiviral therapy among patients with HCV/HIV co-infection have shown that PEG IFN (both $\alpha 2a$ and $\alpha 2b$) plus ribavirin (daily doses ranging from flat-dosed 600–800 mg to weight-based 1000/1200 mg) is superior to standard IFN regimens; however, sustained response rates were lower than in HCV-monoinfected patients, ranging from 14 to 38% for patients with genotypes 1 and 4 and from 44 to 73% for patients with genotypes 2 and 3. In the three largest trials, all patients, including those with genotypes 2 and 3, were treated for a full 48 weeks. In addition, tolerability of therapy was lower than in HCV-monoinfected patients; therapy was discontinued because of side effects in 12–39% of patients in these

clinical trials. Based on these trials, weekly PEG IFN plus daily ribavirin at a daily dose of at least 600–800 mg, up to full weight-based doses if tolerated, is recommended for a full 48 weeks, regardless of genotype. An alternative recommendation for ribavirin doses was issued by a European Consensus Conference and consisted of standard, weight-based 1000–1200 mg for genotypes 1 and 4, but 800 mg for genotypes 2 and 3. In HCV/HIV-infected patients, ribavirin can potentiate the toxicity of—and should not be used together with—didanosine.

Persons with a history of injection-drug use and alcoholism can be treated successfully for chronic hepatitis C, preferably in conjunction with drug and alcohol treatment programs. Because ribavirin is excreted renally, patients with end-stage renal disease, including those undergoing dialysis (which does not clear ribavirin), are not candidates for ribavirin therapy. Rare reports suggest that reduced-dose ribavirin can be used, but the frequency of anemia is very high and data on efficacy are limited. In addition, the manufacturer of PEG IFN- α 2a recommends a dose reduction from 180 to 135 μ g daily in patients with renal failure. Neither the optimal regimen nor the efficacy of therapy is established in this population.

NOVEL ANTIVIRALS Among the new approaches to antiviral therapy are direct antivirals (so-called specifically targeted antiviral therapy), including orally administered polymerase and protease inhibitors. For example, in preliminary studies among small numbers of subjects, one of the protease inhibitors being investigated has been shown to suppress HCV RNA by 4 logs₁₀ in 14 days when used as monotherapy, to suppress HCV RNA by 5.5 logs₁₀ in 14 days when combined with PEG IFN injections, and to suppress HCV RNA to undetectable levels in 12 of 12 subjects treated for 28 days when combined with PEG IFN and ribavirin. Because resistance to these oral agents used alone has been both anticipated and observed, polymerase and protease inhibitors are being evaluated in combinations with PEG IFN (\pm ribavirin) to preempt the emergence of resistance. Potentially, in the future, combinations of specifically targeted antiviral agents will be used in drug cocktails that may replace IFN-based regimens entirely.

AUTOIMMUNE HEPATITIS

DEFINITION

Autoimmune hepatitis is a chronic disorder characterized by continuing hepatocellular necrosis and inflammation, usually with fibrosis, which can progress to cirrhosis and liver failure. When fulfilling criteria of severity, this type of chronic hepatitis, when untreated, may have a 6-month mortality of as high as 40%. Based on contemporary estimates of the natural history of treated autoimmune hepatitis, the 10-year survival is 80–90%. The prominence of extrahepatic features of autoimmunity as well as seroimmunologic abnormalities in this disorder supports an autoimmune process in its pathogenesis; this concept is reflected in the labels

lupoid, plasma cell, or autoimmune hepatitis. Autoantibodies and other typical features of autoimmunity, however, do not occur in all cases; among the broader categories of “idiopathic” or cryptogenic chronic hepatitis, many, perhaps the majority, are probably autoimmune in origin. Cases in which hepatotropic viruses, metabolic/genetic derangements, and hepatotoxic drugs have been excluded represent a spectrum of heterogeneous liver disorders of unknown cause, a proportion of which are most likely autoimmune hepatitis.

IMMUNOPATHOGENESIS

The weight of evidence suggests that the progressive liver injury in patients with autoimmune hepatitis is the result of a cell-mediated immunologic attack directed against liver cells. In all likelihood, predisposition to autoimmunity is inherited, while the liver specificity of this injury is triggered by environmental (e.g., chemical or viral) factors. For example, patients have been described in whom apparently self-limited cases of acute hepatitis A, B, or C led to autoimmune hepatitis, presumably because of genetic susceptibility or predisposition. Evidence to support an autoimmune pathogenesis in this type of hepatitis includes the following: (1) In the liver, the histopathologic lesions are composed predominantly of cytotoxic T cells and plasma cells; (2) circulating autoantibodies (nuclear, smooth muscle, thyroid, etc.; see below), rheumatoid factor, and hyperglobulinemia are common; (3) other autoimmune disorders—such as thyroiditis, rheumatoid arthritis, autoimmune hemolytic anemia, ulcerative colitis, membranoproliferative glomerulonephritis, juvenile diabetes mellitus, celiac disease, and Sjögren’s syndrome—occur with increased frequency in patients who have autoimmune hepatitis and in their relatives; (4) histocompatibility haplotypes associated with autoimmune diseases, such as HLA-B1, -B8, -DR3, and -DR4 as well as extended haplotype DRB1 alleles, are common in patients with autoimmune hepatitis; and (5) this type of chronic hepatitis is responsive to glucocorticoid/immunosuppressive therapy, effective in a variety of autoimmune disorders.

Cellular immune mechanisms appear to be important in the pathogenesis of autoimmune hepatitis. In vitro studies have suggested that in patients with this disorder, lymphocytes are capable of becoming sensitized to hepatocyte membrane proteins and of destroying liver cells. Abnormalities of immunoregulatory control over cytotoxic lymphocytes (impaired regulatory CD4+CD25+ T cell influences) may play a role as well. Studies of genetic predisposition to autoimmune hepatitis demonstrate that certain haplotypes are associated with the disorder, as enumerated above. The precise triggering factors, genetic influences, and cytotoxic and immunoregulatory mechanisms involved in this type of liver injury remain poorly defined.

Intriguing clues into the pathogenesis of autoimmune hepatitis come from the observation that circulating autoantibodies are prevalent in patients with this disorder. Among the autoantibodies described in these patients are antibodies to nuclei [so-called antinuclear antibodies (ANAs), primarily in a homogeneous pattern]

and smooth muscle (so-called anti-smooth-muscle antibodies, directed at actin), anti-LKM (see below), antibodies to “soluble liver antigen/liver pancreas antigen” (directed against a uracil-guanine-adenine transfer RNA suppressor protein), as well as antibodies to the liver-specific asialoglycoprotein receptor (or “hepatic lectin”) and other hepatocyte membrane proteins. Although some of these provide helpful diagnostic markers, their involvement in the pathogenesis of autoimmune hepatitis has not been established.

Humoral immune mechanisms have been shown to play a role in the extrahepatic manifestations of autoimmune and idiopathic hepatitis. Arthralgias, arthritis, cutaneous vasculitis, and glomerulonephritis occurring in patients with autoimmune hepatitis appear to be mediated by the deposition of circulating immune complexes in affected tissue vessels, followed by complement activation, inflammation, and tissue injury. While specific viral antigen-antibody complexes can be identified in acute and chronic viral hepatitis, the nature of the immune complexes in autoimmune hepatitis has not been defined.

Many of the *clinical features* of autoimmune hepatitis are similar to those described for chronic viral hepatitis. The onset of disease may be insidious or abrupt; the disease may present initially like, and be confused with, acute viral hepatitis; a history of recurrent bouts of what had been labeled *acute hepatitis* is not uncommon. A subset of patients with autoimmune hepatitis has distinct features. Such patients are predominantly young to middle-aged women with marked hyperglobulinemia and high-titer circulating ANAs. This is the group with positive lupus erythematosus (LE) preparations (initially labeled “lupoid” hepatitis) in whom other autoimmune features are common. Fatigue, malaise, anorexia, amenorrhea, acne, arthralgias, and jaundice are common. Occasionally arthritis, maculopapular eruptions (including cutaneous vasculitis), erythema nodosum, colitis, pleurisy, pericarditis, anemia, azotemia, and sicca syndrome (keratoconjunctivitis, xerostomia) occur. In some patients, complications of cirrhosis, such as ascites and edema (associated with hypoalbuminemia), encephalopathy, hypersplenism, coagulopathy, or variceal bleeding may bring the patient to initial medical attention.

The course of autoimmune hepatitis may be variable. In those with mild disease or limited histologic lesions (e.g., piecemeal necrosis without bridging), progression to cirrhosis is limited. In those with severe symptomatic autoimmune hepatitis (aminotransferase levels >10 times normal, marked hyperglobulinemia, “aggressive” histologic lesions—bridging necrosis or multilobular collapse, cirrhosis), the 6-month mortality without therapy may be as high as 40%. Such severe disease accounts for only 20% of cases; the natural history of milder disease is variable, often accentuated by spontaneous remissions and exacerbations. Especially poor prognostic signs include the presence histologically of multilobular collapse at the time of initial presentation and failure of the bilirubin to improve after 2 weeks of therapy. Death may result from hepatic failure, hepatic coma, other complications of cirrhosis (e.g., variceal hemorrhage), and intercurrent infection. In patients with established cirrhosis, HCC may be a late

complication but occurs less frequently than in cirrhosis associated with viral hepatitis.

Laboratory features of autoimmune hepatitis are similar to those seen in chronic viral hepatitis. Liver biochemical tests are invariably abnormal but may not correlate with the clinical severity or histopathologic features in individual cases. Many patients with autoimmune hepatitis have normal serum bilirubin, alkaline phosphatase, and globulin levels with only minimal aminotransferase elevations. Serum AST and ALT levels are increased and fluctuate in the range of 100–1000 units. In severe cases, the serum bilirubin level is moderately elevated [51–171 $\mu\text{mol/L}$ (3–10 mg/dL)]. Hypoalbuminemia occurs in patients with very active or advanced disease. Serum alkaline phosphatase levels may be moderately elevated or near normal. In a small proportion of patients, marked elevations of alkaline phosphatase activity occur; in such patients, clinical and laboratory features overlap with those of primary biliary cirrhosis. The prothrombin time is often prolonged, particularly late in the disease or during active phases.

Hypergammaglobulinemia (>2.5 g/dL) is common in autoimmune hepatitis. Rheumatoid factor is common as well. As noted above, circulating autoantibodies are also prevalent. The most characteristic are ANAs in a homogeneous staining pattern. Smooth-muscle antibodies are less specific, seen just as frequently in chronic viral hepatitis. Because of the high levels of globulins achieved in the circulation of some patients with autoimmune hepatitis, occasionally the globulins may bind nonspecifically in solid-phase binding immunoassays for viral antibodies. This has been recognized most commonly in tests for antibodies to hepatitis C virus, as noted above. In fact, studies of autoantibodies in autoimmune hepatitis have led to the recognition of new categories of autoimmune hepatitis. *Type I autoimmune hepatitis* is the classic syndrome occurring in young women, associated with marked hyperglobulinemia, lupoid features, circulating ANAs, and HLA-DR3 or HLA-DR4. Also associated with type I autoimmune hepatitis are autoantibodies against actin as well as atypical perinuclear antineutrophilic cytoplasmic antibodies (pANCA).

Type II autoimmune hepatitis, often seen in children, more common in Mediterranean populations, and linked to HLA-DRB1 and HLA-DQB1 haplotypes, is associated not with ANA but with anti-LKM. Actually, anti-LKM represent a heterogeneous group of antibodies. In type II autoimmune hepatitis, the antibody is anti-LKM1, directed against cytochrome P450 2D6. This is the same anti-LKM seen in some patients with chronic hepatitis C. Anti-LKM2 is seen in drug-induced hepatitis, and anti-LKM3 is seen in patients with chronic hepatitis D. Another autoantibody observed in type II autoimmune hepatitis is directed against liver cytosol formiminotransferase cyclodeaminase (anti-liver cytosol 1). Another type of autoimmune hepatitis has been recognized, *type III autoimmune hepatitis*. These patients lack ANA and anti-LKM1 but have circulating antibodies to soluble liver antigen/liver pancreas antigen. Most of these patients are women and have clinical features similar to, perhaps more severe than, those of patients with type I

autoimmune hepatitis. Whether type III autoimmune hepatitis actually represents a distinct category or is part of the spectrum of type I autoimmune hepatitis remains controversial, and this subcategory has not been adopted by a consensus of international experts.

Liver biopsy abnormalities are similar to those described for chronic viral hepatitis. Expanding portal tracts and extending beyond the plate of periportal hepatocytes into the parenchyma (designated *interface hepatitis* or *piecemeal necrosis*) is a mononuclear cell infiltrate that, in autoimmune hepatitis, may include the presence of plasma cells. Necroinflammatory activity characterizes the lobular parenchyma, and evidence of hepatocellular regeneration is reflected by “rosette” formation, the occurrence of thickened liver cell plates, and regenerative “pseudolobules.” Septal fibrosis, bridging fibrosis, and cirrhosis are frequent. Bile duct injury and granulomas are uncommon; however, a subgroup of patients with autoimmune hepatitis have histologic, biochemical, and serologic features overlapping those of primary biliary cirrhosis.

DIAGNOSTIC CRITERIA

An international group has suggested a set of criteria for establishing a diagnosis of autoimmune hepatitis. Exclusion of liver disease caused by genetic disorders, viral hepatitis, drug hepatotoxicity, and alcohol are linked with such inclusive diagnostic criteria as hyperglobulinemia, autoantibodies, and characteristic histologic features. This international group has also suggested a comprehensive diagnostic scoring system that, rarely required for typical cases, may be helpful when typical features are not present. Factors that weigh in favor of the diagnosis include female gender; predominant aminotransferase elevation; presence and level of globulin elevation; presence of nuclear, smooth muscle, LKM1, and other autoantibodies; concurrent other autoimmune diseases; characteristic histologic features (interface hepatitis, plasma cells, rosettes); HLA DR3 or DR4 markers; and response to treatment (see below). Weighing against the diagnosis are predominant alkaline phosphatase elevation, mitochondrial antibodies, markers of viral hepatitis, history of hepatotoxic drugs or excessive alcohol, histologic evidence of bile duct injury, or such atypical histologic features as fatty infiltration, iron overload, and viral inclusions.

DIFFERENTIAL DIAGNOSIS

Early during the course of chronic hepatitis, autoimmune hepatitis may resemble typical *acute viral hepatitis*. Without histologic assessment, severe chronic hepatitis cannot be readily distinguished based on clinical or biochemical criteria from mild chronic hepatitis. In adolescence, *Wilson's disease* may present with features of chronic hepatitis long before neurologic manifestations become apparent and before the formation of Kayser-Fleischer rings. In this age group, serum ceruloplasmin and serum and urinary copper determinations plus measurement of liver copper levels will establish the correct

diagnosis. *Postnecrotic* or *cryptogenic cirrhosis* and *primary biliary cirrhosis* share clinical features with autoimmune hepatitis, and both alcoholic hepatitis and nonalcoholic steatohepatitis may present with many features common to autoimmune hepatitis; historic, biochemical, serologic, and histologic assessments are usually sufficient to allow these entities to be distinguished from autoimmune hepatitis. Of course, the distinction between autoimmune and chronic viral hepatitis is not always straightforward, especially when viral antibodies occur in patients with autoimmune disease or when autoantibodies occur in patients with viral disease. Furthermore, the presence of extrahepatic features such as arthritis, cutaneous vasculitis, or pleuritis—not to mention the presence of circulating autoantibodies—may cause confusion with *rheumatologic disorders* such as rheumatoid arthritis and systemic lupus erythematosus. The existence of clinical and biochemical features of progressive necroinflammatory liver disease distinguishes chronic hepatitis from these other disorders, which are not associated with severe liver disease.

Finally, occasionally, features of autoimmune hepatitis overlap with features of autoimmune biliary disorders such as primary biliary cirrhosis, primary sclerosing cholangitis, or, even more rarely, mitochondrial antibody-negative autoimmune cholangitis. Such overlap syndromes are difficult to categorize, and often response to therapy may be the distinguishing factor that establishes the diagnosis.

Rx Treatment: AUTOIMMUNE HEPATITIS

The mainstay of management in autoimmune hepatitis is glucocorticoid therapy. Several controlled clinical trials have documented that such therapy leads to symptomatic, clinical, biochemical, and histologic improvement as well as increased survival. A therapeutic response can be expected in up to 80% of patients. Unfortunately, therapy has not been shown to prevent ultimate progression to cirrhosis; however, instances of reversal of fibrosis and cirrhosis have been reported in patients responding to treatment. Although some advocate the use of prednisolone (the hepatic metabolite of prednisone), prednisone is just as effective and is favored by most authorities. Therapy may be initiated at 20 mg/d, but a popular regimen in the United States relies on an initiation dose of 60 mg/d. This high dose is tapered successively over the course of a month down to a maintenance level of 20 mg/d. An alternative but equally effective approach is to begin with half the prednisone dose (30 mg/d) along with azathioprine (50 mg/d). With azathioprine maintained at 50 mg/d, the prednisone dose is tapered over the course of a month down to a maintenance level of 10 mg/d. The advantage of the combination approach is a reduction, over the span of an 18-month course of therapy, in serious, life-threatening complications of steroid therapy from 66% down to under 20%. In combination regimens,

6-mercaptopurine may be substituted for its prodrug azathioprine, but this is rarely required. Azathioprine alone, however, is not effective in achieving remission, nor is alternate-day glucocorticoid therapy. Although therapy has been shown to be effective for severe autoimmune hepatitis (AST ≥ 10 times the upper limit of normal or ≥ 5 times the upper limit of normal in conjunction with serum globulin \geq twice normal; bridging necrosis or multilobular necrosis on liver biopsy; presence of symptoms), therapy is not indicated for mild forms of chronic hepatitis, and the efficacy of therapy in mild or asymptomatic autoimmune hepatitis has not been established.

Improvement of fatigue, anorexia, malaise, and jaundice tends to occur within days to several weeks; biochemical improvement occurs over the course of several weeks to months, with a fall in serum bilirubin and globulin levels and an increase in serum albumin. Serum aminotransferase levels usually drop promptly, but improvements in AST and ALT alone do not appear to be a reliable marker of recovery in individual patients; histologic improvement, characterized by a decrease in mononuclear infiltration and in hepatocellular necrosis, may be delayed for 6–24 months. Still, if interpreted cautiously, aminotransferase levels are valuable indicators of relative disease activity, and many authorities do *not* advocate serial liver biopsies to assess therapeutic success or to guide decisions to alter or stop therapy. Therapy should continue for at least 12–18 months. After tapering and cessation of therapy, the likelihood of relapse is at least 50%, even if posttreatment histology has improved to show mild chronic hepatitis, and the majority of patients require therapy at maintenance doses indefinitely. Continuing azathioprine alone (2 mg/kg body weight daily) after cessation of prednisone therapy may reduce the frequency of relapse.

In medically refractory cases, an attempt should be made to intensify treatment with high-dose glucocorticoid monotherapy (60 mg daily) or combination glucocorticoid (30 mg daily) plus high-dose azathioprine (150 mg daily) therapy. After a month, doses of prednisone can be reduced by 10 mg a month, and doses of azathioprine can be reduced by 50 mg a month toward ultimate, conventional maintenance doses. Patients refractory to this regimen may be treated with cyclosporine, tacrolimus, or mycophenolate mofetil; however, to date only limited anecdotal reports support these approaches. If medical therapy fails, or when chronic hepatitis progresses to cirrhosis and is associated with life-threatening complications of liver decompensation, liver transplantation is the only recourse; failure of the bilirubin to improve after 2 weeks of therapy should prompt early consideration of the patient for liver transplantation. Recurrence of autoimmune hepatitis in the new liver occurs rarely in most experiences but in as many as 35–40% of cases in others.

CHAPTER 94

ENTEROVIRUSES AND REOVIRUSES

Jeffrey I. Cohen

ENTEROVIRUSES

CLASSIFICATION AND CHARACTERIZATION

Enteroviruses are so named because of their ability to multiply in the gastrointestinal tract. Despite their name, these viruses are not a prominent cause of gastroenteritis. Enteroviruses encompass 65 human serotypes: 3 serotypes of poliovirus, 23 serotypes of coxsackievirus A, 6 serotypes of coxsackievirus B, 29 serotypes of echovirus, and enteroviruses 68–71. Enteroviruses 73–102 have recently been identified in humans by molecular techniques, but their clinical features have not been described. Enterovirus surveillance conducted in the United States by the Centers for Disease Control and Prevention (CDC) in 2007–2008 showed that the most common serotype, coxsackievirus B1, was followed in frequency by echoviruses 18, 9, and 6, which together accounted for 52% of all isolates.

Human enteroviruses contain a single-stranded RNA genome surrounded by an icosahedral capsid comprising four viral proteins. These viruses have no lipid envelope and are stable in acidic environments, including the stomach. They are resistant to inactivation by standard disinfectants (e.g., alcohol, detergents) and can persist for days at room temperature.

PATHOGENESIS AND IMMUNITY

Much of what is known about the pathogenesis of enteroviruses has been derived from studies of poliovirus infection. After ingestion, poliovirus is thought to infect epithelial cells in the mucosa of the gastrointestinal tract and then to spread to and replicate in the submucosal lymphoid tissue of the tonsils and Peyer's patches. The virus next spreads to the regional lymph nodes, a viremic phase ensues, and the virus replicates in organs of the reticuloendothelial system. In some cases, a second viremia occurs and the virus replicates further in various tissues, sometimes causing symptomatic disease.

It is uncertain whether poliovirus reaches the central nervous system (CNS) during viremia or whether it also spreads via peripheral nerves. Since viremia precedes the onset of neurologic disease in humans and in experimentally infected chimpanzees, it has been assumed that the virus enters the CNS via the bloodstream. The poliovirus receptor is a member of the immunoglobulin superfamily. Poliovirus infection is limited to primates, largely because their cells express the viral receptor. Studies demonstrating the poliovirus receptor in the end-plate region of

muscle at the neuromuscular junction suggest that, if the virus enters the muscle during viremia, it could travel across the neuromuscular junction up the axon to the anterior horn cells. Studies of monkeys and of transgenic mice expressing the poliovirus receptor show that, after IM injection, poliovirus does not reach the spinal cord if the sciatic nerve is cut. Taken together, these findings suggest that poliovirus can spread directly from muscle to the CNS by neural pathways. Intercellular adhesion molecule 1 (ICAM-1) is a receptor for coxsackieviruses A13, A18, and A21; CAR for coxsackievirus B; VLA-2 integrin for echovirus types 1 and 8; and CD55 for enterovirus 70 and some serotypes of coxsackievirus A and B and echovirus.

Poliovirus can usually be cultured from the blood 3–5 days after infection, before the development of neutralizing antibodies. While viral replication at secondary sites begins to slow 1 week after infection, it continues in the gastrointestinal tract. Poliovirus is shed from the oropharynx for up to 3 weeks after infection and from the gastrointestinal tract for as long as 12 weeks; immunodeficient patients can shed poliovirus for up to 20 years. During replication in the gastrointestinal tract, attenuated oral poliovirus can mutate, reverting to a more neurovirulent phenotype within a few days. The clinical significance of this increased neurovirulence is unknown.

Humoral and secretory immunity in the gastrointestinal tract is important for the control of enterovirus infections. Enteroviruses induce specific IgM, which usually persists for <6 months, and specific IgG, which persists for life. Capsid protein VP1 is the predominant target of neutralizing antibody, which generally confers lifelong protection against subsequent disease caused by the same serotype but does not prevent infection or virus shedding. Enteroviruses also induce cellular immunity, but the significance of this mechanism in limiting infection is uncertain. Patients with impaired cellular immunity are not known to develop unusually severe disease when infected with enteroviruses. In contrast, the severe infections in patients with agammaglobulinemia emphasize the importance of humoral immunity in controlling enterovirus infections. Disseminated enterovirus infections have occurred in stem cell transplant recipients. IgA antibodies are instrumental in reducing poliovirus replication in and shedding from the gastrointestinal tract. Breast milk contains IgA specific for enteroviruses and can protect humans from infection.

EPIDEMIOLOGY

Enteroviruses have a worldwide distribution. More than 50% of nonpoliovirus enterovirus infections and more than 90% of poliovirus infections are subclinical. When symptoms do develop, they are usually nonspecific and occur in conjunction with fever; only a minority of infections are associated with specific clinical syndromes. The incubation period for most enterovirus infections ranges from 2 to 14 days but usually is <1 week.

Enterovirus infection is more common in socioeconomically disadvantaged areas, especially in those where conditions are crowded and in tropical areas where hygiene is poor. Infection is most common among infants and young children; serious illness develops most often during the first few days of life and in older children and adults. In developing countries, where children are infected at an early age, poliovirus infection has less often been associated with paralysis; in countries with better hygiene, older children and adults are more likely to be seronegative, become infected, and develop paralysis. Passively acquired maternal antibody reduces the risk of symptomatic infection in neonates. Young children are the most frequent shedders of enteroviruses and are usually the index cases in family outbreaks. In temperate climates, enterovirus infections occur most often in the summer and fall; no seasonal pattern is apparent in the tropics.

Most enteroviruses are transmitted primarily by the fecal-oral route from fecally contaminated fingers or inanimate objects. Patients are most infectious shortly before and after the onset of symptomatic disease, when virus is present in the stool and throat. The ingestion of virus-contaminated food or water can also cause disease. Certain enteroviruses (such as enterovirus 70, which causes acute hemorrhagic conjunctivitis) can be transmitted by direct inoculation from the fingers to the eye. Airborne transmission is important for some viruses that cause respiratory tract disease, such as coxsackievirus A21. Enteroviruses can be transmitted across the placenta from mother to fetus, causing severe disease in the newborn. The transmission of enteroviruses through blood transfusions or insect bites has not been documented. Nosocomial spread of coxsackievirus and echovirus has taken place in hospital nurseries.

CLINICAL FEATURES

Poliovirus Infection

Most infections with poliovirus are asymptomatic. After an incubation period of 3–6 days, ~5% of patients present with a minor illness (abortive poliomyelitis) manifested by fever, malaise, sore throat, anorexia, myalgias, and headache. This condition usually resolves in 3 days. About 1% of patients present with aseptic meningitis (nonparalytic poliomyelitis). Examination of cerebrospinal fluid (CSF) reveals lymphocytic pleocytosis, a normal glucose level, and a normal or slightly elevated protein level; CSF polymorphonuclear leukocytes may be present early. In some patients, especially children, malaise and fever precede the onset of aseptic meningitis.

Paralytic Poliomyelitis

The least common presentation is that of paralytic disease. After one or several days, signs of aseptic meningitis are followed by severe back, neck, and muscle pain and by the rapid or gradual development of motor weakness. In some cases the disease appears to be biphasic, with aseptic meningitis followed first by apparent recovery but then (1–2 days later) by the return of fever and the development of paralysis; this form is more common among children than among adults. Weakness is generally asymmetric, is proximal more than distal, and may involve the legs (most commonly); the arms; or the abdominal, thoracic, or bulbar muscles. Paralysis develops during the febrile phase of the illness and usually does not progress after defervescence. Urinary retention may also occur. Examination reveals weakness, fasciculations, decreased muscle tone, and reduced or absent reflexes in affected areas. Transient hyperreflexia sometimes precedes the loss of reflexes. Patients frequently report sensory symptoms, but objective sensory testing usually yields normal results. Bulbar paralysis may lead to dysphagia, difficulty in handling secretions, or dysphonia. Respiratory insufficiency due to aspiration, involvement of the respiratory center in the medulla, or paralysis of the phrenic or intercostal nerves may develop, and severe medullary involvement may lead to circulatory collapse. Most patients with paralysis recover some function weeks to months after infection. About two-thirds of patients have residual neurologic sequelae.

Paralytic disease is more common among older individuals, pregnant women, and persons exercising strenuously or undergoing trauma at the time of CNS symptoms. Tonsillectomy predisposes to bulbar poliomyelitis, and IM injections increase the risk of paralysis in the involved limb(s).

Vaccine-Associated Poliomyelitis

Until recently, poliomyelitis due to live poliovirus vaccine occurred in the United States. The risk of developing poliomyelitis after oral vaccination is estimated at 1 case per 2.5 million doses. The risk is ~2000 times higher among immunodeficient persons, especially in persons with hypo- or agammaglobulinemia. Before 1997, an average of eight cases of vaccine-associated poliomyelitis occurred—in both vaccinees and their contacts—in the United States each year. With the change in recommendations first to a sequential regimen of inactivated poliovirus vaccine (IPV) and oral poliovirus vaccine (OPV) in 1997 and then to an all-IPV regimen in 2000, the number of cases of vaccine-associated polio declined. From 1997 to 1999, six such cases were reported in the United States; no cases have been reported since 1999.

Postpolio Syndrome

The *postpolio syndrome* presents as a new onset of weakness, fatigue, fasciculations, and pain with additional atrophy of the muscle group involved during the initial paralytic disease 20–40 years earlier. The

syndrome is more common among women and with increasing time after acute disease. The onset is usually insidious, and weakness occasionally extends to muscles that were not involved during the initial illness. The prognosis is generally good; progression to further weakness is usually slow, with plateau periods of 1–10 years. The postpolio syndrome is thought to be due to progressive dysfunction and loss of motor neurons that compensated for the neurons lost during the original infection and not to persistent or reactivated poliovirus infection.

Other Enteroviruses

An estimated 5–10 million cases of symptomatic disease due to enteroviruses other than poliovirus occur in the United States each year. Among neonates, enteroviruses are the most common cause of aseptic meningitis and nonspecific febrile illnesses. Certain clinical syndromes are more likely to be caused by certain serotypes (Table 94-1), but there is much overlap. In 2002–2004, 85% of enterovirus infections were caused by only 9 human serotypes. Echoviruses 9 and 30 accounted for 60% of recognized enterovirus infections.

TABLE 94-1

MANIFESTATIONS COMMONLY ASSOCIATED WITH ENTEROVIRUS SEROTYPES

| MANIFESTATION | SEROTYPE(S) OF INDICATED VIRUS | |
|------------------------------------|--------------------------------|--|
| | COXSACKIEVIRUS | ECHOVIRUS (E) AND ENTEROVIRUS (Ent) |
| Acute hemorrhagic conjunctivitis | A24 | E70 |
| Aseptic meningitis | A2, 4, 7, 9, 10; B1-5 | E4, 6, 7, 9, 11, 13, 16, 18, 19, 30, 33; Ent70, 71 |
| Encephalitis | A9; B1-5 | E3, 4, 6, 9, 11, 25, 30; Ent71 |
| Exanthem | A4, 5, 9, 10, 16; B1, 3-5 | E4-7, 9, 11, 16-19, 25, 30; Ent71 |
| Generalized disease of the newborn | B1-5 | E4-6, 7, 9, 11, 14, 16, 18, 19 |
| Hand-foot-and-mouth disease | A5, 7, 9, 10, 16; B1, 2, 5 | Ent71 |
| Herpangina | A1-10, 16, 22; B1-5 | E6, 9, 11, 16, 17, 25; Ent71 |
| Myocarditis, pericarditis | A4, 9, 16; B1-5 | E6, 9, 11, 22 |
| Paralysis | A4, 7, 9; B1-5 | E2, 4, 6, 9, 11, 30; Ent70, 71 |
| Pleurodynia | A1, 2, 4, 6, 9, 10, 16; B1-6 | E1-3, 6, 7, 9, 11, 12, 14, 16, 19, 24, 25, 30 |
| Pneumonia | A9, 16; B1-5 | E6, 7, 9, 11, 12, 19, 20, 30; Ent68, 71 |

Nonspecific Febrile Illness (Summer Grippe)

The most common clinical manifestation of enterovirus infection is a nonspecific febrile illness. After an incubation period of 3–6 days, patients present with an acute onset of fever, malaise, and headache. Occasional cases are associated with upper respiratory symptoms, and some cases include nausea and vomiting. Symptoms often last for 3–4 days, and most cases resolve in a week. While infections with other respiratory viruses occur more often from late fall to early spring, enterovirus febrile illness frequently occurs in the summer and early fall.

Generalized Disease of the Newborn

Most serious enterovirus infections in infants develop during the first week of life, although severe disease can occur up to 3 months of age. Neonates often present with an illness resembling bacterial sepsis, with fever, irritability, and lethargy. Laboratory abnormalities include leukocytosis with a left shift, thrombocytopenia, elevated values in liver function tests, and CSF pleocytosis. The illness can be complicated by myocarditis and hypotension, fulminant hepatitis and disseminated intravascular coagulation, meningitis or meningoencephalitis, or pneumonia. It may be difficult to distinguish neonatal enterovirus infection from bacterial sepsis, although a history of a recent virus-like illness in the mother provides a clue.

Aseptic Meningitis and Encephalitis

Enteroviruses are the cause of up to 90% of cases of aseptic meningitis in children and young adults in which an etiologic agent can be identified. Patients with aseptic meningitis typically present with an acute onset of fever, chills, headache, photophobia, and pain on eye movement. Nausea and vomiting are also common. Examination reveals meningismus without localizing neurologic signs; drowsiness or irritability may also be apparent. In some cases, a febrile illness may be reported that remits but returns several days later in conjunction with signs of meningitis. Other systemic manifestations may provide clues to an enteroviral cause, including diarrhea, myalgias, rash, pleurodynia, myocarditis, and herpangina. Examination of the CSF invariably reveals pleocytosis; early in the course, polymorphonuclear leukocytes may be present or even predominant—a finding that raises the possibility of bacterial or other nonviral causes of meningitis. Partially treated bacterial meningitis may be particularly difficult to exclude in some instances. A useful rule is that the CSF cell count in enteroviral meningitis shows a shift to lymphocytic predominance within 24 h of presentation, and the total count generally does not exceed 1000 cells/ μ L. Additional CSF findings consist of a normal glucose content and a normal or only slightly elevated (by ≤ 100 mg/dL) level of protein. Enteroviruses and mumps virus may produce a similar picture of meningitis; a low CSF glucose level suggests mumps, whereas a normal CSF glucose level and transient CSF polymorphonuclear pleocytosis suggest enterovirus infection. Enteroviral meningitis is more frequent in summer and fall in temperate climates, while viral meningitis of other

etiologies (e.g., mumps) is more common in winter and spring. Symptoms ordinarily resolve within a week, although CSF abnormalities can persist for several weeks. Enteroviral meningitis is often more severe in adults than in children. Neurologic sequelae are rare, and most patients have an excellent prognosis.

Enteroviral encephalitis is much less common than enteroviral aseptic meningitis. Occasional highly inflammatory cases of enteroviral meningitis may be complicated by a mild form of encephalitis that is recognized on the basis of progressive lethargy, disorientation, and sometimes seizures. Less commonly, severe primary encephalitis may develop. An estimated 10–20% of cases of viral encephalitis are due to enteroviruses. Immunocompetent patients generally have a good prognosis.

Patients with hypogammaglobulinemia or agammaglobulinemia or severe combined immunodeficiency may develop chronic meningitis or encephalitis; about half of these patients have a dermatomyositis-like syndrome, with peripheral edema, rash, and myositis. They may also have chronic hepatitis. Patients may develop neurologic disease while receiving gamma globulin replacement therapy. Echoviruses (especially echovirus 11) are the most common pathogens in this situation.

Paralytic disease due to enteroviruses other than poliovirus occurs sporadically and is usually less severe than poliomyelitis. Most cases are due to enterovirus 70 or 71 or to coxsackievirus A7 or A9. Guillain-Barré syndrome is also associated with enterovirus infection. While some studies have suggested a link between enteroviruses and the chronic fatigue syndrome, most recent studies have not demonstrated such an association.

■ Pleurodynia (Bornholm Disease)

Patients with pleurodynia present with an acute onset of fever and spasms of pleuritic chest or upper abdominal pain. Chest pain is more common in adults, and abdominal pain is more common in children. Paroxysms of severe, knifelike pain usually last 15–30 min and are associated with diaphoresis and tachypnea. Fever peaks within an hour after the onset of paroxysms and subsides when pain resolves. The involved muscles are tender to palpation, and a pleural rub may be detected. The white blood cell count and chest x-ray are usually normal. Most cases are due to coxsackievirus B and occur during epidemics. Symptoms resolve in a few days, and recurrences are rare. Treatment includes the administration of nonsteroidal anti-inflammatory agents or the application of heat to the affected muscles.

■ Myocarditis and Pericarditis

Enteroviruses are estimated to cause up to one-third of cases of acute myocarditis. Coxsackievirus B and its RNA have been detected in pericardial fluid and myocardial tissue in some cases of acute myocarditis and pericarditis. Most cases of enteroviral myocarditis or pericarditis occur in newborns, adolescents, or young adults. More than two-thirds of patients are male. Patients often present with an upper respiratory tract infection that is followed by fever, chest pain, dyspnea,

arrhythmias, and occasionally heart failure. A pericardial friction rub is documented in half of cases, and the electrocardiogram shows ST-segment elevations or ST- and T-wave abnormalities. Serum levels of myocardial enzymes are often elevated. Neonates commonly have severe disease, while most older children and adults recover completely. Up to 10% of cases progress to chronic dilated cardiomyopathy. Chronic constrictive pericarditis may also be a sequela.

■ Exanthems

Enterovirus infection is the leading cause of exanthems in children in the summer and fall. While exanthems are associated with many enteroviruses, certain types have been linked to specific syndromes. Echoviruses 9 and 16 have frequently been associated with exanthem and fever. Rashes may be discrete (rubelliform) or confluent (morbilliform), beginning on the face and spreading to the trunk and extremities. Echovirus 9 is the most common cause of rubelliform rash. Unlike the rash of rubella, the enteroviral rash occurs in the summer and is not associated with lymphadenopathy. Roseola-like rashes develop after defervescence, with macules and papules on the face and trunk. The Boston exanthem, caused by echovirus 16, is a roseola-like rash that often affects multiple members of a family. A variety of other rashes have been associated with enteroviruses, including erythema multiforme and vesicular, urticarial, petechial, or purpuric lesions. Exanthems also occur, including lesions that resemble the Koplik's spots seen with measles.

■ Hand-Foot-and-Mouth Disease

After an incubation period of 4–6 days, patients with hand-foot-and-mouth disease present with fever, anorexia, and malaise; these manifestations are followed by the development of sore throat and vesicles ([Fig. 94-1A](#)) on the buccal mucosa and often on the tongue and then by the appearance of tender vesicular lesions on the dorsum of the hands, sometimes with involvement of the palms. The vesicles may form bullae and quickly ulcerate. About one-third of patients also have lesions on the palate, uvula, or tonsillar pillars, and one-third have a rash on the feet (including the soles) or on the buttocks. The disease is highly infectious, with attack rates of close to 100% among young children. The lesions usually resolve in 1 week. Most cases are due to coxsackievirus A16 or enterovirus 71.

An epidemic of enterovirus 71 infection in Taiwan in 1998 resulted in thousands of cases of hand-foot-and-mouth disease or herpangina. Severe complications included CNS disease, myocarditis, and pulmonary hemorrhage. About 90% of those who died were children ≤5 years old, and these deaths were associated with pulmonary edema or pulmonary hemorrhage. CNS disease included aseptic meningitis, flaccid paralysis (similar to poliomyelitis), or rhombencephalitis with myoclonus and tremor or ataxia. The mean age of patients with CNS complications was 2.5 years, and MRI in cases with encephalitis usually showed brain-stem lesions. Follow-up of children at 6 months showed persistent dysphagia,

cranial nerve palsies, hypoventilation, limb weakness, and atrophy.

Herpangina

Herpangina is usually caused by coxsackievirus A and presents as acute-onset fever, sore throat, dysphagia, and grayish-white papulovesicular lesions on an erythematous base that ulcerate (Fig. 94-1B). The lesions can persist for weeks; are present on the soft palate, anterior pillars of the tonsils, and uvula; and are concentrated in the posterior portion of the mouth. In contrast to herpes stomatitis, enteroviral herpangina is not associated with gingivitis. Acute lymphonodular pharyngitis associated with coxsackievirus A10 presents as white or yellow nodules surrounded by erythema in the posterior oropharynx. The lesions do not ulcerate.

Acute Hemorrhagic Conjunctivitis

Patients with acute hemorrhagic conjunctivitis present with an acute onset of severe eye pain, blurred vision, photophobia, and watery discharge from the eye. Examination reveals edema, chemosis, and subconjunctival hemorrhage and often shows punctate keratitis and conjunctival follicles as well (Fig. 94-1C). Preauricular adenopathy is often found. Epidemics and nosocomial spread have been associated with enterovirus 70 and coxsackievirus A24. Systemic symptoms, including headache and fever, develop in 20% of cases, and recovery is usually complete in 10 days. The sudden onset and short duration of the illness help to distinguish acute hemorrhagic conjunctivitis from other ocular infections such as those due to adenovirus and *Chlamydia*. Paralysis has been associated with some cases of acute

Other Manifestations

Enteroviruses are an infrequent cause of childhood pneumonia and the common cold. Coxsackievirus B has been isolated at autopsy from the pancreas of a few children presenting with type 1 diabetes mellitus; however, most attempts to isolate the virus have been unsuccessful. Other diseases that have been associated with enterovirus infection include parotitis, bronchitis, bronchiolitis, croup, infectious lymphocytosis, polymyositis, acute arthritis, and acute nephritis.

DIAGNOSIS

Isolation of enterovirus in cell culture is the traditional diagnostic procedure. While cultures of stool, nasopharyngeal, or throat samples from patients with enterovirus diseases are often positive, isolation of the virus from these sites does not prove that it is directly associated with disease because these sites are frequently colonized for weeks in patients with subclinical infections. Isolation of virus from the throat is more likely to be associated with disease than isolation from the stool since virus is shed for shorter periods from the throat. Cultures of CSF, serum, fluid from body cavities, or tissues are positive less frequently, but a positive result is indicative of disease caused by enterovirus. In some cases, the virus is isolated only from the blood or only from the CSF; therefore, it is important to culture multiple sites. Cultures are more likely to be positive earlier than later in the course of infection. Most human enteroviruses can be detected within a week after inoculation of cell cultures. Cultures may be negative because of the presence of neutralizing antibody, lack of susceptibility of the cells used, or inappropriate handling of the specimen. Coxsackievirus A may require inoculation into special cell-culture lines or into suckling mice.

Identification of the enterovirus serotype is useful primarily for epidemiologic studies and, with a few exceptions, has little clinical utility. It is important to identify serious infections with enterovirus during epidemics and to distinguish the vaccine strain of poliovirus from the other enteroviruses in the throat or in the feces. Stool and throat samples for culture as well as acute- and convalescent-phase serum specimens should be obtained from all patients with suspected poliomyelitis. In the absence of a positive CSF culture, a positive culture of stool obtained within the first 2 weeks after the onset of symptoms is most often used to confirm the diagnosis of poliomyelitis. If poliovirus infection is suspected, two or more fecal and throat swab samples should be obtained at least 1 day apart and cultured for enterovirus as soon as possible. If poliovirus is isolated, it should be sent to the CDC for identification as either wild-type or vaccine virus.

The polymerase chain reaction (PCR) has been used to amplify viral nucleic acid from CSF, serum, urine, throat swabs, and tissues. A single pair of PCR primers can detect >92% of the serotypes that infect humans.

With the proper controls, PCR of the CSF is highly sensitive ($\geq 95\%$) and specific ($>80\%$) and is more rapid than culture. PCR of the CSF is less likely to be positive when patients present ≥ 3 days after the onset of meningitis rather than earlier; in these cases, PCR of fecal specimens should be considered, although the test is less specific than PCR of CSF.

PCR of serum is also highly sensitive and specific in the diagnosis of disseminated disease. PCR may be particularly helpful for the diagnosis and follow-up of enterovirus disease in immunodeficient patients receiving immunoglobulin therapy, whose viral cultures may be negative. Antigen detection and hybridization of enterovirus sequences in human tissues with a specific probe are additional options, but these techniques are generally less sensitive than PCR.

Serologic diagnosis of enterovirus infection is limited by the large number of serotypes and the lack of a common antigen. Demonstration of seroconversion may be useful in rare cases for confirmation of culture results, but serologic testing is usually limited to epidemiologic studies. Serum should be collected and frozen soon after the onset of disease and again ~ 4 weeks later. Measurement of neutralizing titers is the most accurate method for antibody determination; measurement of complement-fixation titers is usually less sensitive. Titers of virus-specific IgM are elevated in both acute and chronic infection.

Rx Treatment: ENTEROVIRUS INFECTIONS

Most enterovirus infections are mild and resolve spontaneously; however, intensive supportive care may be needed for cardiac, hepatic, or CNS disease. IV, intrathecal, or intraventricular immunoglobulin has been used with apparent success for the treatment of chronic enterovirus meningoencephalitis and dermatomyositis in patients with hypogammaglobulinemia or agammaglobulinemia. The disease may stabilize or resolve during therapy; however, some patients decline inexorably despite therapy. IV administration of immunoglobulin with high titers of antibody to the infecting virus has been used in some cases of life-threatening infection in neonates, who may not have maternally acquired antibody. In one trial involving neonates with enterovirus infections, immunoglobulin containing very high titers of antibody to the infecting virus reduced rates of viremia; however, the study was too small to show a substantial clinical benefit. The level of enteroviral antibodies varies with the immunoglobulin preparation. For a time, pleconaril was given to patients with severe enterovirus infections on a compassionate-use basis, but this drug is no longer available for this use. Glucocorticoids are contraindicated.

Good hand-washing practices and the use of gowns and gloves are important in limiting nosocomial transmission of enteroviruses during epidemics. Enteric precautions are indicated for 7 days after the onset of enterovirus infections.

PREVENTION AND ERADICATION OF POLIOVIRUS

(See also Chap. 3) After a peak of 57,879 cases of poliomyelitis in the United States in 1952, the introduction of inactivated vaccine in 1955 and of oral vaccine in 1961 ultimately eradicated disease due to wild-type poliovirus in the Western Hemisphere. Such disease has not been documented in the United States since 1979, when cases occurred among religious groups who had declined immunization. In the Western Hemisphere, paralysis due to wild-type poliovirus was last documented in 1991.

In 1988, the World Health Organization adopted a resolution to eradicate poliomyelitis by the year 2000. From 1988 to 2001, the number of cases worldwide decreased by >99%, with fewer than 1000 confirmed cases reported in 2001. In 2002, however, there were ~1900 cases of polio, with ~1500 reported in India. Wild-type poliovirus type 2 has not been detected in the world since 1999. The Americas were certified free of indigenous wild-type poliovirus transmission in 1994, the Western Pacific Region in 2000, and the European Region in 2002. The total number of cases worldwide fell to a nadir of 498 in 2001. However, from 2002 to 2005, 21 countries previously free of polio reported cases imported from 6 polio-endemic countries. By 2006, polio transmission had been reduced in most of these 21 countries; in 2008, 1730 cases were reported, ~90% of them from Nigeria, India, Pakistan, and Afghanistan—the only countries where polio remains endemic (**Table 94-2**). Polio is a source of concern for unimmunized and partially immunized travelers to these regions. In 2008–2009, the importation of wild-type poliovirus into

15 countries in Africa resulted in 96 cases of polio, with persistent transmission of virus in 5 countries previously free of the virus. In 2008, ~8% of polio cases were imported from Nigeria and India. Outbreaks of polio in Europe and North America have been traced to cases imported from the Indian subcontinent. Clearly, global eradication of polio is necessary to eliminate the risk of importation of wild-type virus. Outbreaks are thought to have been facilitated by suboptimal rates of vaccination, isolated pockets of unvaccinated children, poor sanitation and crowding, improper vaccine-storage conditions, and a reduced level of response to one of the serotypes in the vaccine. While the global eradication campaign has markedly reduced the number of cases of polio, doubts have been raised as to whether eradication is a realistic goal given the large number of asymptomatic cases and the political instability in developing countries.

Outbreaks of poliomyelitis due to circulating vaccine-derived poliovirus have recently occurred. In Egypt, 30 cases of vaccine-derived polio occurred in 1988–1993; in the Dominican Republic and Haiti, 21 cases occurred in 2000–2001; and fewer than 5 cases each occurred in the Philippines (2001), Madagascar (2002), and China (2004). These OPV-derived viruses reverted to a more neurovirulent phenotype after undetected circulation (probably for >2 years). The epidemic in Hispaniola was rapidly terminated after intensive vaccination with OPV. In 2005, a case of vaccine-derived polio occurred in an unvaccinated U.S. woman returning from a visit to Central and South America. In the same year, an unvaccinated immunocompromised infant in Minnesota was found to be shedding vaccine-derived poliovirus; further investigation identified 3 other infants in the same community who were shedding the virus. All 4 infants were asymptomatic. These outbreaks emphasize the need for maintaining high levels of vaccine coverage and continued surveillance for circulating virus.

IPV is used in most industrialized countries and OPV in most developing countries, including those in which polio still is or recently was endemic. After several doses of OPV alone, the seropositivity rate for individual poliovirus serotypes may still be suboptimal for children in developing countries; one or more supplemental doses of IPV can increase the rate of seropositivity for these serotypes. While IM injections of other vaccines (live or attenuated) can be given concurrently with OPV, unnecessary IM injections should be avoided during the first month after vaccination because they increase the risk of vaccine-associated paralysis. Since 1988, an enhanced-potency inactivated poliovirus vaccine has been available in the United States.

OPV and IPV induce antibodies that persist for at least 5 years. Both vaccines induce IgG and IgA antibodies. Compared with recipients of IPV, recipients of OPV shed less virus and less frequently develop reinfection with wild-type virus after exposure to poliovirus. Although IPV is safe and efficacious, OPV offers the advantages of ease of administration, lower cost, and induction of intestinal immunity resulting in a reduction

TABLE 94-2

LABORATORY-CONFIRMED CASES OF POLIOMYELITIS IN 2008

| COUNTRY | TYPE OF TRANSMISSION | NUMBER OF CASES |
|---------------------|----------------------|------------------|
| Nigeria | Endemic | 860 ^a |
| India | Endemic | 559 |
| Pakistan | Endemic | 117 |
| Chad | Imported | 37 |
| Afghanistan | Endemic | 31 |
| Angola | Imported | 29 |
| Sudan | Imported | 26 |
| Niger | Imported | 12 |
| Others ^b | Imported | 42 |
| Others ^c | Vaccine-derived | 17 |
| Total | | 1730 |

^aOf these cases, 62 were vaccine-derived.

^bGhana, 8; Benin, 6; Burkina Faso, 6; Nepal, 6; Democratic Republic of the Congo, 5; Central African Republic, 3; Ethiopia, 3; Togo, 3; Cote d'Ivoire, 1; Mali, 1.

TABLE 94-3**RECOMMENDATIONS FOR POLIOVIRUS VACCINATION OF ADULTS**

1. Most adults in the United States have been vaccinated during childhood and have little risk of exposure to wild-type virus in the United States. Immunization is recommended for those with a higher risk of exposure than the general population, including:
 - a. Travelers to areas where poliovirus is or may be epidemic or endemic;
 - b. Members of communities or population groups with disease caused by wild-type polioviruses;
 - c. Laboratory workers handling specimens that may contain wild-type polioviruses;
 - d. Health care workers in close contact with patients who may be excreting wild-type polioviruses.
2. Three doses of IPV are recommended for adults who need to be immunized. The second dose should be given 1–2 months after the first dose; the third dose should be given 6–12 months after the second dose.
3. Adults who are at increased risk of exposure to wild-type poliovirus and who have previously completed primary immunization should receive a single dose of IPV. Adults who did not complete primary immunization should receive the remaining vaccinations with IPV.

Note: IPV, inactivated poliovirus vaccine.

Source: Modified from Pickering LK, ed. Redbook 2006: Committee on Infectious Diseases, 27th ed. Elk Grove Village, IL: American Academy of Pediatrics.

in the risk of community transmission of wild-type virus. Because of progress toward global eradication of polio (with a reduced risk of imported cases) and the continued occurrence of cases of vaccine-associated polio, an all-IPV regimen was recommended in 2000 for childhood poliovirus vaccination in the United States, with vaccine administration at 2, 4, and 6–18 months and 4–6 years of age. The risk of vaccine-associated polio should be discussed before OPV is administered. Recommendations for vaccination of adults are listed in **Table 94-3**.

There are concerns about discontinuing vaccination in the event that endemic spread of poliovirus is eliminated. Among the reasons for these concerns are that poliovirus is shed from some immunocompromised persons for several years, that vaccine-derived poliovirus can circulate and cause disease, and that wild-type poliovirus is present in a large number of laboratories. A national survey began in October 2002 to encourage laboratories to dispose of all unneeded wild-type poliovirus materials and to identify laboratories

that have wild-type poliovirus or specimens that may contain virus.

REOVIRUSES

Reoviruses are double-stranded RNA viruses encompassing three serotypes. Serologic studies indicate that most humans are infected with reoviruses during childhood. Most infections either are asymptomatic or cause very mild disease. One outbreak of reovirus infection in children resulted in minor upper respiratory tract symptoms. Reovirus is considered a rare cause of mild gastroenteritis in infants and children. Speculation regarding an association of reovirus type 3 with idiopathic neonatal hepatitis and extrahepatic biliary atresia is based on an elevated prevalence of antibody to reovirus among some of these patients and the detection of viral RNA by PCR in hepatobiliary tissues in some studies.

CHAPTER 95

MEASLES (RUBEOLA)

Anne Gershon

DEFINITION

Measles (rubeola) is a highly contagious, acute, exanthematous respiratory disease with a characteristic clinical picture and a pathognomonic enanthem: Koplik's spots, an eruption on the buccal mucous membranes (**Fig. 95-1**).

A successful live attenuated measles vaccine became available in 1963 in the United States and elsewhere, and measles is now an unusual disease in most developed countries where this vaccine is widely used. However, measles continues to occur sporadically in miniepidemics in the United States, and major epidemics in developing nations make this disease a persistent cause of childhood morbidity and mortality.

In 2000, measles was the fifth leading cause of childhood mortality worldwide, with an estimated 777,000 deaths. The global incidence of measles in 2004 is shown in **Fig. 95-2**.

ETIOLOGIC AGENT

Measles virus is the only member of the genus *Morbillivirus* that infects humans. Part of the family Paramyxoviridae, it is related to viruses causing similar infections in other mammals: distemper, rinderpest, morbilli, and *peste des petits ruminants*. There is only one antigenic type. Virions—pleomorphic spheres with a diameter of

FIGURE 95-1

Koplik's spots, which manifest as white or bluish lesions with an erythematous halo on the buccal mucosa, usually occur in the first 2 days of measles symptoms and may briefly overlap the measles exanthem. The presence of the erythematous halo differentiates Koplik's spots from Fordyce's spots (ectopic sebaceous glands), which occur in the mouths of healthy individuals. (Source: Centers for Disease Control and Prevention. Photo selected by Dr. Kenneth Kaye.)

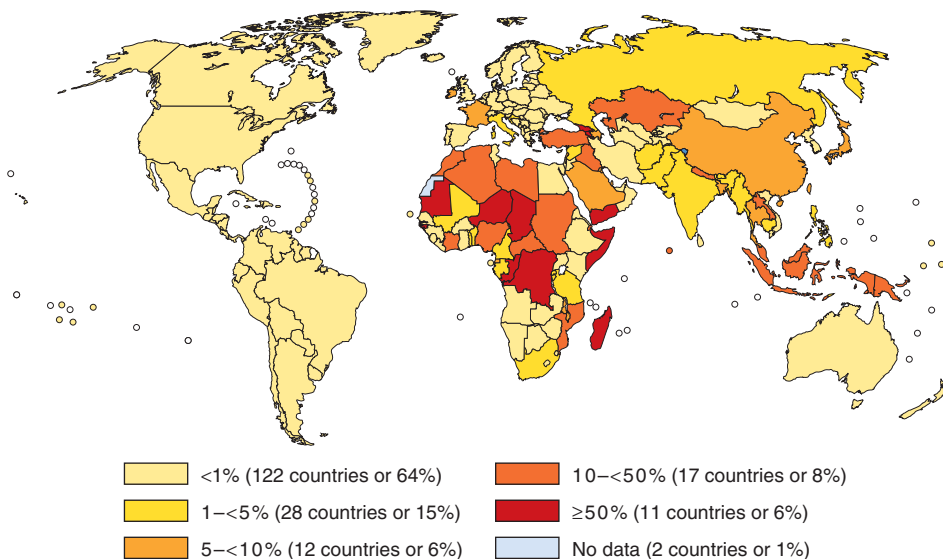

FIGURE 95-2

Worldwide reported measles incidence rate per 100,000 population, 2004. (Source: WHO/IBV database, 2005. This map does not imply the expression of any opinion whatsoever on the part of the World Health Organization concerning the legal status of any country, territory, city, or area of its authorities or concerning the delimitation of its frontiers or boundaries.)

100–250 nm—consist of six proteins. The inner capsid is composed of RNA and three proteins. The outer envelope consists of a matrix protein bearing short surface-glycoprotein projections or peplomers, one a hemagglutinin (H) and the other a fusion (F) protein. Sequencing of the single-stranded genome makes it possible to distinguish vaccine-type from wild-type virus. The genetic variability of wild-type virus (23 genotypes identified) permits identification of strains endemic within a given locale where measles cases have occurred. The cellular receptors for measles virus are the CD46 and CD150 molecules expressed on many human cells.

EPIDEMIOLOGY

Measles has a worldwide distribution; humans are the only natural hosts, although other primates can be experimentally infected. During the prevaccination era in the United States, measles epidemics took place every 2–5 years. In epidemic years, roughly half a million measles cases occurred; 99% of adults had serologic evidence of previous measles infection. After the live attenuated vaccine became available, the number of cases reported to the Centers for Disease Control and Prevention fell, with a nadir of 1497 cases in 1983. In 1990, after an upsurge to more than 27,000 cases (with 89 deaths), the disease was once more brought under control, mainly through the routine administration of two doses of vaccine. Reasons for the resurgence included failure to immunize young children, especially in inner-city areas; primary vaccine failure (rate, ~5%); and (rarely) waning immunity.

Between 1993 and 1996, fewer than 1000 cases per year were reported in the United States; 309 cases were reported in 1995, 116 in 2001, and only 37 in 2004. Molecular studies indicated interruption of transmission of indigenous measles in 1993. Most cases since have resulted from international importations of the virus by immigrants or U.S. citizens returning from travel abroad. Mortality rates are highest among children <2 years of age and among adults. Patients with impaired cell-mediated immunity are at especially high risk for severe or even fatal measles. The measles-associated mortality rate in the United States is ~0.3%; in developing countries, it frequently exceeds 1% and sometimes approaches 10% because of malnutrition and associated immunodeficiency and HIV infection.

Measles virus is transmitted by respiratory secretions, predominantly through exposure to aerosols but also through direct contact with larger droplets. Patients are contagious from 1 or 2 days before symptom onset until 4 days after the rash appears. Infectivity peaks during the prodromal phase. The mean intervals from infection to symptom onset and rash appearance are 10 and 14 days, respectively.

PATHOGENESIS, IMMUNITY, AND PATHOLOGY

Measles virus invades the respiratory epithelium and spreads via the bloodstream to the reticuloendothelial system, from which it infects white blood cells, thereby

establishing infection of the skin, respiratory tract, and other organs. Both viremia and viruria develop. Multinucleated giant cells with inclusion bodies in the nucleus and cytoplasm (Warthin-Finkeldey cells) are found in respiratory and lymphoid tissues and are pathognomonic for measles. Direct invasion of T lymphocytes and increased levels of suppressive cytokines (e.g., interleukin 4) may play a role in the temporary depression of cellular immunity that accompanies and transiently follows measles. The major infected cell in the blood is the monocyte. Infection of the entire respiratory tract accounts for the characteristic cough and coryza of measles and for the less frequent manifestations of croup, bronchiolitis, and pneumonia. Generalized damage to the respiratory tract, with loss of cilia, predisposes to secondary bacterial infections such as pneumonia and otitis media.

Specific antibodies are not detectable before the onset of rash. Cellular immunity (consisting of cytotoxic T cells and possibly natural killer cells) plays a prominent role in host defense, and patients who are deficient in cellular immunity are at high risk for severe measles. Children with isolated agammaglobulinemia are not at increased risk. Immune reactions to the virus in the endothelial cells of dermal capillaries play a substantial role in the development of Koplik's spots (the pathognomonic enanthem) and rash; in immunodeficient hosts, measles may be severe despite the absence of these manifestations. Measles antigens have been demonstrated in involved skin during early stages of the illness.

Pathologic changes in measles encephalitis include focal hemorrhage, congestion, and perivascular demyelination. Measles virus is rarely isolated from cerebrospinal fluid (CSF) in cases of encephalitis, which are thought to be due to the interaction of virus-infected cells with local cellular immune factors.

CLINICAL MANIFESTATIONS

Measles begins with a 2- to 4-day respiratory prodrome of malaise, cough, coryza, conjunctivitis with lacrimation, nasal discharge, and increasing fever [with temperatures as high as 40.6°C (105°F), probably reflecting secondary viremia]. At this stage of the illness, in which the rash has not yet developed, influenza may be suspected. Just before rash onset, Koplik's spots appear as 1- to 2-mm blue-white spots on a bright red background (Fig. 95-1). Without adequate illumination for examination, they may be overlooked. Koplik's spots are typically located on the buccal mucosa, alongside the second molars, and may be extensive; they are not associated with any other infectious disease. The spots wane after the onset of rash and soon disappear. The entire buccal and inner labial mucosa may be inflamed, and the lips may be reddened.

The characteristic erythematous, nonpruritic, maculopapular rash of measles begins at the hairline and behind the ears, spreads down the trunk and limbs to include the palms and soles, and often becomes confluent (Fig. 95-3). At this time, the patient is at the most severe point of the illness. By the fourth day, the rash begins to fade in the order in which it appeared. Brownish discoloration of the skin and desquamation

**FIGURE 95-3**

In measles, discrete erythematous lesions become confluent as the rash spreads downward. (Reprinted with permission from Fitzpatrick TB et al: *Color Atlas & Synopsis of Clinical Dermatology*, 4th ed. New York, McGraw-Hill, 2001, p 775.)

may occur later. Fever usually resolves by the fourth or fifth day after the onset of rash; prolonged fever suggests a complication of measles. Lymphadenopathy, diarrhea, vomiting, and splenomegaly are common features. The chest x-ray may be abnormal, even in uncomplicated measles, because of the propensity of measles virus to invade the respiratory tract. The entire illness, which usually lasts ~10 days, tends to be more severe in adults than in children, with higher fever, more prominent rash, and a higher incidence of complications.

Milder forms of the illness with less intense symptoms and a milder rash, termed *modified measles*, may occur in individuals with preexisting partial immunity induced by active or passive vaccination. These patients include infants <1 year of age who retain some proportion of passively acquired maternal antibodies. On occasion, individuals with a history of immunization may develop modified measles.

COMPLICATIONS

The complications of measles (Table 95-1) can be divided into three groups, according to the site involved: the respiratory tract, the central nervous system (CNS), and the gastrointestinal tract. Respiratory tract involvement, manifested as laryngitis, croup, or bronchitis, occurs in the majority of cases of uncomplicated measles. In young children, otitis media is the most common complication. Pneumonia is a frequent reason for hospitalization, especially of adults. The pneumonia is of viral origin in the majority of cases, but secondary bacterial infection (most commonly caused by streptococci, pneumococci, or staphylococci) also develops with some frequency. Primary giant-cell (Hecht's) pneumonia is most often documented in immunocompromised and/or malnourished patients.

TABLE 95-1

COMPLICATIONS OF MEASLES

| COMPLICATION | COMMENTS |
|--|--|
| Otitis media | Very common in infants with measles |
| Pneumonia | May be primary viral pneumonia or bacterial superinfection; frequent reason for hospitalization of adults; measles rash sometimes lacking in immunocompromised patients with measles pneumonia |
| Croup | Occasionally severe, requiring intubation in infants |
| Gastroenteritis | Diarrhea can be life threatening in infants |
| Cervical adenitis | Due to lymphoid hyperplasia as host response to virus; common |
| Acute encephalitis | May be mild to severe/fatal; occurs in 1 in 1000 cases of measles; cerebral and cerebellar forms; immune-mediated pathogenesis |
| Subacute sclerosing panencephalitis (SSPE) | In 1 in 100,000 cases of measles, usually when measles occurs in infancy; seen 5–10 years later. In the United States, most children with SSPE were born in another country where measles vaccine is not routinely used. |

Encephalographic abnormalities in the absence of symptoms of CNS disease are extremely common in measles. Symptomatic CNS disease may present with fever, headache, drowsiness, coma, and/or seizures. Symptoms usually begin within days after the onset of rash but occasionally appear for the first time several weeks later. About 10% of patients do not survive acute measles encephalitis; a significant percentage of survivors have permanent sequelae (e.g., mental retardation or epilepsy). Most cases appear to result from an immune-mediated response to myelin proteins (postinfectious encephalomyelitis) and not directly from viral infection of the CNS. Rarely, transverse myelitis follows measles. Immunocompromised patients are at risk for progressive fatal encephalitis 1–6 months after measles; in some cases, even though prior measles has not been recognized, the virus is identified at autopsy. Subacute sclerosing panencephalitis (SSPE)—a protracted, chronic, extremely rare form of measles encephalitis—sometimes follows measles and is particularly common among children who have measles before the age of 2 years (Chap. 29). As a result of widespread vaccination, SSPE has virtually disappeared in the United States. Typically, progressive dementia evolves over several months. SSPE is thought to be due to a complex interaction of the host with defective measles virus.

Gastrointestinal complications of measles include gastroenteritis, hepatitis, appendicitis, ileocolitis, and mesenteric adenitis. It is not uncommon to detect high levels of alanine and aspartate aminotransferases in the absence of gastrointestinal signs such as jaundice.

**FIGURE 95-4**

Petechial lesions in a patient with atypical measles. (Photo courtesy of Stephen E. Gellis, MD; with permission.)

Rare complications include myocarditis, glomerulonephritis, and postinfectious thrombocytopenic purpura. Measles can exacerbate preexisting tuberculosis, presumably through virus-induced depression of cellular immunity. Natural measles and immunization against measles can result in tuberculin skin-test anergy lasting for ~1 month.

ATYPICAL MEASLES

An atypical form of measles has been reported in individuals who received formalin-inactivated measles vaccine (used in the United States in 1963–1967 and in Canada until 1970) and subsequently were exposed to measles virus. After a several-day prodrome of fever, myalgia, and headache, the rash appears (**Fig. 95-4**); it begins peripherally and can be urticarial, maculopapular, hemorrhagic, and/or vesicular. Fever is high and accompanied by edema of the extremities, interstitial pulmonary infiltrates, hepatitis, and (on occasion) pleural effusion. The differential diagnosis includes Rocky Mountain spotted fever, Henoch-Schönlein purpura, meningococcemia, drug allergy, toxic shock syndrome, and varicella. Despite its severity, the illness is self-limited. Measles virus cannot be isolated from these patients. This disease is believed to be due to hypersensitivity to measles virus induced by the inactivated vaccine. To prevent it, adults who received formalin-inactivated measles vaccine should be immunized with live attenuated measles vaccine. Because inactivated measles vaccine has not been available for >35 years, atypical measles has virtually disappeared.

MEASLES IN THE IMMUNOCOMPROMISED HOST

Patients with defects in cell-mediated immunity are at risk for severe protracted and fatal measles. Included in this category are patients with congenital cellular immune defects or malignancy, recipients of immunosuppressive

therapy, or persons infected with HIV. In these patients, measles may not be accompanied by a rash. Complications are primary measles (giant-cell) pneumonia, progressive encephalitis beginning weeks or months after initial infection, and (in HIV-infected patients) progression to AIDS.

MEASLES IN ADULTS

Measles is naturally a disease of childhood and, like many other viral infections, is more severe in adults than in children. About 3% of young adults with measles develop primary viral pneumonia and require hospitalization. Hepatitis and bronchospasm are more common among adults with measles than among children, and the rash is more severe and more confluent in adults. Bacterial superinfection is more common among adults, more than one-third of whom develop respiratory complications such as otitis media, sinusitis, and pneumonia. Adults may develop measles because they were never immunized or (more rarely) because their vaccine-induced immunity has waned. Very low titers of antibody to measles virus have been associated with lack of protection.

LABORATORY FINDINGS

Lymphopenia and neutropenia are common in measles and may be due to invasion of leukocytes by the virus, with subsequent cell death. Leukocytosis may herald a bacterial superinfection. Patients with measles encephalitis usually have an elevated protein concentration in CSF as well as lymphocytosis.

DIAGNOSIS

A specific diagnosis of measles can be made quickly by immunofluorescent staining of a smear of respiratory secretions for measles antigen; monoclonal antibodies conjugated to fluorescein are commercially available. Secretions can be examined microscopically for multinucleated giant cells. Measles virus can be demonstrated by culture or polymerase chain reaction in respiratory secretions or urine. A number of serologic tests are available. A serologic diagnosis by enzyme immunoassay (EIA) cannot necessarily be made rapidly if acute- and convalescent-phase serum specimens are examined. However, EIA measurement of specific IgM permits diagnosis on the basis of an acute-phase serum sample. Specific IgM antibodies are detectable within 1–2 days after rash onset, and the IgG titer rises significantly after 10 days. Atypical measles and SSPE are associated with extremely high levels of measles antibodies in blood and/or CSF.

DIFFERENTIAL DIAGNOSIS

Classic measles—with Koplik's spots, cough, coryza, conjunctivitis, and a rash beginning on the head—is easily diagnosed on clinical grounds. Modified measles is more difficult to diagnose because one or more characteristic signs or symptoms may be lacking. The differential diagnosis of measles includes Kawasaki disease, scarlet fever, infectious mononucleosis, toxoplasmosis, drug eruption, and

Mycoplasma pneumoniae infection. In the differential diagnosis of measles, attention should be paid to the current epidemiology of the disease in the community and to the patient's history of measles vaccination and foreign travel.

PREVENTION

The development of live attenuated measles vaccine by Enders and colleagues was a milestone in American medicine. This vaccine, used in the United States for the routine immunization of children since 1963, induces seroconversion in ~95% of recipients and probably confers lifelong protection. Waning immunity to measles after immunization is rare. For the past three decades, measles vaccine has been available as the combination vaccine measles-mumps-rubella (MMR); this vaccine should be administered to children at 12–15 months of age. (Vaccination at 12 months is preferred for infants whose mothers were immunized against measles in childhood.) A second dose of MMR vaccine is recommended for school-age children. This two-dose policy was developed in the late 1980s in response to measles outbreaks in the United States. MMR vaccine is likely to be supplanted by MMRV vaccine, which also covers varicella and was licensed by the U.S. Food and Drug Administration in 2005. MMRV vaccine is licensed only for children 1–13 years of age.

Older susceptible persons should be immunized. Individuals should be considered susceptible to measles unless they have documentation of physician-diagnosed measles or of the receipt of two doses of vaccine, have laboratory evidence of measles immunity, or were born before 1957. Rarely, individuals born before 1957 develop measles, and those who are at risk of exposure to measles (e.g., health care workers, teachers, and international travelers) should be tested for measles antibody and immunized if necessary. Approximately 10% of healthy vaccinees develop a fever, with temperatures up to 39.4°C (103°F), 5–7 days after vaccination; this fever lasts 1–5 days and is accompanied by a transient rash. Individuals previously immunized only with killed vaccine are considered susceptible and should receive at least one dose—preferably two doses—of MMR vaccine. Transient adverse reactions in these individuals include fever, malaise, and redness and swelling at the injection site.

Because of the severity of measles in this group and the lack of reported problems following vaccination, children with asymptomatic HIV infection should receive MMR vaccine; those with severe immunosuppression (<15% CD4+ T lymphocytes) should not. A case of fatal measles due to vaccine-type virus was reported in a college student with AIDS in 1998. Measles vaccine is contraindicated for persons with impaired cell-mediated immunity, for pregnant women, and for persons with a history of anaphylaxis due to egg protein or neomycin. Minor illnesses, with or without fever and a history of convulsions, are not contraindications to vaccination. Vaccination should be deferred for 6–11 months after the receipt of immune globulin or of blood products containing antibodies and for at least 3 months after the discontinuation of immunosuppressive

treatment. Vaccine failures have been ascribed to faulty vaccine storage, the presence of maternally derived antibodies in infants, and simultaneous administration of measles vaccine and immune globulin.

The only temporally related causal complications of measles vaccination are febrile seizures, which rarely have long-term sequelae; self-limited thrombocytopenia; and rare anaphylaxis. An exhaustive analysis conducted in 2000 by a number of official committees, including those of the American Academy of Pediatrics and the Institute of Medicine, found no causal relationship between MMR vaccination and subsequent development of autism.

Children and adults who are susceptible to measles and are exposed to the disease should receive postexposure prophylaxis. Standard immune globulin, given intramuscularly within 6 days of exposure, can exert a protective or modifying effect. The dose is 0.25 mL/kg for healthy persons and 0.5 mL/kg for immunocompromised persons, with a maximum dose of 15 mL. Immune globulin is particularly strongly indicated for susceptible household contacts, especially those <1 year of age, and for immunocompromised persons. HIV-infected individuals, particularly those with severe immunosuppression, should be given immune globulin after exposure, regardless of their measles immune status and whether or not they are receiving intravenous immune globulin. Vaccination within 72 h of exposure may also provide protection against clinical measles but is contraindicated in immunocompromised patients. Vaccine and immune globulin should not be given concurrently.

Rx Treatment: MEASLES

Therapy for measles is largely supportive and symptom based. Patients with otitis media and pneumonia should be given standard antibiotics. Patients with encephalitis need supportive care, including observation for increased intracranial pressure. Controlled trials suggest clinical benefit from high doses of vitamin A in severe or potentially severe measles, especially in children <2 years old who are or may be malnourished. On the basis of limited data, a dose of 50,000 IU is used for infants 1–6 months old; 100,000 IU is recommended for infants 7–12 months old and 200,000 IU for children >1 year old. A single dose is administered on two consecutive days. In the United States, vitamin A treatment is recommended for young children hospitalized for measles and for pediatric measles patients with immunodeficiency, clinical evidence of vitamin A deficiency, impaired intestinal absorption, moderate to severe malnutrition, or recent immigration from an area where there is high mortality from measles. Transient vomiting and headache may be associated with the administration of vitamin A. Ribavirin is effective against measles virus *in vitro* and may be considered for use in immunocompromised individuals.

CHAPTER 96

RUBELLA (GERMAN MEASLES)

Anne Gershon

DEFINITION

Rubella is an acute viral infection of children and adults that characteristically includes rash, fever, and lymphadenopathy and has a broad spectrum of other possible manifestations. However, a high percentage of rubella infections in both children and adults are subclinical. In addition, the illness can resemble a mild attack of measles (rubeola) and can cause arthritis, especially in adults. Rubella was formerly known as *German measles* because it was first distinguished clinically from rubeola in Germany, where it generated much medical interest in the mid-eighteenth and early nineteenth centuries. Rubella during pregnancy can lead to fetal infection, with the production of a significant constellation of malformations (*congenital rubella syndrome*) in a high proportion of infected fetuses. Rubella virus was first isolated in cell culture just before the last pandemic of the disease began in 1962. Since the licensing of rubella vaccine in the United States in 1969, there have been no further epidemics in this country.

ETIOLOGIC AGENT

Rubella virus, a togavirus, is the only member of the *Rubivirus* genus and is closely related to the alphaviruses. Unlike these agents, however, it does not require a vector for transmission. Moreover, there is no RNA sequence homology between rubella virus and the alphaviruses.

The rubella virion is composed of an inner icosahedral capsid of RNA and protein that is surrounded by a lipid-containing envelope with glycoprotein spikes and a diameter of ~60 nm. The structural proteins associated with

rubella virus are E1 and E2 (transmembrane envelope glycoproteins) and C (the capsid protein that surrounds the viral RNA). Only one serotype has been identified.

EPIDEMIOLOGY

In the United States during the prevaccine era, rubella was most common in the spring and most often affected school-age children; only 80–90% of adults were immune; and major epidemics occurred every 6–9 years. The most recent epidemic in the United States occurred in 1964–1965, when more than 12 million cases of postnatal rubella and more than 20,000 cases of the congenital rubella syndrome were reported. Although there have been no epidemics since the introduction of live attenuated rubella vaccine in 1969, limited outbreaks have been reported in settings where susceptible individuals come into close contact with one another (e.g., schools and workplaces). Since 2001, the annual incidences of rubella have been the lowest ever recorded in the United States. In 2001–2004, an average of only 14 cases of postnatally acquired rubella were reported annually to the Centers for Disease Control and Prevention (CDC). During these 4 years, only 4 confirmed cases of congenital rubella syndrome were reported. Three of the affected infants were born to women who had immigrated to the United States. Currently, 91% of U.S. residents are estimated to be immune to rubella, and at least 95% of schoolchildren have been immunized. When rubella is reported in the United States, the genotype of the virus is consistent with an imported agent.

Although rubella is no longer considered endemic in the United States, global challenges remain. According to the World Health Organization, 57% of countries included rubella vaccine in their national programs in 2003, but rubella continues to be endemic in many areas of the world.

Whether symptomatic or subclinical, rubella is contagious, albeit less so than measles. Its incubation period is 18 days on average, with a range of 12–23 days. The virus, which is spread in droplets shed in respiratory secretions, infects the respiratory tract and then the bloodstream. In postnatally acquired infections, rubella virus is shed during the prodromal phase of the illness, and shedding from the pharynx can continue for ~1 week after onset. Despite high titers of specific neutralizing antibodies, infants with congenital rubella may excrete rubella virus from the respiratory tract and in the urine until the age of 2 years. This excretion raises important issues related to infection control in hospital and day-care settings. Persons recently immunized with live attenuated rubella vaccine do not transmit the vaccine virus to others, although low titers of rubella virus may be detected transiently in the pharynx.

After an attack of rubella, specific antibodies and cell-mediated immunity develop and probably play a significant role in protection against future disease. Asymptomatic reinfection at the level of the respiratory tract is common upon re-exposure to the virus but is rarely, if ever, associated with viremia.

Rubella virus has been cultured from respiratory secretions during reinfection. Fetal infection may occur during maternal reinfection but is acknowledged to be extremely rare because of the absence of maternal viremia under these circumstances. Viremia following reinfection of individuals immunized against rubella also is rare.

Although the current level of congenital rubella in the United States is exceedingly low, it has been observed that young immigrants to the United States from countries in Latin America and the Caribbean, where rubella vaccine is not routinely given to children, are at increased risk for rubella susceptibility. Because infants with the congenital rubella syndrome have been born to immigrant Hispanic women, increasing efforts have been made to identify and vaccinate such women before they become pregnant.

PATHOGENESIS AND PATHOLOGY

Little is known about the microscopic pathology of postnatally acquired rubella because the disease is invariably self-limited. Like that of measles, the rash of rubella is immunologically mediated; its onset coincides with the development of specific antibodies. Viremia can be demonstrated for ~1 week before and ends within a few days after the onset of rash.

The cause of the damage to cells and organs in congenital rubella is not well understood. Proposed mechanisms of fetal damage include mitotic arrest of cells, tissue necrosis without inflammation, and chromosomal

damage. The growth of the fetus may be retarded. Other findings may include decreased numbers of megakaryocytes in the bone marrow, extramedullary hematopoiesis, and interstitial pneumonia.

CLINICAL MANIFESTATIONS

Postnatally Acquired Rubella

Infection acquired after birth usually results in an extremely mild or subclinical illness. A prodromal phase is uncommon in children; adults may have more severe disease, with a brief prodrome of malaise, fever, and anorexia. The foremost symptoms of postnatally acquired rubella include posterior auricular, cervical, and suboccipital lymphadenopathy; fever; and rash. The rash often begins on the face (**Fig. 96-1**) and spreads down the body. It is maculopapular but not confluent, is sometimes accompanied by mild coryza and conjunctivitis, and generally lasts for 3–5 days. A petechial enanthem on the soft palate, designated *Forschheimer spots*, may occur but is not specific for rubella. Fever may be absent entirely or may be present for only several days in the early phase of the illness.

Complications of postnatally acquired rubella are uncommon; bacterial superinfection is rare. One particularly troublesome complication is seen almost exclusively in women: arthritis, most frequently involving the fingers, wrists, and/or knees. Arthritis develops as the rash is appearing and may take several weeks to resolve. Chronic arthritis resulting from rubella is extremely rare. Rubella virus has been isolated from joint fluid during acute

FIGURE 96-1

In rubella, an erythematous exanthem spreads from the hairline downward and clears as it spreads. (Photo courtesy of Stephen E. Gellis, MD; with permission.)

rubella arthritis and from peripheral blood in chronic rubella arthritis.

Another complication of postnatally acquired rubella is hemorrhage due to both thrombocytopenia and vascular damage; this complication occurs in 1 of every 3000 patients. Thrombocytopenia may last for weeks or months; it can have long-term consequences if there is bleeding into organs such as the eye or the brain.

Both children and adults may develop encephalitis after rubella; the incidence is about five times lower than that of encephalitis following measles. Adults are more likely than children to develop encephalitis; the mortality rate from this complication is 20–50%. Mild hepatitis is an unusual complication. Immunosuppressed patients are not at increased risk for rubella as they are for measles.

Congenital Rubella

Maternal infection in early pregnancy can lead to fetal infection, with resultant congenital rubella. The classic signs of congenital rubella are cataract, heart disease, deafness, and myriad other defects (Table 96-1). The most important factor in the pathogenicity of rubella virus for the fetus is gestational age at the time of infection. Maternal infection during the first trimester leads to fetal infection in ~50% of cases; maternal infection early in the second trimester leads to fetal infection in about one-third of cases. Fetal malformations not only are more common after maternal infection in the first trimester but also tend to be more severe and to involve more organ systems. Whereas a

fetus infected in the fourth week of gestation may develop many problems, one infected later (e.g., in the twentieth week) may have isolated deafness as the only symptom.

DIAGNOSIS

Because postnatally acquired rubella is often a mild disease and because many cases are subclinical, diagnosis on clinical grounds can be difficult. Other diseases that may mimic rubella include toxoplasmosis, scarlet fever, modified measles, roseola, fifth disease (erythema infectiosum due to parvovirus B19), and enteroviral infection. Routine laboratory tests usually reveal leukopenia and atypical lymphocytes.

The isolation of rubella virus in cell cultures of throat samples, urine, or other secretions is difficult and expensive but is sometimes undertaken. Polymerase chain reaction (PCR) is also useful for diagnosis. These techniques are particularly useful when congenital rubella is suspected. A laboratory diagnosis may also be made serologically. The most commonly used test is an enzyme-linked immunosorbent assay (ELISA) for IgG and IgM antibodies. Acute rubella is diagnosed by the documentation of a fourfold or greater rise in the titer of IgG antibodies in paired acute- and convalescent-phase serum specimens or by the detection of rubella-specific IgM antibodies in one serum specimen. However, false-negative and false-positive IgM reactions are sometimes obtained. Moreover, true-positive IgM reactions can occur in both primary infection and reinfection. Congenital rubella is diagnosed by the isolation of rubella virus, a positive PCR assay, the detection of IgM antibodies in a single serum sample, and/or the documentation of either the persistence of rubella antibodies in serum beyond 1 year of age or a rising antibody titer anytime during infancy in an unvaccinated child. Biopsied tissues and/or blood and cerebrospinal fluid have also been used for the demonstration of rubella antigens with monoclonal antibodies and for the detection of rubella RNA by in situ hybridization and PCR.

Cases of suspected postnatal or congenital rubella should be reported to the CDC.

PREVENTION

Live attenuated rubella vaccine was licensed in 1969, 7 years after rubella virus was first isolated in culture. This vaccine was developed as a strategy to prevent congenital rubella by ensuring that very few pregnant women would be susceptible and that there would be little circulating wild-type virus. Rubella vaccine induces seroconversion in >95% of recipients. Since its licensure, there have been no major epidemics in the United States, and the number of cases has declined by 98%. The vaccine currently licensed in the United States, RA 27/3, is propagated in human diploid cells and is more immunogenic (particularly with regard to the stimulation of secretory immunity) than previously licensed vaccines. The present vaccination strategy,

TABLE 96-1

CLINICAL PROBLEMS ASSOCIATED WITH THE CONGENITAL RUBELLA SYNDROME

| TRANSIENT SIGNS/ SYMPTOMS (AT BIRTH ONLY) | PERMANENT SIGNS/ SYMPTOMS (DEVELOPMENTAL) |
|---|---|

| | Spastic diplegia |
| | Thyroid disorders |

developed in part when measles was not being adequately controlled, is to immunize all infants at 12–15 months of age with measles-mumps-rubella (MMR) vaccine and to administer a second dose in early childhood. Rubella vaccine may also be administered to anyone who is thought to be susceptible to the infection and is not pregnant; it is particularly important that hospital workers of either sex be immune to rubella so that nosocomial transmission is avoided. Although there has been little change in the prevalence of immunity to rubella among women of childbearing age (~80%), the incidence of congenital rubella is extremely low, with fewer than 10 cases annually. It is likely that, although antibody may be undetectable years after immunization, protection against infection—possibly due to cell-mediated immunity—is the rule. At present, there is little if any evidence of significant waning of clinically important immunity to rubella with time.

On occasion, rubella vaccine may cause arthralgia or arthritis, especially in young women. Very rarely, rubella vaccination results in chronic arthritis; however, even cases of frank arthritis in vaccinees are generally self-limited, lasting only ~1 week.

After investigation of a series of more than 400 women who were inadvertently immunized during pregnancy and who carried their infants to term, the CDC has concluded that vaccine-type rubella virus either does not cause the congenital rubella syndrome at all or does so at an incidence too low to be detected. Nonetheless, rubella vaccine is contraindicated for use in pregnant women, and it is recommended that pregnancy be avoided for at least 3 months after rubella vaccination. It is acceptable for rubella-susceptible children whose mothers also are susceptible to be immunized, as vaccine recipients do not shed rubella virus or transmit it to susceptible individuals. Although it is recommended that rubella vaccine not be given to immunosuppressed persons, the vaccine is given to children infected with HIV. No adverse effects of rubella vaccine have been reported in immunocompromised patients.

R_x Treatment: **RUBELLA**

There is no specific therapy for rubella. At one time, immune globulin was used in an effort to prevent congenital rubella when pregnant women became infected.

However, because administration of immune globulin did not prevent maternal viremia, this approach was discarded. Symptom-based treatment is given for manifestations such as fever, arthralgia, and arthritis.

CHAPTER 97

MUMPS

Anne Gershon

DEFINITION

Mumps is an acute, systemic, communicable viral infection whose most distinctive feature is swelling of one or both parotid glands. Involvement of other salivary glands, the meninges, the pancreas, and the gonads also is common.

ETIOLOGIC AGENT

Mumps virus, a paramyxovirus, is pleomorphic and has a diameter ranging from 100 to 300 nm. The virion is composed of RNA and seven proteins. The RNA is surrounded by an envelope composed of glycoproteins, including a hemagglutinin-neuraminidase (HN), a hemolysis cell fusion antigen (F), and a matrix envelope protein (M). A fourth protein (SH) may also be membrane-associated. There are three internal components: a nucleocapsid protein (NP), a phosphoprotein (P), and a large protein (L). There is only one antigenic type of mumps virus. Polymerase chain reaction (PCR) has detected geographic differences among mumps viruses from different locales.

EPIDEMIOLOGY

After the introduction of mumps vaccine in 1967, the incidence of clinical mumps declined significantly in the United States. In 1968 (before widespread immunization), 185,691 cases of mumps were reported in this country. The 231–277 cases reported annually in 2001–2005 represent a >99% reduction from prevaccine levels. Before widespread vaccination, the incidence of mumps was highest in the winter and spring, with epidemics every 2–5 years. At that time, mumps was principally a disease of childhood, although today >50% of cases occur in young adults. Epidemics tended to occur in confined populations (e.g., in schools and the military services).

The incubation period of mumps generally ranges from 14 to 18 days, with extremes of 7 and 23 days. However, because a contact may be shedding virus before the onset of clinical disease or (like one-third of patients) may have subclinical infection, the incubation period in individual cases is often uncertain. One attack of mumps usually confers lifelong immunity. Long-term immunity is also associated with immunization.

PATHOGENESIS

Mumps virus is transmitted by droplet nuclei, saliva, and fomites. Replication of the virus in the epithelium of the upper respiratory tract leads to viremia, which is followed

by infection of glandular tissues and/or the central nervous system (CNS).

Little is known of the pathology of mumps since the disease is rarely fatal. The affected glands contain perivascular and interstitial mononuclear cell infiltrates with prominent edema. Necrosis of acinar and epithelial duct cells is evident in the salivary glands and in the germinal epithelium of the seminiferous tubules.

CLINICAL MANIFESTATIONS

The prodrome of mumps consists of fever, malaise, myalgia, and anorexia. Parotitis, if it develops, usually does so within the next 24 h but may be delayed for as long as a week; it is generally bilateral, although the onset on the two sides may not be synchronous and at times only one side is affected. The submaxillary and sublingual glands are involved less often than the parotid and are almost never involved alone. Swelling of the parotid is accompanied by tenderness and obliteration of the space between the ear lobe and the angle of the mandible (**Fig. 97-1**). The patient frequently reports an earache and finds it difficult to eat, swallow, or talk. Glandular swelling increases for a few days and then gradually subsides, disappearing within a week. The orifice of Stensen's duct is commonly red and swollen. Presternal pitting edema has been described in ~5% of mumps cases, often in association with sub-mandibular adenitis.

FIGURE 97-1

(Reprinted with permission from Gershon A et al: *Mumps*, in *Krugman's Infectious Diseases of Children*, 11th ed. Philadelphia, Elsevier, 2004, p 392.)

Other than parotitis, orchitis is the most common manifestation of mumps among postpubertal males, developing in ~20% of cases. The testis is painful, tender, and enlarged to several times its normal size; accompanying fever is common. Later, testicular atrophy develops in half of the affected men. Since orchitis is bilateral in <15% of cases, sterility after mumps is rare. Oophoritis in women—far less common than orchitis in men—may cause lower abdominal pain but does not lead to sterility.

Aseptic meningitis, which may develop before, during, after, or in the absence of parotitis, is common in both children and adults. Symptoms include stiff neck, headache, and drowsiness. Pleocytosis of the cerebrospinal fluid (CSF), with up to 1000 cells/ μ L, may develop in up to 50% of cases of clinical mumps, but clinical signs of meningeal irritation are documented in only 5–25% of cases. Within the first 24 h, polymorphonuclear leukocytes may predominate in CSF, but by the second day nearly all the cells are lymphocytes. The glucose level in CSF may be abnormally low, and this finding may arouse suspicion of bacterial meningitis. Aseptic meningitis due to mumps without parotitis is indistinguishable clinically from that caused by other viruses. Mumps meningitis is almost invariably self-limited, although cranial nerve palsies have occasionally led to permanent sequelae, particularly deafness. More rarely, mumps virus may cause encephalitis, which presents as high fever with marked changes in the level of consciousness and frequently results in permanent sequelae in survivors. Other CNS problems occasionally associated with mumps include cerebellar ataxia, facial palsy, transverse myelitis, Guillain-Barré syndrome, and aqueductal stenosis leading to hydrocephalus.

Mumps pancreatitis, which may present as abdominal pain, is difficult to diagnose because an elevated serum amylase level can be associated with either parotitis or pancreatitis. Other unusual complications of mumps include myocarditis, mastitis, thyroiditis, nephritis, arthritis, and thrombocytopenic purpura. An excessive number of spontaneous abortions are associated with gestational mumps when the disease occurs during the first trimester. Mumps in pregnancy does not lead to premature birth or fetal malformations.

DIFFERENTIAL DIAGNOSIS

Because of widespread vaccination, mumps is currently a rare disease in the United States. The diagnosis is made easily in patients with acute bilateral parotitis and a history of recent exposure. When parotitis is unilateral or absent or when sites other than the parotid gland are involved, laboratory diagnosis may be required.

The differential diagnosis of parotitis is presented in **Table 97-1**. Other entities should be considered when manifestations consistent with mumps appear in organs other than the parotid. Testicular torsion may produce a painful scrotal mass resembling that seen in mumps orchitis. Other viruses (e.g., enteroviruses) may cause aseptic meningitis that is clinically indistinguishable from that due to mumps virus.

TABLE 97-1

DIFFERENTIAL DIAGNOSIS OF PAROTITIS

| ETIOLOGY | COMMENTS |
|---|--|
| Systemic Infections | |
| Mumps | Rare in countries with vaccination programs |
| Coxsackievirus infection | Particularly likely in children |
| HIV infection | In HIV-positive children receiving no antiretroviral therapy; additional disease manifestations likely |
| Parainfluenza virus type 3 infection | Particularly likely in children; associated with acute respiratory tract symptoms |
| Influenza A virus infection | Seasonal (winter, spring); associated with acute respiratory tract symptoms |
| Cat-scratch disease | Unusual but described |
| Epstein-Barr virus infection | Unusual but described |
| Systemic Noninfectious Causes | |
| Sarcoidosis | Additional manifestations of disease likely |
| Sjögren's syndrome | Additional manifestations of disease likely |
| Uremia | Additional manifestations of disease likely |
| Diabetes mellitus | Additional manifestations of disease likely |
| Drugs | Phenylbutazone, thiouracil |
| Unilateral Parotitis | |
| Ductal obstruction due to stones or strictures | Unilateral, gradual onset, suppurative |
| Parotid cyst | Unilateral, gradual onset |
| Parotid tumor | Unilateral, gradual onset |
| Acute Suppurative Parotitis | |
| <i>Staphylococcus aureus</i> , <i>Streptococcus</i> species, and (rarely) gram-negative bacteria, anaerobes | |

Myocarditis as a severe but usually self-limited complication of mumps has been described. Molecular diagnostic assays have implicated mumps virus in some cases of endocardial fibroelastosis following myocarditis.

LABORATORY DIAGNOSIS

Mumps virus is readily isolated after inoculation of appropriate clinical specimens into cell cultures. The virus can be identified rapidly in shell vial cultures by immunofluorescence. Mumps virus may be recovered from saliva, throat, and urine during the first few days of illness and from the CSF of patients with mumps meningitis. Shedding of virus in the urine may persist for as long as 2 weeks. PCR also is used to detect mumps virus in clinical specimens. No particular peripheral blood cell count is characteristic of mumps.

Highly sensitive enzyme-linked immunosorbent assays are useful for serologic diagnosis of mumps and for determination of susceptibility to the disease. Acute mumps can be diagnosed either by the examination of acute- and convalescent-phase sera for a significant increase in IgG antibody levels or by the demonstration of specific IgM in one serum specimen. The mumps skin test is no longer used.

PREVENTION

Live attenuated mumps vaccine (Jeryl Lynn strain) induces antibodies that protect the recipient against infection in >95% of cases. Mumps vaccine is usually administered as part of the measles-mumps-rubella (MMR) vaccine at the age of 12–15 months and again at 4–12 years of age. MMR vaccine will probably be supplanted by MMRV vaccine, which also covers varicella. Licensed by the U.S. Food and Drug Administration in 2005, MMRV is licensed for use only in children 1–13 years of age. Vaccination is also recommended for susceptible older children, adolescents, and adults, particularly male adolescents who have not had mumps. For these patients, either MMR or monovalent mumps vaccine may be given; two doses are preferred. Inadvertent immunization of individuals who are already immune is not associated with significant adverse reactions. Mumps vaccine is not recommended for pregnant women, for patients receiving glucocorticoids, or for other immunocompromised hosts. However, children with HIV infection who are not severely immunocompromised can safely be immunized against mumps; MMR vaccine is usually used for this purpose (Chap. 3). Occasionally, febrile reactions and parotitis have been reported soon after mumps vaccination. Allergic reactions after vaccination, such as rash and pruritus, occur uncommonly and are usually mild and self-limited. In the United States, the incidence of encephalitis during the month after mumps vaccination is no greater than the background incidence rate of encephalitis in the population.

R_x Treatment: MUMPS

Therapy for parotitis and other manifestations of mumps is symptom-based. The administration of analgesics and the application of warm or cold compresses

to the parotid area may be helpful. Mumps immune globulin is of no value. Testicular pain may be minimized by the local application of cold compresses and gentle support for the scrotum. Anesthetic blocks also may be used. Neither the administration of glucocorticoids nor incision of the tunica albuginea is of proven value for the treatment of severe orchitis. Anecdotal information on a small number of patients with orchitis suggests that administration of interferon α may be helpful.

CHAPTER 98

RABIES AND OTHER RHABDOVIRUS INFECTIONS

Alan C. Jackson ■ Eric C. Johannsen

RABIES

Rabies is an acute viral disease of the central nervous system (CNS) that is transmitted to humans by infected animals. After a prodromal phase, rabies manifests most often as encephalitis—or less frequently as a paralytic form of the disease—and then progresses to coma and death.

ETIOLOGIC AGENT

Rabies virus is a member of the genus *Lyssavirus* in the family Rhabdoviridae, which includes vesicular stomatitis virus (VSV), a bovine pathogen of significant economic importance that can infect humans (see “Other Rhabdoviruses” later in the chapter). *Rhabdos*, meaning “rod-like,” refers to the distinctive elongated shape of these viruses. Their enveloped virions contain a single-strand, nonsegmented, negative-sense RNA. The rabies virus genome consists of 11,932 nucleotides and encodes five proteins: nucleocapsid, matrix, phosphoprotein, glycoprotein, and an RNA polymerase. Each animal reservoir harbors one or more distinct rabies virus variants that can be distinguished by the sequence of the nucleocapsid gene.

EPIDEMIOLOGY

Rabies is a zoonosis that is generally transmitted to humans by the bite of a rabid animal. Understanding the epizootiology of rabies is essential in evaluating the need for rabies postexposure prophylaxis (PEP; see “Prevention” later in the chapter). Rabies virus can infect most mammals and is worldwide in distribution.

Historically, dogs were the primary reservoir and vector for rabies, and they remain the major source of transmission to humans in Asia and Africa (see “Global Considerations” later in the chapter). Coordinated vaccination and surveillance programs have essentially eliminated the rabies reservoir in dogs in North America and Europe and have uncovered previously unsuspected reservoirs in wildlife species. Surveillance data from 2006 identified 6940 confirmed animal cases of rabies in the United States. Only 8% of these cases were in domestic animals, including 318 cases in cats, 82 in cattle, and 79 in dogs. Essentially all infections of domestic animals were the result of “spillover” from wildlife reservoirs, not of transmission from one domestic animal to another. In North America, bats, raccoons, skunks, and foxes have endemic rabies virus infection. The importance of each reservoir

varies geographically: rabies in raccoons is endemic on the east coast; rabies in skunks occurs predominantly in the Midwest, with another focus in California; and rabies in foxes is found in parts of Texas, Arizona, and Alaska. Rabies in bats is not geographically restricted.

Because each species harbors one or more specific rabies virus variants (or strains), it is possible to trace the source of a human infection even when there is no known exposure. Since 1990, bats have accounted for most cases of human rabies in the United States, with the majority of the remaining cases due to dog exposures occurring in other countries. The majority of human rabies cases acquired from bats have been associated with a single variant (Ln/Ps) harbored by silver-haired and eastern pipistrelle bats. The implication is that the Ln/Ps variant may have particular attributes that render it capable of readily establishing human infections—e.g., an affinity for specific cell receptors or more efficient initial replication in nonneuronal tissues. A contributing factor may be that rabies virus can be transmitted by minor, seemingly unimportant or unrecognized bat bites. In contrast, bites of terrestrial mammals are more likely to receive medical attention. Fatal cases of rabies have resulted when the significance of a known bat exposure was not appreciated. In circumstances where a bat bite or bat salivary contact with broken skin or mucous membranes cannot be excluded (e.g., when a bat is found in a room with an infant or a sleeping adult), the bat should be tested for rabies and expert consultation sought.

Nonbite exposures only rarely transmit rabies virus infection. Exposures to aerosols in the laboratory or in caves containing millions of bats have resulted in human rabies. Transplanted corneal tissue has been the source of eight cases of human rabies, and strict guidelines for donor screening have been adopted in an effort to eliminate this risk. In 2004, three deaths resulted from transplantation of solid organs and another death from transplantation of a vascular conduit from a donor who was initially thought to have died from an intracranial hemorrhage but was retrospectively diagnosed with rabies. Although all organ donors are screened and tested for infectious risks, routine testing of donors for rabies in the absence of epidemiologic risk has not been recommended. There are no known instances in which health care workers have acquired rabies from infected patients. However, standard universal and respiratory precautions should be observed by care givers because contact of the patients’ saliva or neuronal tissue with mucous membranes or nonintact skin could result in transmission.

PATHOGENESIS

The incubation period of rabies (defined as the interval between virus exposure and onset of clinical disease) is usually 1–3 months but in rare cases is as short as 2 weeks or >1 year. During most of the incubation period, rabies virus is thought to be present at or close to the site of inoculation (Fig. 98-1), predominantly in muscle cells. Administration of rabies PEP during this incubation period is critical; the benefit of PEP in preventing disease progression once rabies virus has entered peripheral nerves is limited. Several receptors probably account for the ability of rabies virus to infect both sensory and motor neurons. The virus is known to bind to nicotinic acetylcholine receptors, and acetylcholine receptor blockade inhibits rabies virus attachment. Experimental evidence also supports a role for the neural cell adhesion molecule and the p75^{NTR} neurotrophin receptor as receptors for rabies virus. After entering sensory and motor neurons, rabies virus spreads centripetally at a rate of 100–400 mm/d via fast axonal transport to the spinal cord or brainstem. Once the virus

enters the CNS, it spreads rapidly throughout the gray matter via established neuroanatomic connections. There are inflammatory changes, but there are few degenerative changes involving neurons and little evidence of neuronal death. These observations have led to the concept that neuronal dysfunction—rather than neuronal death—is responsible for clinical disease in rabies. The basis for the behavioral changes, including aggression, is not well understood. After CNS infection is established, there is centrifugal spread along peripheral nerves to other tissues, including the salivary glands, liver, muscle, skin, adrenal glands, and heart. Rabies virus replication in acinar cells of the salivary glands results in viral excretion in the saliva of rabid animals.

Pathology studies show mild inflammatory changes in the CNS in rabies, with mononuclear inflammatory infiltration in the leptomeninges, perivascular regions, and parenchyma, including microglial nodules called *Babes nodules*. Degenerative neuronal changes are usually not prominent, and neuronophagia is observed occasionally. The most characteristic pathologic finding in rabies is

FIGURE 98-1

Schematic representation of the pathogenetic events following peripheral inoculation of rabies virus. (Adapted from Jackson AC: *Human disease, in Rabies*, edited by AC Jackson

and Wunner, Academic Press, San Diego, pp 29-32 with permission.)

**FIGURE 98-2**

Three large Negri bodies in the cytoplasm of a cerebellar Purkinje cell from an 8-year-old boy who died of rabies after being bitten by a rabid dog in Mexico. (From AC Jackson, E LopeCorella, *NEngl JMed* 336 1996. ©Massachusetts Medical Society.)

the *Negri body* (Fig. 98-2). Negri bodies are eosinophilic cytoplasmic inclusions in brain neurons and are composed of randomly oriented rabies virus nucleocapsids embedded in an amorphous substance or matrix. These inclusions occur in a minority of infected cells, are most commonly present in Purkinje cells of the cerebellum and in pyramidal cells in the hippocampus, and are less frequently seen in cortical neurons and in the brainstem. For obscure reasons, Negri bodies are rarely produced in infections caused by laboratory variants of rabies virus, whereas wild, or “street,” rabies infection results in Negri bodies in ~80% of cases. Thus, the absence of Negri bodies does not exclude the diagnosis.

CLINICAL MANIFESTATIONS

Rabies has the highest case-fatality rate of any infectious disease. Although the diagnosis of rabies should be considered in any case of unexplained encephalitis or flaccid paralysis accompanied by fever, efforts to prevent the disease are appropriately focused on early identification of rabies exposure and administration of PEP. After an asymptomatic incubation period, clinical rabies progresses through three general phases: a prodrome, an acute neurologic phase, and coma/death (Table 98-1).

Prodromal Features

Clinically apparent rabies infection begins with nonspecific prodromal symptoms, including fever, malaise, headache, nausea, and vomiting. Anxiety or agitation

TABLE 98-1

PROGRESSION OF RABIES VIRUS INFECTION

| PHASE | DURATION | SIGNS/SYMPTOMS |
|------------------------|-------------------------|---|
| Incubation period | 1–3 months ^a | None |
| Prodrome | 1–7 days | Fever, malaise, headache, nausea, vomiting, agitation, focal paresthesias, pain |
| Acute neurologic phase | | |
| Encephalitic (80%) | 1–7 days | Fever, confusion, hallucinations, hyperactivity, pharyngeal spasms (hydrophobia/aerophobia), seizures |
| Paralytic (20%) | 2–10 days | Ascending flaccid paralysis |
| Coma/death | 1–14 days | ... |

^aTypical duration, with a possible range of 2 weeks to >1 year.

may also occur. Paresthesias, pain, or pruritus near the site of the exposure occurs in 50–80% of patients and suggests rabies. The wound has usually healed by this point, and these symptoms may reflect infection of local dorsal root or cranial sensory ganglia.

Encephalitic Rabies

Two acute neurologic forms of rabies are seen in humans: encephalitic (furious) in 80% and paralytic in 20%. Manifestations of encephalitic rabies may be seen in many other viral encephalitides as well. These features include fever, confusion, hallucinations, combativeness, muscle spasms, hyperactivity, and seizures. Autonomic dysfunction is common and may result in hypersalivation, excessive perspiration, gooseflesh, pupillary dilation, and/or priapism. In encephalitic rabies, episodes of hyperexcitability are typically followed by periods of complete lucidity that become shorter as the disease progresses. Rabies encephalitis is most distinguished by early brainstem involvement, which results in the classic symptoms of hydrophobia and aerophobia: involuntary, painful contraction of the diaphragm and accessory respiratory, laryngeal, and pharyngeal muscles in response to swallowing liquids (hydrophobia) or a draft of air (aerophobia). These symptoms are probably due to dysfunction of infected brainstem neurons that normally inhibit inspiratory neurons near the nucleus ambiguus, resulting in exaggerated defense reflexes that protect the respiratory tract. The combination of hypersalivation and pharyngeal dysfunction is also responsible for the classic appearance of “foaming at the mouth” (Fig. 98-3). Brainstem dysfunction progresses rapidly, and coma followed within days by death is the rule unless the course is prolonged by supportive measures. With such measures, late complications can include disturbances of

**FIGURE 98-3**

Hydrophobic spasm of inspiratory muscles associated with terror in a patient with encephalitic (furious) rabies who is attempting to swallow water. (Copyright DA Wyll, Oxford with permission.)

water balance (syndrome of inappropriate antidiuretic hormone secretion or diabetes insipidus), noncardiogenic pulmonary edema, and cardiac arrhythmias due to brainstem dysfunction and/or myocarditis.

Paralytic Rabies

For unknown reasons, muscle weakness predominates and cardinal features of encephalitic rabies (hydrophobia, aerophobia, fluctuating consciousness) are lacking in ~20% of rabies cases. Paralytic rabies is characterized by early and prominent muscle weakness, often beginning in the bitten extremity and spreading to produce quadriplegia and facial weakness. Sphincter involvement is common, but sensory involvement is usually mild. Guillain-Barré syndrome is a common misdiagnosis. Transplantation of corneal tissue from donors in whom paralytic rabies was misdiagnosed as Guillain-Barré syndrome has resulted in clinical rabies and death in recipients. Patients with paralytic rabies generally survive a few days longer than is typical in encephalitic rabies, but multiple-organ failure ensues even with aggressive supportive care.

LABORATORY INVESTIGATIONS

During the early clinical stages of rabies, laboratory findings are nonspecific. Complete blood counts are usually normal. Examination of cerebrospinal fluid (CSF) often reveals mild mononuclear cell pleocytosis with a mildly elevated protein level. Severe pleocytosis (>1000 cells/ μ L) is unusual and should prompt a search for an alternative diagnosis. CT head scans are usually normal

in rabies. MRI brain scans sometimes show signal abnormalities in the brainstem or other areas, but these findings are variable and nonspecific. Electroencephalograms show only nonspecific abnormalities. The most important tests in suspected cases of rabies are those that may identify an alternative, potentially treatable diagnosis (see “Differential Diagnosis” later in the chapter).

DIAGNOSIS

In North America, a diagnosis of rabies often is not considered until relatively late in the clinical course, even with a typical clinical presentation. This diagnosis should be considered in patients presenting with acute encephalitis or with unexplained ascending paralysis, including those in whom Guillain-Barré syndrome is suspected. A lack of animal-bite history or a lack of hydrophobia is not unusual in rabies. Once rabies is suspected, rabies-specific tests should be employed to confirm the diagnosis. Diagnostically useful specimens include serum, CSF, fresh saliva, brain tissue (when available), and skin biopsy samples from the neck. Because skin biopsy relies on the demonstration of rabies virus in cutaneous nerves at the base of hair follicles, samples from the neck should include at least 10 hair follicles. Multiple testing modalities are required to ensure a high negative predictive value. For example, because rabies virus infects immunologically privileged neuronal tissues, serum antibodies often do not develop until very late in the disease.

Rabies Virus-Specific Antibodies

In a previously unimmunized patient, serum neutralizing antibodies to rabies virus are diagnostic. Antibodies may be detected within a few days after the onset of symptoms, but some patients die without detectable antibodies. The presence of rabies virus-specific antibodies in the CSF suggests rabies, regardless of immunization status.

Reverse Transcription Polymerase Chain Reaction (RT-PCR)

Detection of rabies virus RNA by RT-PCR is highly sensitive and specific. This technique can detect virus in fresh saliva samples, CSF, and tissue. In addition, RT-PCR can distinguish between rabies virus variants, permitting the investigator to infer the likely source of an infection.

Direct Fluorescent Antibody (DFA) Testing

DFA testing with rabies antibodies conjugated to fluorescent dyes is highly sensitive and specific and can be applied to brain tissue or skin biopsies from the nape of the neck. In the latter samples, rabies virus can be detected in cutaneous nerves at the base of hair follicles.

DIFFERENTIAL DIAGNOSIS

Early in the course of illness, rabies is frequently indistinguishable from other causes of encephalitis. Herpes simplex virus type 1 and rarely other herpesviruses cause sporadic cases of encephalitis and are important

considerations because they require specific treatment. During summer months, enteroviruses and arthropod-borne viruses are an important diagnostic consideration. PCR testing of CSF for specific viruses should be guided by local epidemiologic patterns. Immune-mediated postviral encephalitis may follow infection with influenza, measles, mumps, varicella-zoster, and other viruses. It is important to recognize that immune-mediated encephalitis may occur as a sequela of immunization with rabies vaccine derived from neural tissues (e.g., Semple vaccine). Drug reactions and vasculitis are other important noninfectious causes of encephalitis that must be considered. A conversion disorder due to an exaggerated fear of rabies (“rabies hysteria”) can produce symptoms that closely resemble those of rabies (e.g., aggressive behavior, inability to swallow or communicate); an unusually short “incubation period” can be an important clue to the correct diagnosis.

As previously mentioned, paralytic rabies may mimic Guillain-Barré syndrome. In these cases, the documentation of fever or bladder dysfunction can suggest the diagnosis of rabies. Conversely, Guillain-Barré syndrome may rarely occur as a complication of rabies vaccination and may be mistaken for paralytic rabies (i.e., vaccine failure).

Rx Treatment: RABIES

There is no established treatment for rabies. There have been several recent treatment failures of antiviral therapy, ketamine, and therapeutic coma—measures that were used in a healthy survivor who had rabies virus antibodies present at the time of presentation. Expert opinion should be sought before any course of experimental therapy is embarked upon. A palliative approach may be appropriate for some patients.

PROGNOSIS

Rabies is an almost uniformly fatal disease but is almost always preventable with appropriate postexposure therapy during the incubation period (described in the next section). There are only six well-documented cases of survival after symptomatic rabies infection. All but one of the patients involved had received rabies vaccine before disease onset; these patients represented failures of postexposure rabies prophylaxis. Most patients with rabies die within several days, even with aggressive care in a critical care unit.

PREVENTION

Postexposure Prophylaxis

Since there is no effective therapy for rabies, it is extremely important to prevent the disease after an animal exposure. [Figure 98-4](#) shows the steps involved in making decisions about rabies PEP. On the basis of the history of the exposure and local epidemiologic information, the physician must decide whether initiation of

FIGURE 98-4

Algorithm for rabies postexposure prophylaxis. RIG, rabies immune globulin. [From L Corey, in *Principles of Internal Medicine*, 15th ed. E Braunwald et al (eds): New York:McGraw-Hill, 2001, adapted with permission.]

PEP is warranted. Healthy dogs, cats, or ferrets may be confined and observed for 10 days. PEP is not necessary if the animal remains healthy. If the animal develops signs of rabies during the observation period, it should be euthanized immediately, and the head should be transported to the laboratory under refrigeration and examined for the presence of rabies virus by DFA testing and viral isolation using cell culture or mouse inoculation. Any animal other than a dog, cat, or ferret should be euthanized immediately and the head submitted for examination. In high-risk exposures and in areas where canine rabies is endemic, rabies prophylaxis should be initiated without waiting for laboratory results. If the laboratory results prove to be negative, it may safely be concluded that the animal's saliva did not contain rabies virus, and immunization should be discontinued. If an animal escapes after an exposure, it must be considered rabid, and PEP must be initiated unless information from public health officials indicates otherwise (i.e., there is no endemic rabies in the area). PEP may be warranted when a person present in the same space as a bat (e.g., a small child or a sleeping adult) cannot reliably rule out contact with an unrecognized bite.

PEP includes local wound care and both active and passive immunization. Local wound care is essential and

may decrease the risk of rabies virus infection by as much as 90%. Wound care should not be delayed, even if the initiation of immunization is postponed pending the results of the 10-day observation period. All bite wounds and scratches should be washed thoroughly with soap and water. Devitalized tissues should be debrided, tetanus prophylaxis given, and antibiotic treatment initiated whenever indicated.

All previously unvaccinated persons should be passively immunized with rabies immune globulin (RIG). If RIG is not immediately available, it should be administered no later than 7 days after the first vaccine dose. After day 7, endogenous antibodies are being produced, and passive immunization may actually be counterproductive. If anatomically feasible, the entire dose of RIG (20 IU/kg) should be infused at the site of the bite; otherwise, any RIG remaining after infiltration of the bite site should be administered IM at a distant site. With multiple or large wounds, the RIG preparation may need to be diluted in order to obtain a sufficient volume for adequate infiltration of all wound sites. If the exposure involves a mucous membrane, the entire dose should be administered IM. Rabies vaccine and RIG should never be administered at the same site or with the same syringe. Commercially available RIG in the United States is purified from the serum of hyperimmunized human donors. These human RIG preparations are much better tolerated than are the equine-derived preparations still in use in some countries (see “Global Considerations” later in the chapter). Serious adverse effects of human RIG are uncommon. Local pain and low-grade fever may occur.

Two purified inactivated rabies vaccines are available for rabies PEP in the United States. They are highly immunogenic and remarkably safe compared with earlier vaccines. The traditional recommendation has been to give five 1-mL doses of rabies vaccine IM in the deltoid area on days 3, 7, 14, and 28. (The anterolateral aspect of the thigh is also acceptable in children.) Gluteal injections, which may not always reach muscle, should not be given and have been associated with rare vaccine failures. Ideally, the first dose should be given as soon as possible after exposure; failing that, it should be given without further delay. Pregnancy is not a contraindication for immunization. In June of 2009, the ACIP advised the CDC to change the recommendation to 4 doses of vaccine, administered on days 0, 3, 7, and 14 after exposure. These recommendations will become official once they are accepted by the CDC Director and published in the MMWR. While the new ACIP recommendations are based on evidence that supports a 4-dose regimen, vaccine manufacturers are expected to continue to support the product insert that was developed at the time the product was licensed by the FDA, which instructs providers to administer 5 doses. Glucocorticoids and other immunosuppressive medications may interfere with the development of active immunity and should not be administered during PEP unless they are essential. In several studies, all persons vaccinated with the above schedule developed a serologic response

within 2–4 weeks. Routine measurement of serum neutralizing antibody titers is not required, but titers should be measured 2–4 weeks after immunization in immunocompromised persons. Local reactions (pain, erythema, edema, and pruritus) and mild systemic reactions (fever, myalgias, headache, and nausea) are common; anti-inflammatory and antipyretic medications may be used, but immunization should not be discontinued. Systemic allergic reactions are uncommon, but anaphylaxis does occur rarely and can be treated with epinephrine and antihistamines. The risk of rabies development should be carefully considered before the decision is made to discontinue vaccination because of an adverse reaction. Advice and assistance from state health officials or the Centers for Disease Control and Prevention may be helpful in managing adverse reactions to vaccine.

Preexposure Rabies Vaccination

Preexposure rabies prophylaxis should be considered for people with an occupational or recreational risk of rabies exposures, including certain travelers to rabies-endemic areas. This primary schedule consists of three doses of rabies vaccine given on days 0, 7, and 21 or 28. Serum neutralizing antibody tests help determine the need for subsequent booster doses. When a previously immunized individual is exposed to rabies, two booster doses of vaccine should be administered on days 0 and 3. Wound care remains critical. RIG should not be administered to previously vaccinated persons.

GLOBAL CONSIDERATIONS

Worldwide, endemic canine rabies is estimated to cause 55,000 human deaths annually. Most of these deaths occur in Asia and Africa, with rural populations and children most frequently affected. Because of this distribution, most of the burden of rabies PEP is borne by those least able to pay. In Latin America, rabies control efforts in dogs have been quite successful in recent years. In Europe and Canada, an epizootic of rabies in red foxes has been partly controlled by widespread use of baits containing rabies vaccine.

In addition to the rabies vaccines discussed above, vaccines grown in either primary cell lines (hamster or dog kidney) or continuous cell lines (Vero cells) are satisfactory and are available in many countries outside the United States. Less expensive vaccines derived from neural tissues have been used in developing countries; however, these vaccines are associated with serious neuroparalytic complications, and their use should be discontinued as soon as possible. Worldwide, >10 million individuals receive postexposure vaccination against rabies each year.

If human RIG is unavailable, purified equine RIG can be used in the same manner at a dose of 40 IU/kg. Before the administration of equine RIG, hypersensitivity should be assessed by intradermal testing with a 1:10 dilution. The incidence of anaphylactic reactions and serum sickness has been low with recent equine RIG products.

OTHER RHABDOVIRUSES

OTHER LYSSAVIRUSES

A growing number of lyssaviruses other than rabies virus have been discovered to infect bat populations throughout the world. Four of these viruses have produced at least one case of human illness indistinguishable from rabies: European bat lyssaviruses 1 and 2, Australian bat lyssavirus, and the Duvenhage virus (in Africa). Mokola virus, a lyssavirus that has been isolated from shrews with an unknown reservoir species, has also produced human illness in Africa.

VESICULAR STOMATITIS VIRUS

Vesicular stomatitis is a viral disease of cattle, horses, pigs, and some wild mammals. VSV is a member of the genus *Vesiculovirus* in the family Rhabdoviridae. Outbreaks of vesicular stomatitis in animals occur sporadically in the southwestern United States. The infection is associated with severe vesiculation and ulceration of oral tissues, teats, and feet and may be clinically indistinguishable from the more dangerous foot-and-mouth disease. Epidemics are usually seasonal and are probably due to arthropod vectors. Direct animal-to-animal spread can also occur, although the virus cannot penetrate intact skin. Transmission to humans usually results from direct contact with infected animals (particularly cattle) and occasionally follows laboratory exposure. In human disease, early conjunctivitis is followed by an acute influenza-like illness with fever, chills, nausea,

vomiting, headache, retrobulbar pain, myalgias, substernal pain, malaise, pharyngitis, and lymphadenitis. Small vesicular lesions may be present on the buccal mucosa or on the fingers. The illness usually lasts 3–6 days, with a subsequent full recovery. Subclinical infections are common. A serologic diagnosis can be made on the basis of a rise in titer of complement-fixing or neutralizing antibodies. Therapy is symptom-based.

CHAPTER 99

INFECTIONS CAUSED BY ARTHROPOD- AND RODENT-BORNE VIRUSES

Clarence J. Peters

Some zoonotic viruses are transmitted in nature without regard to humans and only incidentally infect and produce disease in humans; in addition, a few agents are regularly spread among humans by arthropods. Most of these viruses either are maintained by arthropods or chronically infect rodents. Obviously, the mode of transmission is not a rational basis for taxonomic classification. Indeed, zoonotic viruses from at least seven families act as significant human pathogens (Table 99-1). The virus families differ fundamentally from one another in terms of morphology, replication mechanisms, and genetics. Information on a virus's membership in a family or genus is enlightening with regard to maintenance strategies, sensitivity to antiviral

agents, and some aspects of pathogenesis but does not necessarily predict which clinical syndromes (if any) the virus will cause in humans.

FAMILIES OF ARTHROPOD- AND RODENT-BORNE VIRUSES

(Table 99-1)

The Arenaviridae

The Arenaviridae are spherical, 110- to 130-nm particles that bud from the cell's plasma membrane and utilize ambisense RNA genomes with two segments for

TABLE 99-1

MAJOR ZOOTIC VIRUS FAMILIES AND SOME CHARACTERISTICS OF TYPICAL MEMBERS

| FAMILY | GENUS OR GROUP | SYNDROME(S): TYPICAL VIRUSES | MAINTENANCE STRATEGY |
|----------------------------|--|--|---|
| Arenaviridae | Old World complex | FM, E: Lymphocytic choriomeningitis virus HF: Lassa fever virus | Chronic infection of rodents, often with persistent viremia; vertical transmission common |
| | New World or Tacaribe complex | HF: South American HF viruses (Machupo, Junin, Guanarito, Sabia) | Chronic infection of rodents, sometimes with persistent viremia; vertical infection may occur |
| Bunyaviridae | <i>Bunyavirus</i> | E: California serogroup viruses (La Crosse, Jamestown Canyon, California encephalitis) FM: Bunyamwera, group C, Tahyna viruses FM: Oropouche virus | Mosquito-vertebrate cycle; transovarial transmission in mosquito common |
| | <i>Phlebovirus</i> | FM: Sandfly fever, Toscana viruses FM: Punta Toro virus HF, FM, E: Rift Valley fever virus | Transmitted by <i>Culicoides</i> Sandfly transmission between vertebrates, with prominent transovarial component in sandfly Mosquito-vertebrate transmission, with transovarial component in mosquito |
| | <i>Nairovirus</i> | HF: Crimean-Congo HF virus | Tick-vertebrate, with transovarial transmission in tick |
| | <i>Hantavirus</i> | HF: Hantaan, Dobrava, Puumala viruses | Rodent reservoir; chronic virus shedding, but chronic viremia unknown |
| | | HF: Sin Nombre and related hantaviruses HF: Marburg viruses, Ebola viruses (4 species) | Sigmodontine rodent reservoir Unknown |
| Filoviridae ^a | <i>Ebolavirus</i> , <i>Marburgvirus</i> | | |
| Flaviviridae | <i>Flavivirus</i> (mosquito-borne) | HF: Yellow fever virus FM, HF: Dengue viruses (4 serotypes) E: St. Louis, Japanese, West Nile, and Murray Valley encephalitis viruses; Rocio viruses | Mosquito-vertebrate; transovarial rare |
| | <i>Flavivirus</i> (tick-borne) | E: Central European tick-borne encephalitis, Russian spring-summer encephalitis, Powassan viruses HF: Omsk HF, Kyasanur Forest disease viruses | Tick-vertebrate |
| Reoviridae | <i>Coltivirus</i> <i>Orbivirus</i> | FM, E: Colorado tick fever virus FM, E: Orungo, Kemerovo viruses | Tick-vertebrate Arthropod-vertebrate |
| Rhabdoviridae ^b | <i>Vesiculovirus</i> | FM: Vesicular stomatitis virus (Indiana, New Jersey); Chandipura, Piry viruses | Sandfly-vertebrate, with prominent transovarial component in sandfly |
| Togaviridae | <i>Alphavirus</i> | AR: Sindbis, chikungunya, Mayaro, Ross River, Barmah Forest viruses E: Eastern, western, and Venezuelan equine encephalitis viruses | Mosquito-vertebrate |

^a The Filoviridae are discussed in Chap. 100.

^b The Rhabdoviridae are discussed in Chap. 98.

Note: Abbreviations refer to the disease syndrome most commonly associated with the virus: FM, fever, myalgia; AR, arthritis, rash; E, encephalitis; HF, hemorrhagic fever.

replication. There are two main phylogenetic branches of Arenaviridae: the Old World viruses, such as Lassa fever and lymphocytic choriomeningitis (LCM) viruses, and the New World viruses, including those causing the South American hemorrhagic fevers (HFs). Arenaviruses persist in nature by chronically infecting rodents with a striking one-virus-one-rodent species relationship. These rodent infections result in long-term virus excretion and perhaps in lifelong viremia; vertical infection is common with some arenaviruses. Humans become infected through the inhalation of aerosols containing

arenaviruses, which are then deposited in the terminal air passages, and probably also through close contact with rodents and their excreta, which results in the contamination of mucous membranes or breaks in the skin.

The Bunyaviridae

The family Bunyaviridae includes four medically significant genera. All of these spherical viruses have three negative-sense RNA segments maturing into 90- to 120-nm particles in the Golgi complex and exiting the cell by exocytosis. Viruses of the genus *Bunyavirus* are largely

mosquito-borne and have a viremic vertebrate intermediate host; many are also transovarially transmitted in their specific mosquito host. One serologic group also uses biting midges as vectors. Sandflies or mosquitoes are the vectors for the genus *Phlebovirus* (named after phlebotomus fever or sandfly fever, the best-known disease associated with the genus), while ticks serve as vectors for the genus *Nairovirus*. Viruses of both of these genera are also associated with vertical transmission in the arthropod host and with horizontal spread through viremic vertebrate hosts. The genus *Hantavirus* is unique among the Bunyaviridae in that it is not transmitted by arthropods but is maintained in nature by rodent hosts that chronically shed virus. Like the arenaviruses, the hantaviruses usually display striking virus-rodent species specificity. Hantaviruses do not cause chronic viremia in their rodent hosts and are transmitted only horizontally from rodent to rodent.

Other Families

The Flaviviridae are positive-sense, single-strand RNA viruses that form particles of 40–50 nm in the endoplasmic reticulum. The flaviviruses discussed here are from the genus *Flavivirus* and make up two phylogenetically and antigenically distinct divisions transmitted among vertebrates by mosquitoes and ticks, respectively. The mosquito-borne viruses fall into phylogenetic groups that include yellow fever virus, the four dengue viruses, and encephalitis viruses, while the tick-borne group encompasses a geographically varied spectrum of species, some of which are responsible for encephalitis or for hemorrhagic disease with encephalitis. The Reoviridae are double-strand RNA viruses with multisegmented genomes. These 80-nm particles are the only viruses discussed in this chapter that do not have a lipid envelope and thus are insensitive to detergents. The Togaviridae have a single positive-strand RNA genome and bud particles of ~60–70 nm from the plasma membrane. The togaviruses discussed here are all members of the genus *Alphavirus* and are transmitted among vertebrates by mosquitoes in their natural cycle. The Filoviridae and the Rhabdoviridae are discussed in Chaps. 100 and 98, respectively.

PROMINENT FEATURES OF ARTHROPOD- AND RODENT-BORNE VIRUSES

Although this chapter discusses the major features of selected arthropod- and rodent-borne viruses, it does not deal with >500 other distinct recognized zoonotic viruses, about one-fourth of which infect humans. Zoonotic viruses are undergoing genetic evolution, “new” zoonotic viruses are being discovered, and the epidemiology of zoonotic viruses is continuing to evolve through environmental changes affecting vectors, reservoirs, and humans. These zoonotic viruses are most numerous in the tropics but are also found in temperate and frigid climates. Their distribution and seasonal activity may be variable and often depend largely on ecologic conditions such as rainfall and temperature, which in turn affect the density of vectors and reservoirs and the development of infection therein.

Maintenance and Transmission

Arthropod-borne viruses infect their vectors after the ingestion of a blood meal from a viremic vertebrate. The vectors then develop chronic, systemic infection as the viruses penetrate the gut and spread throughout the body. The viruses eventually reach the salivary glands during a period that is referred to as *extrinsic incubation* and that typically lasts 1–3 weeks in mosquitoes. At this point, an arthropod is competent to continue the chain of transmission by infecting another vertebrate when a subsequent blood meal is taken. The arthropod generally is unharmed by the infection, and the natural vertebrate partner usually has only transient viremia with no overt disease. An alternative mechanism for virus maintenance in its arthropod host is transovarial transmission, which is common among members of the family Bunyaviridae.

Rodent-borne viruses such as the hantaviruses and arenaviruses are maintained in nature by chronic infection transmitted between rodents. As in arthropod-borne virus cycles, there is usually a high degree of rodent-virus specificity, and there is no overt disease in the reservoir/vector.

Epidemiology

The distribution of arthropod- and rodent-borne viruses is restricted by the areas inhabited by their reservoir/vectors and provides an important clue in the differential diagnosis. [Table 99-2](#) shows the approximate geographic distribution of the most important of these viruses. Members of each family, each genus, and even each serologically related group usually occur in each area but may not be pathogenic in all areas or may not be a commonly recognized cause of disease in all areas and so may not be included in the table.

Most of these diseases are acquired in a rural setting; a few have urban vectors. Seoul, sandfly fever, and Oropouche viruses are examples of urban viruses, but the most notable are yellow fever, dengue, and chikungunya viruses. A history of mosquito bite has little diagnostic significance in the individual; a history of tick bite is more diagnostically specific. Rodent exposure is often reported by persons infected with an arenavirus or a hantavirus but again has little specificity. Indeed, aerosols may infect persons who have no recollection of having even seen rodents.

Syndromes

Human disease caused by arthropod- and rodent-borne viruses is often subclinical. The spectrum of possible responses to infection is wide, and our knowledge of the outcome of most of these infections is limited. The usual disease syndromes associated with these viruses have been grouped into four categories: fever and myalgia, arthritis and rash, encephalitis, and hemorrhagic fever. Although for the purposes of this discussion most viruses have been placed in a single group, the categories often overlap. For example, West Nile and Venezuelan equine encephalitis viruses are discussed as encephalitis viruses, but during epidemics they may cause many cases

TABLE 99-2

GEOGRAPHIC DISTRIBUTION OF SOME IMPORTANT AND COMMONLY ENCOUNTERED HUMAN ZOONOTIC VIRAL DISEASES

| AREA | ARENAVIRIDAE | BUNYAVIRIDAE | FLAVIVIRIDAE | RHABDOVIRIDAE | TOGAVIRIDAE |
|-------------------|---|---|--|--|--|
| North America | Lymphocytic choriomeningitis | La Crosse, Jamestown Canyon, California encephalitis; hantavirus pulmonary syndrome | St. Louis, Powassan, West Nile encephalitis; dengue | Vesicular stomatitis | Eastern, western equine encephalitis |
| South America | Bolivian, Argentine, Venezuelan, and Brazilian HF; lymphocytic choriomeningitis | Oropouche, group C, Punta Toro infection; hantavirus pulmonary syndrome | Yellow fever, dengue, Rocio virus infection | Vesicular stomatitis, Piry virus infection | Mayaro virus infection, Venezuelan equine encephalitis |
| Europe | Lymphocytic choriomeningitis | Tahyna, Toscana, sandfly fever; HF with renal syndrome | West Nile, Central European tick-borne, Russian spring-summer encephalitis | — | Sindbis virus infection |
| Middle East | — | Sandfly fever, Crimean-Congo HF | West Nile encephalitis, dengue | — | — |
| Eastern Asia | — | Sandfly fever; Hantaan, Seoul virus infection | Dengue; Japanese, Russian spring-summer encephalitis; Omsk HF | Chandipura virus infection | — |
| Southwestern Asia | — | Sandfly fever, Crimean-Congo HF | West Nile, Japanese encephalitis; dengue; Kyasanur Forest disease | — | Chikungunya virus infection |
| Southeast Asia | — | Seoul virus infection | Japanese encephalitis, dengue | — | Chikungunya virus infection |
| Africa | Lassa fever | Bunyamwera virus infection, Rift Valley fever | Yellow fever, dengue | — | Sindbis, chikungunya virus infection |
| Australia | — | — | Murray Valley encephalitis, dengue | — | Ross River, Barmah Forest virus infection |

Note: HF, hemorrhagic fever.

of milder febrile syndromes and relatively uncommon cases of encephalitis. Similarly, Rift Valley fever virus is best known as a cause of HF, but the attack rates for febrile disease are far higher, and encephalitis is occasionally seen as well. LCM virus is classified as a cause of fever and myalgia because this syndrome is its most common disease manifestation and because, even when central nervous system (CNS) disease occurs, it is usually mild and is preceded by fever and myalgia. Dengue virus infection is considered as a cause of fever and myalgia (dengue fever) because this is by far the most common manifestation worldwide and is the syndrome most likely to be seen in the United States; however, dengue HF is also discussed in the HF section because of its complicated pathogenesis and importance in pediatric practice in certain areas of the world.

Diagnosis

Laboratory diagnosis is required in any given case, although epidemics occasionally provide clinical and epidemiologic clues on which an educated guess as to etiology can be based. For most arthropod- and rodent-borne viruses, acute-phase serum samples (collected within 3 or 4 days of onset) have yielded isolates, and paired sera have been used to demonstrate rising antibody titers by a variety of tests. Intensive efforts to develop rapid tests for HF have resulted in an antigen-detection enzyme-linked immunosorbent assay (ELISA) and an IgM-capture ELISA that can provide a diagnosis based on a single serum sample within a few hours and are particularly useful in severe cases. More sensitive reverse-transcription polymerase chain reaction (RT-PCR) tests may yield diagnoses based on samples without detectable antigen

and may also provide useful genetic information about the virus. Hantavirus infections differ from others discussed here in that severe acute disease is immunopathologic; patients present with serum IgM that serves as the basis for a sensitive and specific test.

At diagnosis, patients with encephalitis are generally no longer viremic or antigenemic and usually do not have virus in cerebrospinal fluid (CSF). In this situation, the value of serologic methods and RT-PCR is being validated. IgM capture is increasingly being used for the simultaneous testing of serum and CSF. IgG ELISA or classic serology is useful in the evaluation of past exposure to the viruses, many of which circulate in areas with a minimal medical infrastructure and sometimes cause mild or subclinical infection.

The remainder of this chapter offers general descriptions of the broad syndromes caused by arthropod- and rodent-borne viruses. Most of the diseases under consideration have not been studied in detail with modern medical approaches; thus available data may be incomplete or biased.

FEVER AND MYALGIA

Fever and myalgia constitute the syndrome most commonly associated with zoonotic virus infection. Many of the numerous viruses belonging to the families listed in Table 99-1 probably cause this syndrome, but several viruses have been selected for inclusion in the table because of their prominent associations with the syndrome and their biomedical importance.

The syndrome typically begins with the abrupt onset of fever, chills, intense myalgia, and malaise. Patients may also report joint pains, but no true arthritis is detectable. Anorexia is characteristic and may be accompanied by nausea or even vomiting. Headache is common and may be severe, with photophobia and retroorbital pain. Physical findings are minimal and are usually confined to conjunctival injection with pain on palpation of muscles or the epigastrium. The duration of symptoms is quite variable but generally is 2–5 days, with a biphasic course in some instances. The spectrum of disease varies from subclinical to temporarily incapacitating.

Less constant findings include a maculopapular rash. Epistaxis may occur but does not necessarily indicate a bleeding diathesis. A minority of the cases caused by some viruses are known or suspected to include aseptic meningitis, but this diagnosis is difficult to make in remote areas, given the patients' photophobia and myalgia as well as the lack of opportunity to examine the CSF. Although pharyngitis may be noted or radiographic evidence of pulmonary infiltrates found in some cases, these viruses are not primary respiratory pathogens. The differential diagnosis includes anicteric leptospirosis, rickettsial diseases, and the early stages of other syndromes discussed in this chapter. These diseases are often described as "flu-like," but the usual absence of cough and coryza makes influenza an unlikely confounder except at the earliest stages.

Complete recovery is generally the outcome in this syndrome, although prolonged asthenia and nonspecific

symptoms have been described in some cases, particularly after infection with LCM or dengue virus. Treatment is supportive, with aspirin avoided because of the potential for exacerbated bleeding and Reye's syndrome. Efforts at prevention are best based on vector control, which, however, may be expensive or impossible. For mosquito control, destruction of breeding sites is generally the most economically and environmentally sound approach. Measures taken by the individual to avoid the vector can be valuable. Avoiding the vector's habitat and times of peak activity, using screens or other barriers (e.g., permethrin-impregnated bed nets) to prevent the vector from entering dwellings, judiciously applying arthropod repellents such as diethyltoluamide (DEET) to the skin, and wearing permethrin-impregnated clothing are all possible approaches, depending on the vector and its habits.

LYMPHOCYTIC CHORIOMENINGITIS

LCM is transmitted from the common house mouse (*Mus musculus*) to humans by aerosols of excreta and secretions. LCM virus, an arenavirus, is maintained in the mouse mainly by vertical transmission from infected dams. The vertically infected mouse remains viremic for life, with high concentrations of virus in all tissues. Infected colonies of pet hamsters have also served as a link to humans. LCM virus is widely used in immunology laboratories as a model of T-cell function and can silently infect cell cultures and passaged tumor lines, resulting in infections among scientists and animal caretakers. Patients with LCM may have a history of residence in rodent-infested housing or other exposure to rodents. An antibody prevalence of ~5–10% has been reported among adults from the United States, Argentina, and endemic areas of Germany.

LCM differs from the general syndrome of fever and myalgia in that its onset is gradual. Among the conditions occasionally associated with LCM are orchitis, transient alopecia, arthritis, pharyngitis, cough, and maculopapular rash. An estimated one-fourth of patients or fewer experience a febrile phase of 3–6 days and then, after a brief remission, develop renewed fever accompanied by severe headache, nausea and vomiting, and meningeal signs lasting for ~1 week. These patients virtually always recover fully, as do the uncommon patients with clear-cut signs of encephalitis. Recovery may be delayed by transient hydrocephalus.

During the initial febrile phase, leukopenia and thrombocytopenia are common and virus can usually be isolated from blood. During the CNS phase, virus may be found in the CSF, but antibodies are present in blood. The pathogenesis of LCM is thought to resemble that following direct intracranial inoculation of the virus into adult mice; the onset of the immune response leads to T-cell-mediated immunopathologic meningitis. During the meningeal phase, CSF mononuclear-cell counts range from the hundreds to the low thousands per microliter, and hypoglycorrhachia is found in one-third of cases. The IgM-capture ELISA of serum and CSF is usually positive; RT-PCR assays have been developed for application to CSF. Recent infections transmitted by

organ transplantation did not include evidence of an immune response, followed a fulminant course (not unlike that of Lassa fever), and required immunohistochemistry or RT-PCR for diagnosis.

Infection with LCM virus should be suspected in acutely ill febrile patients with marked leukopenia and thrombocytopenia. In cases of aseptic meningitis, any of the following should suggest LCM: well-marked febrile prodrome, adult age, autumn seasonality, low CSF glucose levels, or CSF mononuclear cell counts of $>1000/\mu\text{L}$.

In pregnant women, LCM virus infection may lead to fetal invasion with consequent congenital hydrocephalus and chorioretinitis. Since the maternal infection may be mild, consisting of only a short febrile illness, antibodies to the virus should be sought in both the mother and the fetus in suspicious circumstances, particularly TORCH-negative neonatal hydrocephalus. [TORCH is a battery of tests encompassing toxoplasmosis, other conditions (congenital syphilis and viral infection), rubella, cytomegalovirus infection, and herpes simplex virus infection.]

BUNYAMWERA VIRUS INFECTION

The mosquito-transmitted Bunyamwera serogroup viruses are found on every continent except Australia and Antarctica. Bunyamwera virus and its close relative Ilshah virus commonly cause febrile disease in Africa. Nigari virus, a reassortant of Bunyamwera virus, has recently been identified as an important human pathogen in Africa. Other related viruses are implicated in such disease in Southeast Asia (Batai virus), Europe (Calovo virus), and South America (Wyeomyia virus). In North America, Cache Valley virus has been implicated in febrile human disease and in rare instances of more serious systemic illness; the presence of serum antibodies to this virus may be associated with congenital malformations. In Central America, the closely related Fort Sherman virus causes the fever-myalgia syndrome.

GROUP C VIRUS INFECTION

The group C viruses include at least 11 agents transmitted by mosquitoes in neotropical forests. These agents are among the most common causes of arboviral infection in humans entering American jungles and cause acute febrile disease.

TAHYNA VIRUS INFECTION

This California serogroup virus (see discussion of California encephalitis later in the chapter) occurs in central and western Europe, and related viruses are emerging in Russia. The significance of Tahyna virus in human health has been well studied only in the Czech and Slovak Republics; there, the virus was found to be a prominent cause of febrile disease, in some cases causing pharyngitis, pulmonary syndromes, and aseptic meningitis. The potential for arboviruses to be unexpectedly involved in such cases in areas of high mosquito prevalence needs to be kept in mind.

OROPOUCHE FEVER

Oropouche virus is transmitted in Central and South America by a biting midge, *Culicoides paraensis*, which often breeds to high density in cacao husks and other vegetable detritus found in towns and cities. Explosive epidemics involving thousands of cases have been reported from several towns in Brazil and Peru. Rash and aseptic meningitis have been detected in a number of cases.

SANDFLY FEVER

The sandfly *Phlebotomus papatasi* transmits sandfly fever. Female sandflies may be infected by the oral route as they take a blood meal and may transmit the virus to offspring when they lay their eggs after a second blood meal. This prominent transovarial pattern was the first to be recognized among dipterans and complicates virus control. A previous designation for sandfly fever, "3-day fever," instructively describes the brief, debilitating course associated with this essentially benign infection. There is neither a rash nor CNS involvement, and complete recovery is the rule.

Sandfly fever is found in the circum-Mediterranean area, extending to the east through the Balkans into China as well as into the Middle East and southwestern Asia. The vector is found in both rural and urban settings and is known for its small size, which enables it to penetrate standard mosquito screens and netting, and for its short flight range. Epidemics have been described in the wake of natural disasters and wars. In parts of Europe, sandfly populations and virus transmission were greatly reduced by the extensive residual spraying conducted after World War II to control malaria, and the incidence continues to be low. A common pattern of disease in endemic areas consists of high attack rates among travelers and military personnel with little or no disease in the local population, who are protected after childhood infection. More than 30 related phleboviruses are transmitted by sandflies and mosquitoes, but most are of unknown significance in terms of human health.

TOSCANA VIRUS DISEASE

Toscana virus is a *Phlebovirus* (family *Bunyaviridae*) transmitted primarily by the circum-Mediterranean sandfly *P. perniciosus*. The vertebrate amplifying host, if one exists, is unknown. Toscana virus infection is common during the summer among rural residents and vacationers, particularly in Italy, Spain, and Portugal; a number of cases have been identified in travelers returning to Germany and Scandinavia. The disease may manifest as an uncomplicated febrile illness but is often associated with aseptic meningitis, with virus isolated from the CSF.

PUNTA TORO VIRUS DISEASE

Of the several phleboviruses that are associated with New World sandflies and infect humans, Punta Toro virus is the best known. The disease caused by this virus

is clinically similar to but epidemiologically different from that caused by the Naples or Sicilian sandfly fever viruses. Punta Toro virus infections are sporadic and are acquired in the tropical forest, where the vectors rest on tree buttresses. Epidemics have not been reported, but antibody prevalences among inhabitants of villages in the endemic areas indicate a cumulative lifetime exposure rate of >50%.

DENGUE FEVER

All four distinct dengue viruses (dengue 1–4) have *Aedes aegypti* as their principal vector, and all cause a similar clinical syndrome. In rare cases, second infection with a serotype of dengue virus different from that involved in the primary infection leads to dengue HF with severe shock (see below). Sporadic cases are seen in the settings of endemic transmission and epidemic disease. Year-round transmission between latitudes 25°N and 25°S has been established, and seasonal forays of the viruses to points as far north as Philadelphia are thought to have taken place in the United States. Dengue fever is seen in the Caribbean region, including Puerto Rico. With increasing spread of the vector mosquito throughout the tropics and subtropics, large areas of the world have become vulnerable to the introduction of dengue viruses, particularly through air travel by infected humans, and both dengue fever and the related dengue HF are becoming increasingly common. Conditions favorable to dengue transmission exist in the southern United States, and bursts of dengue fever activity are to be expected in this region, particularly along the Mexican border, where water may be stored in containers and *A. aegypti* numbers may therefore be greatest. This mosquito, which is also an efficient vector of the yellow fever and chikungunya viruses, typically breeds near human habitation, using relatively fresh water from sources such as water jars, vases, discarded containers, coconut husks, and old tires. *A. aegypti* usually inhabits dwellings and bites during the day.

After an incubation period of 2–7 days, the typical patient experiences the sudden onset of fever, headache, retroorbital pain, and back pain along with the severe myalgia that gave rise to the colloquial designation “break-bone fever.” There is often a macular rash on the first day as well as adenopathy, palatal vesicles, and scleral injection. The illness may last a week, with additional symptoms usually including anorexia, nausea or vomiting, marked cutaneous hypersensitivity, and—near the time of defervescence—a maculopapular rash beginning on the trunk and spreading to the extremities and the face. Epistaxis and scattered petechiae are often noted in uncomplicated dengue, and preexisting gastrointestinal lesions may bleed during the acute illness.

Laboratory findings include leukopenia, thrombocytopenia, and, in many cases, serum aminotransferase elevations. The diagnosis is made by IgM ELISA or paired serology during recovery or by antigen-detection ELISA or RT-PCR during the acute phase. Virus is readily isolated from blood in the acute phase if mosquito inoculation or mosquito cell culture is used.

COLORADO TICK FEVER

Several hundred cases of Colorado tick fever are reported annually in the United States. The infection is acquired between March and November through the bite of an infected *Dermacentor andersoni* tick in mountainous western regions at altitudes of 1200–3000 m (4000–10,000 ft). Small mammals serve as the amplifying host. The most common presentation consists of fever and myalgia; meningoencephalitis is not uncommon, and hemorrhagic disease, pericarditis, myocarditis, orchitis, and pulmonary presentations are also reported. Rash develops in a substantial minority of cases. The disease usually lasts 7–10 days and is often biphasic. The most important differential diagnostic considerations since the beginning of the twentieth century have been Rocky Mountain spotted fever and tularemia. In Colorado, Colorado tick fever is much more common than Rocky Mountain spotted fever.

Infection of erythroblasts and other marrow cells by Colorado tick fever virus results in the appearance and persistence (for several weeks) of erythrocytes containing the virus. This feature, detected in smears stained by immunofluorescence, can be diagnostically helpful. The clinical laboratory detects leukopenia and thrombocytopenia.

ORBIVIRUS INFECTION

The orbiviruses encompass many human and veterinary pathogens. For example, Orungo virus is widely transmitted by mosquitoes in tropical Africa and causes febrile disease in humans. The Kemerovo complex includes the Kemerovo, Lipovnik, and Tribec viruses of Russia and central Europe; these viruses are transmitted by ticks and are associated with febrile and neurologic disease.

ENCEPHALITIS

Arboviral encephalitis is a seasonal disease, commonly occurring in the warmer months. Its incidence varies markedly with time and place, depending on ecologic factors. The causative viruses differ substantially in terms of case-infection ratio (i.e., the ratio of clinical to subclinical infections), mortality rate, and residua (Table 99-3). Humans are not an important amplifier of these viruses.

All the viral encephalitides discussed in this section have a similar pathogenesis as far as is known. An infected arthropod ingests a blood meal from a human and infects the host. The initial period of viremia is thought to originate most commonly from the lymphoid system. Viremia leads to CNS invasion, presumably through infection of olfactory neuroepithelium with passage through the cribriform plate or through infection of brain capillaries and multifocal entry into the CNS. During the viremic phase, there may be little or no recognized disease except in the case of tick-borne flaviviral encephalitis, in which there may be a clearly delineated phase of fever and systemic illness. The disease process in the CNS arises partly from direct neuronal infection and subsequent damage and partly from

PROMINENT FEATURES OF ARBOVIRAL ENCEPHALITIS

| VIRUS | NATURAL CYCLE | INCUBATION PERIOD, DAYS | ANNUAL NO. OF CASES | CASE-TO-INFECTION RATIO | AGE OF CASES | CASE-FATALITY RATE, % | RESIDUA |
|------------------------------|--|-------------------------|---|--|--|-----------------------|---|
| La Crosse | <i>Aedes triseriatus</i> —chipmunk (transovarial component in mosquito also important) | ~3–7 | 70 (U.S.) | <1:1000 | <15 years | <0.5 | Recurrent seizures in ~10%; severe deficits in rare cases; decreased school performance and behavioral change suspected in small proportion |
| St. Louis | <i>Culex tarsalis</i> , <i>C. pipiens</i> , <i>C. quinquefasciatus</i> —birds | 4–21 | 85, with hundreds to thousands in epidemic years (U.S.) | <1:200 | Milder cases in the young; more severe cases in adults >40 years old, particularly the elderly | 7 | Common in the elderly |
| Japanese | <i>Culex tritaeniorhynchus</i> —birds | 5–15 | >25,000 | 1:200–300 | All ages; children in highly endemic areas | 20–50 | Common (approximately half of cases); may be severe |
| West Nile | <i>Culex mosquito</i> es—birds | 3–6 | ? | Very low | Mainly the elderly | 5–10 | Uncommon |
| Central European | <i>Ixodes ricinus</i> —rodents, insectivores | 7–14 | Thousands | 1:12 | All ages; milder in children | 1–5 | 20% |
| Russian spring-summer | <i>I. persulcatus</i> —rodents, insectivores | 7–14 | Hundreds | — | All ages; milder in children | 20 | Approximately half of cases; often severe; limb-girdle paralysis |
| Powassan | <i>I. cookei</i> —wild mammals | ~10 | ~1 (U.S.) | — | All ages; some predilection for children | ~10 | Common (approximately half of cases) |
| Eastern equine | <i>Culiseta melanura</i> —birds | ~5–10 | 5 (U.S.) | 1:40 adult 1:17 child | All ages; predilection for children | 50–75 | Common |
| Western equine | <i>Culex tarsalis</i> —birds | ~5–10 | ~20 (U.S.) | 1:1000 adult 1:50 child 1:1 infant | All ages; predilection for children <2 years old (increased mortality in elderly) | 3–7 | Common only among infants <1 year old |
| Venezuelan equine (epidemic) | Unknown (multiple mosquito species and horses in epidemics) | 1–5 | ? | 1:250 adult 1:25 child (approximate) | All ages; predilection for children | ~10 | — |

edema, inflammation, and other indirect effects. The usual pathologic picture is one of focal necrosis of neurons, inflammatory glial nodules, and perivascular lymphoid cuffing; the severity and distribution of these abnormalities vary with the infecting virus. Involved areas display the “luxury perfusion” phenomenon, with normal or increased total blood flow and low oxygen extraction.

The typical patient presents with a prodrome of nonspecific constitutional symptoms, including fever, abdominal pain, vertigo, sore throat, and respiratory symptoms. Headache, meningeal signs, photophobia, and vomiting follow quickly. Involvement of deeper structures may be signaled by lethargy, somnolence, and intellectual deficit (as disclosed by the mental status

examination or failure at serial 7 subtraction); more severely affected patients are obviously disoriented and may be comatose. Tremors, loss of abdominal reflexes, cranial nerve palsies, hemiparesis, monoparesis, difficulty in swallowing, and frontal lobe signs are all common. Spinal and motor neuron diseases are documented with West Nile and Japanese encephalitis viruses. Convulsions and focal signs may be evident early or may appear during the course of the disease. Some patients present with an abrupt onset of fever, convulsions, and other signs of CNS involvement. The results of human infection range from no significant symptoms through febrile headache to aseptic meningitis and finally to full-blown encephalitis; the proportions and severity of these manifestations vary with the infecting virus.

The acute encephalitis usually lasts from a few days to as long as 2–3 weeks, but recovery may be slow, with weeks or months required for the return of maximal recoupable function. Difficulty concentrating, fatigability, tremors, and personality changes are common during recovery. The acute illness requires management of a comatose patient who may have intracranial pressure elevations, inappropriate secretion of antidiuretic hormone, respiratory failure, and convulsions. There is no specific therapy for these viral encephalitides. The only practical preventive measures are vector management and personal protection against the arthropod transmitting the virus; for Japanese encephalitis or tick-borne encephalitis, vaccination should be considered in certain circumstances (see relevant sections below).

The diagnosis of arboviral encephalitis depends on the careful evaluation of a febrile patient with CNS disease, with rapid identification of treatable herpes simplex encephalitis, ruling out of brain abscess, exclusion of bacterial meningitis by serial CSF examination, and performance of laboratory studies to define the viral etiology. Leptospirosis, neurosyphilis, Lyme disease, cat-scratch fever, and newer viral encephalitides such as Nipah virus infection from Malaysia should be considered. The CSF examination usually shows a modest cell count—in the tens or hundreds or perhaps a few thousand. Early in the process, a significant proportion of these cells may be polymorphonuclear leukocytes, but usually there is a mononuclear cell predominance. CSF glucose levels are usually normal. There are exceptions to this pattern of findings. In eastern equine encephalitis, for example, polymorphonuclear leukocytes may predominate during the first 72 h of disease and hypoglycorrhachia may be detected. In LCM, lymphocyte counts may be in the thousands, and the glucose concentration may be diminished. Experience with imaging studies is still evolving; clearly, however, both CT and MRI may be normal, except for evidence of preexisting conditions, or sometimes may suggest diffuse edema. Several patients with eastern equine encephalitis have had focal abnormalities, and individuals with severe Japanese encephalitis have presented with bilateral thalamic lesions that have often been hemorrhagic. Electroencephalography usually shows diffuse abnormalities and is not directly helpful.

A humoral immune response is usually detectable at or near the onset of disease. Both serum and CSF should be examined for IgM antibodies. Virus generally cannot be isolated from blood or CSF, although Japanese encephalitis virus has been recovered from CSF in severe cases. RT-PCR analysis of CSF may yield positive results. Virus can be obtained from and viral antigen is present in brain tissue, although its distribution may be focal.

CALIFORNIA, LA CROSSE, AND JAMESTOWN CANYON VIRUS ENCEPHALITIS

The isolation of California encephalitis virus established the California serogroup of viruses as a cause of

encephalitis, and its use as a diagnostic antigen led to the description of many cases of “California encephalitis.” In fact, however, this virus has been implicated in only a few cases of encephalitis, and the serologically related La Crosse virus is the major cause of encephalitis among viruses in the California serogroup. “California encephalitis” due to La Crosse virus infection is most commonly reported from the upper Midwest but is also found in other areas of the central and eastern United States, most often in West Virginia, Tennessee, North Carolina, and Georgia. The serogroup includes 13 other viruses, some of which may also be involved in human disease that is misattributed because of the complexity of the group’s serology; these viruses include the Jamestown Canyon, snowshoe hare, Inkoo, and Trivittatus viruses, all of which have *Aedes* mosquitoes as their vector and all of which have a strong element of transovarial transmission in their natural cycles.

The mosquito vector of La Crosse virus is *A. triseriatus*. In addition to a prominent transovarial component of transmission, a mosquito can become infected through feeding on viremic chipmunks and other mammals as well as through venereal transmission from another mosquito. The mosquito breeds in sites such as tree holes and abandoned tires and bites during daylight hours. These habits correlate with the risk factors for human cases: recreation in forested areas, residence at the forest’s edge, and the presence of abandoned tires around the home. Intensive environmental modification based on these findings has reduced the incidence of disease in a highly endemic area in the Midwest. Most cases occur from July through September. The Asian tiger mosquito, *A. albopictus*, efficiently transmits the virus to mice and also transmits the agent transovarially in the laboratory; this aggressive anthropophilic mosquito has the capacity to urbanize, and its possible impact on transmission to humans is of concern.

An antibody prevalence of $\geq 20\%$ in endemic areas indicates that infection is common, but CNS disease has been recognized primarily in children <15 years of age. The illness varies from a picture of aseptic meningitis accompanied by confusion to severe and occasionally fatal encephalitis. Although there may be prodromal symptoms, the onset of CNS disease is sudden, with fever, headache, and lethargy often joined by nausea and vomiting, convulsions (in one-half of patients), and coma (in one-third of patients). Focal seizures, hemiparesis, tremor, aphasia, chorea, Babinski signs, and other evidence of significant neurologic dysfunction are common, but residua are not. Perhaps 10% of patients have recurrent seizures in the succeeding months. Other serious sequelae are rare, although a decrease in scholastic standing has been reported and mild personality change has occasionally been suggested. Treatment is supportive over a 1- to 2-week acute phase during which status epilepticus, cerebral edema, and inappropriate secretion of antidiuretic hormone are important concerns. Ribavirin has been used in severe cases, and a clinical trial of this drug is under way.

The blood leukocyte count is commonly elevated, sometimes reaching levels of $20,000/\mu\text{L}$, and there is usually a left shift. CSF cell counts are typically $30\text{--}500/\mu\text{L}$ with a mononuclear cell predominance

(although 25–90% of cells are polymorphonuclear in some cases). The protein level is normal or slightly increased, and the glucose level is normal. Specific virologic diagnosis based on IgM-capture assays of serum and CSF is efficient. The only human anatomic site from which virus has been isolated is the brain.

Jamestown Canyon virus has been implicated in several cases of encephalitis in adults; in these cases, the disease was usually associated with a significant respiratory illness at onset. Human infection with this virus has been documented in New York, Wisconsin, Ohio, Michigan, Ontario, and other areas of North America where the vector mosquito, *A. stimulans*, feeds on its main host, the white-tailed deer.

ST. LOUIS ENCEPHALITIS

St. Louis encephalitis virus is transmitted between *Culex* mosquitoes and birds. This virus causes low-level endemic infection among rural residents of the western and central United States, where *C. tarsalis* is the vector (see “Western Equine Encephalitis” later in the chapter), but the more urbanized mosquito species *C. pipiens* and *C. quinquefasciatus* have been responsible for epidemics resulting in hundreds or even thousands of cases in cities of the central and eastern United States. Most cases occur in June through October. The urban mosquitoes breed in accumulations of stagnant water and sewage with high organic content and readily bite humans in and around houses at dusk. The elimination of open sewers and trash-filled drainage systems is expensive and may not be possible, but screening of houses and implementation of personal protective measures may be an effective approach for individuals. The rural vector is most active at dusk and outdoors; its bites can be avoided by modification of activities and use of repellents.

Disease severity increases with age: infections that result in aseptic meningitis or mild encephalitis are concentrated in children and young adults, while severe and fatal cases primarily affect the elderly. Infection rates are similar in all age groups; thus the greater susceptibility of older persons to disease is a biologic consequence of aging. The disease has an abrupt onset, sometimes following a prodrome, and begins with fever, lethargy, confusion, and headache. In addition, nuchal rigidity, hypotonia, hyperreflexia, myoclonus, and tremor are common. Severe cases can include cranial nerve palsies, hemiparesis, and convulsions. Patients often report dysuria and may have viral antigen in urine as well as pyuria. The overall mortality rate is generally ~7% but may reach 20% among patients over the age of 60. Recovery is slow. Emotional lability, difficulties in concentration and memory, asthenia, and tremor are commonly prolonged in older patients.

The CSF of patients with St. Louis encephalitis usually contains tens to hundreds of cells, with a lymphocytic predominance and a normal glucose level. Leukocytosis with a left shift is often documented.

JAPANESE ENCEPHALITIS

Japanese encephalitis virus is found throughout Asia, including far eastern Russia, Japan, China, India, Pakistan,

and Southeast Asia, and causes occasional epidemics on western Pacific islands. The virus has been detected in the Torres Strait islands, and a human encephalitis case has been identified on the nearby Australian mainland. This flavivirus is particularly common in areas where irrigated rice fields attract the natural avian vertebrate hosts and provide abundant breeding sites for mosquitoes such as *C. tritaeniorhynchus*, which transmit the virus to humans. Additional amplification by pigs, which suffer abortion, and horses, which develop encephalitis, may be significant as well. Vaccination of these additional amplifying hosts may reduce the transmission of the virus. An effective, formalin-inactivated vaccine purified from mouse brain is produced in Japan and licensed for human use in the United States. It is given on days 0, 7, and 30 or—with some sacrifice in serum neutralizing titer—on days 0, 7, and 14. Vaccination is indicated for summer travelers to rural Asia, where the risk of clinical disease may be 0.05–2.1/10,000 per week (Table 3-2). The severe and often fatal disease reported in expatriates must be balanced against the 0.1–1% chance of a late systemic or cutaneous allergic reaction. These reactions are rarely fatal but may be severe and have been known to begin 1–9 days after vaccination, with associated pruritus, urticaria, and angioedema. Live attenuated vaccines are being used in China but are not recommended in the United States at this time.

WEST NILE VIRUS INFECTION

West Nile virus is transmitted among wild birds by *Culex* mosquitoes in Africa, the Middle East, southern Europe, and Asia. It is a common cause of febrile disease without CNS involvement, but it occasionally causes aseptic meningitis and severe encephalitis; these serious infections are particularly common among the elderly. The febrile-myalgic syndrome caused by West Nile virus differs from many others by the frequent appearance of a maculopapular rash concentrated on the trunk and lymphadenopathy. Headache, ocular pain, sore throat, nausea and vomiting, and arthralgia (but not arthritis) are common accompaniments. In addition, the virus has been implicated in severe and fatal hepatic necrosis in Africa.

West Nile virus was introduced into New York City in 1999 and subsequently spread to other areas of the northeastern United States, causing >60 cases of aseptic meningitis or encephalitis among humans as well as die-offs among crows, exotic zoo birds, and other birds. The virus has continued to spread and is now found in almost all states, Canada, and Mexico. *C. pipiens* remains the major vector in the northeastern United States, but several other *Culex* species are also involved, and blue jays compete with crows as amplifiers and lethal targets in other areas of the country. Annually, ~1000–3000 cases of encephalitis with ~100–300 deaths are reported in the United States. The ratio of CNS involvement to infection is thought to be ~1:100; the remainder of patients have subclinical infection or West Nile fever. Encephalitis, sequelae, and death are all more common among the elderly, diabetics, and patients with previous CNS insults. In addition to the more severe motor and

cognitive sequelae, milder findings may include tremor, slight abnormalities in motor skills, and loss of executive functions. Intense clinical interest and the availability of laboratory diagnostic methods have made it possible to define a number of unusual clinical features, including chorioretinitis, flaccid paralysis with histologic lesions resembling poliomyelitis, and initial presentation with fever and focal neurologic deficits in the absence of diffuse encephalitis. Immunosuppressed patients may have fulminant courses or develop persistent CNS infection. Virus transmission through both transplantation and blood transfusion has necessitated screening of blood and organ donors by nucleic acid–based tests.

West Nile virus falls into the same phylogenetic group of flaviviruses as St. Louis and Japanese encephalitis viruses, as do Murray Valley and Rocio viruses. The latter two viruses are both maintained in mosquitoes and birds and produce a clinical picture resembling that of Japanese encephalitis. Murray Valley virus has caused occasional epidemics and sporadic cases in Australia. Rocio virus caused recurrent epidemics in a focal area of Brazil in 1975–1977 and then virtually disappeared.

CENTRAL EUROPEAN TICK-BORNE ENCEPHALITIS AND RUSSIAN SPRING-SUMMER ENCEPHALITIS

A spectrum of tick-borne flaviviruses has been identified across the Eurasian land mass. Many are known mainly as agricultural pathogens (e.g., louping ill virus in the United Kingdom). From Scandinavia to the Urals, central European tick-borne encephalitis is transmitted by *Ixodes ricinus*. Human cases occur between April and October, with a peak in June and July. A related and more virulent virus is that of Russian spring-summer encephalitis, which is associated with *I. persulcatus* and is distributed from Europe across the Urals to the Pacific Ocean. The ticks transmit the disease primarily in the spring and early summer, with a lower rate of transmission later in summer. Small mammals are the vertebrate amplifiers for both viruses. The risk varies by geographic area and can be highly localized within a given area; human cases usually follow outdoor activities or consumption of raw milk from infected goats or other infected animals.

After an incubation period of 7–14 days or perhaps longer, the central European viruses classically result in a febrile-myalgic phase that lasts for 2–4 days and is thought to correlate with viremia. A subsequent remission for several days is followed by the recurrence of fever and the onset of meningeal signs. The CNS phase varies from mild aseptic meningitis, which is more common among younger patients, to severe encephalitis with coma, convulsions, tremors, and motor signs lasting for 7–10 days before improvement begins. Spinal and medullary involvement can lead to typical limb-girdle paralysis and to respiratory paralysis. Most patients recover, only a minority with significant deficits. Infections with the Far Eastern viruses generally run a more abrupt course. The encephalitic syndrome caused by these viruses sometimes begins without a remission and has more severe manifestations than the European syndrome. Mortality is

high, and major sequelae—most notably, lower motor neuron paralyzes of the proximal muscles of the extremities, trunk, and neck—are common.

In the early stage of the illness, virus may be isolated from the blood. In the CNS phase, IgM antibodies are detectable in serum and/or CSF. Thrombocytopenia sometimes develops during the initial febrile illness, which resembles the early hemorrhagic phase of some other tick-borne flaviviral infections, such as Kyasanur Forest disease. Other tick-borne flaviviruses are less common causes of encephalitis, including louping ill virus in the United Kingdom and Powassan virus.

There is no specific therapy for infection with these viruses. However, effective alum-adsorbed, formalin-inactivated vaccines are produced in Austria, Germany, and Russia. Two doses of the Austrian vaccine separated by an interval of 1–3 months appear to be effective in the field, and antibody responses are similar when vaccine is given on days 0 and 14. Other vaccines have elicited similar neutralizing antibody titers. Since rare cases of postvaccination Guillain-Barré syndrome have been reported, vaccination should be reserved for persons likely to experience rural exposure in an endemic area during the season of transmission. Cross-neutralization for the central European and Far Eastern strains has been established, but there are no published field studies on cross-protection of formalin-inactivated vaccines. Because 0.2–4% of ticks in endemic areas may be infected, tick bites raise the issue of immunoglobulin prophylaxis. Prompt administration of high-titered specific preparations should probably be undertaken, although no controlled data are available to prove the efficacy of this measure. Immunoglobulin should not be administered late because of the risk of antibody-mediated enhancement.

POWASSAN ENCEPHALITIS

Powassan virus is a member of the tick-borne encephalitis virus complex and is transmitted by *I. cookei* among small mammals in eastern Canada and the United States, where it has been responsible for 20 recognized cases of human disease. Other ticks may transmit the virus in a wider geographic area, and there is some concern that *I. scapularis* (also called *I. dammini*), a competent vector in the laboratory, may become involved as it becomes more prominent in the United States. Patients with Powassan encephalitis (many of whom are children) present in May through December after outdoor exposure and an incubation period thought to be ~1 week. Powassan encephalitis is severe, and sequelae are common.

EASTERN EQUINE ENCEPHALITIS

Eastern equine encephalitis is found primarily within endemic swampy foci along the eastern coast of the United States, with a few inland foci as far removed as Michigan. Human cases present from June through October, when the bird-*Culiseta* mosquito cycle spills over into other mosquito species such as *A. sollicitans* or *A. vexans*, which are more likely to bite mammals. There is concern over the potential role of the introduced

anthropophilic mosquito species *A. albopictus*, which has been found to be naturally infected and is an effective vector in the laboratory. Horses are a common target for the virus; contact with unvaccinated horses may be associated with human disease, but horses probably do not play a significant role in amplification of the virus.

Eastern equine encephalitis is one of the most destructive of the arboviral conditions, with a brusque onset, rapid progression, high mortality, and frequent residua. This severity is reflected in the extensive necrotic lesions and polymorphonuclear infiltrates found at postmortem examination of the brain and the acute polymorphonuclear CSF pleocytosis often occurring during the first 1–3 days of disease. In addition, leukocytosis with a left shift is a common feature. A formalin-inactivated vaccine has been used to protect laboratory workers but is not generally available or applicable.

WESTERN EQUINE ENCEPHALITIS

The primary maintenance cycle for western equine encephalitis virus in the United States is between *C. tarsalis* and birds, principally sparrows and finches. Equines and humans become infected, and both species suffer encephalitis without amplifying the virus in nature. St. Louis encephalitis is transmitted in a similar cycle in the same region but causes human disease about a month earlier than the period (July through October) in which western equine encephalitis virus is active. Large epidemics of western equine encephalitis took place in the western and central United States and Canada during the 1930s to 1950s, but in recent years the disease has been uncommon. There were 41 reported cases in the United States in 1987 but only 5 reported cases from 1988 to 2001. This decline in incidence may reflect in part the integrated approach to mosquito management that has been employed in irrigation projects and the increasing use of agricultural pesticides; it almost certainly reflects the increased tendency for humans to be indoors behind closed windows at dusk—the peak period of biting by the major vector.

Western equine encephalitis virus causes a typical diffuse viral encephalitis with an increased attack rate and increased morbidity among the young, particularly children <2 years old. In addition, mortality rates are high among the young and the very elderly. One-third of individuals who have convulsions during the acute illness have subsequent seizure activity. Infants <1 year old—particularly those in the first months of life—are at serious risk of motor and intellectual damage. Twice as many males as females develop clinical encephalitis after 5–9 years of age; this difference may be related to greater outdoor exposure of boys to the vector but is also likely to be due in part to biologic differences. A formalin-inactivated vaccine has been used to protect laboratory workers but is not generally available or applicable.

VENEZUELAN EQUINE ENCEPHALITIS

There are six known types of virus in the Venezuelan equine encephalitis complex. An important distinction is between the *epizootic* viruses (subtypes IAB and IC) and

the *enzootic* viruses (subtypes ID to IF and types II to VI). The epizootic viruses have an unknown natural cycle but periodically cause extensive epidemics in equines and humans in the Americas. These epidemics rely on the high-level viremia in horses and mules that results in the infection of several species of mosquitoes, which in turn infect humans and perpetuate virus transmission. Humans also have high-level viremia but probably are not important in virus transmission. Enzootic viruses are found primarily in humid tropical forest habitats and are maintained between *Culex* mosquitoes and rodents; these viruses cause human disease but are not pathogenic for horses and do not cause epizootics.

Epizootics of Venezuelan equine encephalitis occurred repeatedly in Venezuela, Colombia, Ecuador, Peru, and other South American countries at intervals of ≤10 years from the 1930s until 1969, when a massive epizootic spread throughout Central America and Mexico, reaching southern Texas in 1972. Genetic sequencing of the virus from the 1969–1972 outbreak suggested that it originated from residual “un-inactivated” virus in veterinary vaccines. The outbreak was terminated in Texas with the use of a live attenuated vaccine (TC-83) originally developed for human use by the U.S. Army; the epizootic virus was then used for further production of inactivated veterinary vaccines. No further epizootic disease was identified until 1995 and subsequently, when additional epizootics took place in Colombia, Venezuela, and Mexico. The viruses involved in these epizootics as well as previously epizootic subtype IC viruses have been shown to be close phylogenetic relatives of known enzootic subtype ID viruses. This finding suggests that active evolution and selection of epizootic viruses are under way in northern South America.

During epizootics, extensive human infection is the rule, with clinical disease in 10–60% of infected individuals. Most infections result in notable acute febrile disease, while relatively few result in encephalitis. A low rate of CNS invasion is supported by the absence of encephalitis among the many infections resulting from exposure to aerosols in the laboratory or from vaccine accidents. The most recent large epizootic of Venezuelan equine encephalitis occurred in Colombia and Venezuela in 1995; of the >85,000 clinical cases, 4% (with a higher proportion among children than adults) included neurologic symptoms and 300 ended in death.

Enzootic strains of Venezuelan equine encephalitis virus are common causes of acute febrile disease, particularly in areas such as the Florida Everglades and the humid Atlantic coast of Central America. Encephalitis has been documented only in the Florida infections; the three cases were caused by type II enzootic virus, also called *Everglades virus*. All three patients had preexisting cerebral disease. Extrapolation from the rate of genetic change suggests that Everglades virus may have been introduced into Florida <200 years ago and that it is most closely related to the ID subtypes that appear to have given evolutionary rise to the epizootic strains active in South America.

The prevention of epizootic Venezuelan equine encephalitis depends on vaccination of horses with the attenuated TC-83 vaccine or with an inactivated vaccine

prepared from that strain. Humans can be protected with similar vaccines, but the use of such products is restricted to laboratory personnel because of reactivity and limited availability. In addition, wild-type virus and perhaps TC-83 vaccine may have some degree of fetal pathogenicity. Enzootic viruses are genetically and antigenically different from epizootic viruses, and protection against the former with vaccines prepared from the latter is relatively ineffective.

ARTHRITIS AND RASH

True arthritis is a common accompaniment of several viral diseases, such as rubella (caused by a non-alphavirus togavirus), parvovirus B19 infection, and hepatitis B; it is an occasional accompaniment of infection due to mumps virus, enteroviruses, herpesviruses, and adenoviruses. It is not generally appreciated that the alphaviruses are also common causes of arthritis. In fact, the alphaviruses discussed below all cause acute febrile diseases accompanied by the development of true arthritis and a maculopapular rash. Rheumatic involvement includes arthralgia alone, periarticular swelling, and (less commonly) joint effusions. Most of these diseases are less severe and have fewer articular manifestations in children than in adults. In temperate climates, these are summer diseases. No specific therapy or licensed vaccines exist.

SINDBIS VIRUS INFECTION

Sindbis virus is transmitted among birds by mosquitoes. Infections with the northern European strains of this virus (which cause, for example, Pogosta disease in Finland, Karelian fever in the independent states of the former Soviet Union, and Ockelbo disease in Sweden) and with the genetically related southern African strains are particularly likely to result in the arthritis-rash syndrome. Exposure to a rural environment is commonly associated with this infection, which has an incubation period of <1 week.

The disease begins with rash and arthralgia. Constitutional symptoms are not marked, and fever is modest or lacking altogether. The rash, which lasts ~1 week, begins on the trunk, spreads to the extremities, and evolves from macules to papules that often vesiculate. The arthritis of this condition is multiarticular, migratory, and incapacitating, with resolution of the acute phase in a few days. Wrists, ankles, phalangeal joints, knees, elbows, and—to a much lesser extent—proximal and axial joints are involved. Persistence of joint pains and occasionally of arthritis is a major problem and may go on for months or even years despite a lack of deformity.

CHIKUNGUNYA VIRUS INFECTION

It is likely that chikungunya virus (“that which bends up”) is of African origin and is maintained among non-human primates on that continent by *Aedes* mosquitoes of the subgenus *Stegomyia* in a fashion similar to yellow fever virus. Like yellow fever virus, chikungunya virus is readily transmitted among humans in urban areas by

A. aegypti. The *A. aegypti*–chikungunya virus transmission cycle has also been introduced into Asia, where it poses a prominent health problem. The disease is endemic in rural areas of Africa, and intermittent epidemics take place in towns and cities of Africa and Asia. In 2004, a massive epidemic in the Indian Ocean region began; it now appears to have been spread totally by travelers. *A. albopictus* was identified as the major vector, and there were multiple exportations to temperate zones and to areas where *A. aegypti* is present. Chikungunya is one more reason (in addition to dengue and yellow fever) that *A. aegypti* must be controlled.

Full-blown disease is most common among adults, in whom the clinical picture may be dramatic. The abrupt onset follows an incubation period of 2–3 days. Fever and severe arthralgia are accompanied by chills and constitutional symptoms such as headache, photophobia, conjunctival injection, anorexia, nausea, and abdominal pain. Migratory polyarthritis mainly affects the small joints of the hands, wrists, ankles, and feet, with lesser involvement of the larger joints. Rash may appear at the outset or several days into the illness; its development often coincides with defervescence, which takes place around day 2 or 3 of disease. The rash is most intense on the trunk and limbs and may desquamate. Petechiae are occasionally seen, and epistaxis is not uncommon, but this virus is not a regular cause of the HF syndrome, even in children. A few patients develop leukopenia. Elevated levels of aspartate aminotransferase (AST) and C-reactive protein have been described, as have mildly decreased platelet counts. Recovery may require weeks. Some older patients continue to experience stiffness, joint pain, and recurrent effusions for several years; this persistence may be especially common in HLA-B27 patients. An investigational live attenuated vaccine has been developed but requires additional testing. It appears to be headed for further development and commercial manufacture stimulated by the Indian Ocean outbreak.

A related virus, O’nyong-nyong, caused a major epidemic of arthritis and rash involving at least 2 million people as it moved across eastern and central Africa in the 1960s. After its mysterious emergence, the virus virtually disappeared, leaving only occasional evidence of its persistence in Kenya until a transient resurgence of epidemic activity in 1997.

MAYARO FEVER

Mayaro virus is maintained in the forests of the Americas by *Haemagogus* mosquitoes and nonhuman primates. It causes a frequently endemic and sometimes epidemic infection of humans and appears to produce a syndrome resembling chikungunya virus infection.

EPIDEMIC POLYARTHRITIS (ROSS RIVER VIRUS INFECTION)

Ross River virus has caused epidemics of distinctive clinical disease in Australia since the beginning of the twentieth century and continues to be responsible for thousands of cases in rural and suburban areas annually. The virus is transmitted by *A. vigilax* and other mosquitoes, and its

persistence is thought to involve transovarial transmission. No definitive vertebrate host has been identified, but several mammalian species, including wallabies, have been suggested. Endemic transmission has also been documented in New Guinea, and in 1979 the virus swept through the eastern Pacific Islands, causing hundreds of thousands of illnesses. The virus was carried from island to island by infected humans and was believed to have been transmitted among humans by *A. polynesiensis* and *A. aegypti*.

The incubation period is 7–11 days long, and the onset of illness is sudden, with joint pain usually ushering in the disease. The rash generally develops coincidentally or follows shortly but in some cases precedes joint pains by several days. Constitutional symptoms such as low-grade fever, asthenia, myalgia, headache, and nausea are not prominent and indeed are absent in many cases. Most patients are incapacitated for considerable periods by joint involvement, which interferes with sleeping, walking, and grasping. Wrist, ankle, metacarpophalangeal, interphalangeal, and knee joints are the most commonly involved, although toes, shoulders, and elbows may be affected with some frequency. Periarticular swelling and tenosynovitis are common, and one-third of patients have true arthritis. Only half of all arthritis patients can resume normal activities within 4 weeks, and 10% still must limit their activity at 3 months. Occasional patients are symptomatic for 1–3 years but without progressive arthropathy. Aspirin and nonsteroidal anti-inflammatory drugs are effective for the treatment of symptoms.

Clinical laboratory values are normal or variable in Ross River virus infection. Tests for rheumatoid factor and antinuclear antibodies are negative, and the erythrocyte sedimentation rate is acutely elevated. Joint fluid contains 1000–60,000 mononuclear cells/ μL , and Ross River virus antigen is demonstrable in macrophages. IgM antibodies are valuable in the diagnosis of this infection, although they occasionally persist for years. The isolation of the virus from blood by mosquito inoculation or mosquito cell culture is possible early in the illness. Because of the great economic impact of annual epidemics in Australia, an inactivated vaccine is being developed and has been found to be protective in mice.

Perhaps because of the local interest in arboviruses in general and in Ross River virus in particular, other arthritogenic arboviruses have been identified in Australia, including Gan Gan virus, a member of the family Bunyaviridae; Kokobera virus, a flavivirus; and Barmah Forest virus, an alphavirus. The last virus is a common cause of infection and must be differentiated from Ross River virus by specific testing.

HEMORRHAGIC FEVERS

The viral HF syndrome is a constellation of findings based on vascular instability and decreased vascular integrity. An assault, direct or indirect, on the microvasculature leads to increased permeability and (particularly when platelet function is decreased) to actual disruption and local hemorrhage. Blood pressure is decreased, and

in severe cases shock supervenes. Cutaneous flushing and conjunctival suffusion are examples of common, observable abnormalities in the control of local circulation. The hemorrhage is inconstant and is in most cases an indication of widespread vascular damage rather than a life-threatening loss of blood volume. Disseminated intravascular coagulation (DIC) is occasionally found in any severely ill patient with HF but is thought to occur regularly only in the early phases of HF with renal syndrome, Crimean-Congo HF, and perhaps some cases of filovirus HF. In some viral HF syndromes, specific organs may be particularly impaired, such as the kidney in HF with renal syndrome, the lung in hantavirus pulmonary syndrome, or the liver in yellow fever, but in all these diseases the generalized circulatory disturbance is critically important.

The pathogenesis of HF is poorly understood and varies among the viruses regularly implicated in the syndrome, which number more than a dozen. In some cases direct damage to the vascular system or even to parenchymal cells of target organs is important, whereas in others soluble mediators are thought to play the major role. The acute phase in most cases of HF is associated with ongoing virus replication and viremia. Exceptions are the hantavirus diseases and dengue HF/dengue shock syndrome (DHF/DSS), in which the immune response plays a major pathogenic role.

The HF syndromes all begin with fever and myalgia, usually of abrupt onset. Within a few days the patient presents for medical attention because of increasing prostration that is often accompanied by severe headache, dizziness, photophobia, hyperesthesia, abdominal or chest pain, anorexia, nausea or vomiting, and other gastrointestinal disturbances. Initial examination often reveals only an acutely ill patient with conjunctival suffusion, tenderness to palpation of muscles or abdomen, and borderline hypotension or postural hypotension, perhaps with tachycardia. Petechiae (often best visualized in the axillae), flushing of the head and thorax, periorbital edema, and proteinuria are common. Levels of AST are usually elevated at presentation or within a day or two thereafter. Hemoconcentration from vascular leakage, which is usually evident, is most marked in hantavirus diseases and in DHF/DSS. The seriously ill patient progresses to more severe symptoms and develops shock and other findings typical of the causative virus. Shock, multifocal bleeding, and CNS involvement (encephalopathy, coma, convulsions) are all poor prognostic signs.

One of the major diagnostic clues is travel to an endemic area within the incubation period for a given syndrome (Table 99-4). Except for Seoul, dengue, and yellow fever virus infections, which have urban vectors, travel to a rural setting is especially suggestive of a diagnosis of HF.

Early recognition is important because of the need for virus-specific therapy and supportive measures, including prompt, atraumatic hospitalization; judicious fluid therapy that takes into account the patient's increased capillary permeability; administration of cardiotoxic drugs; use of pressors to maintain blood pressure at levels that will support renal perfusion; treatment of

TABLE 99-4

VIRAL HEMORRHAGIC FEVER (HF) SYNDROMES AND THEIR DISTRIBUTION

| DISEASE | INCUBATION PERIOD, DAYS | CASE-INFECTION RATIO | CASE-FATALITY RATE, % | GEOGRAPHIC RANGE | TARGET POPULATION |
|----------------------------------|-------------------------|--|------------------------------|---|---|
| Lassa fever | 5–16 | Mild infections probably common | 15 | West Africa | All ages, both sexes |
| South American HF | 7–14 | Most infections (more than half) result in disease | 15–30 | Selected rural areas of Bolivia, Argentina, Venezuela, and Brazil | Bolivia: Men in countryside; all ages, both sexes in villages Argentina: All ages, both sexes; excess exposure and disease in men Venezuela: All ages, both sexes |
| Rift Valley fever | 2–5 | ~1:100 ^a | ~50 | Sub-Saharan Africa, Madagascar, Egypt | All ages, both sexes; more often diagnosed in men; preexisting liver disease may predispose |
| Crimean-Congo HF | 3–12 | ≥1:5 | 15–30 | Africa, Middle East, Turkey, Balkans, southern region of former Soviet Union, western China | All ages, both sexes; men more exposed in some settings |
| HF with renal syndrome | 9–35 | Hantaan, >1:1.25; Puumala, 1:20 | Hantaan, 5–15; Puumala, <1 | Worldwide, depending on rodent reservoir | Excess of male patients (partly due to greater exposure); mainly adults |
| Hantavirus pulmonary syndrome | ~7–28 | Very high | 40–50 | Americas | Excess of male patients due to some occupational exposure; mainly adults |
| Marburg or Ebola HF | 3–16 | High | 25–90 | Sub-Saharan Africa | All ages, both sexes; children less exposed |
| Yellow fever | 3–6 | 1:2–1:20 | 20 | Africa, South America | All ages, both sexes; adults more exposed in jungle setting; preexisting flavivirus immunity may cross-protect |
| Dengue HF/ dengue shock syndrome | 2–7 | Nonimmune, 1:10,000; heterologous immune, 1:100 | <1 with supportive treatment | Tropics and subtropics worldwide | Predominantly children; previous heterologous dengue infection predisposes to HF |
| Kyasanur Forest/ Omsk HF | 3–8 | Variable | 0.5–10 | Mysore State, India/ western Siberia | Variable |

^aFigure is for HF cases only. Most infections with Rift Valley fever virus result in fever and myalgia rather than HF.

the relatively common secondary bacterial infections; replacement of clotting factors and platelets as indicated; and the usual precautionary measures used in the treatment of patients with hemorrhagic diatheses. DIC should be treated only if clear laboratory evidence of its existence is found and if laboratory monitoring of therapy is feasible; there is no proven benefit of such therapy. The available evidence suggests that HF patients have a decreased cardiac output and will respond poorly to fluid loading as it is often practiced in the treatment of shock associated with bacterial sepsis. Specific therapy is available for several of the HF syndromes. In addition, several diseases considered in the differential diagnosis—malaria, shigellosis, typhoid, leptospirosis, relapsing fever,

and rickettsial disease—are treatable and potentially lethal. Strict barrier nursing and other precautions against infection of medical staff and visitors are indicated in HF except that due to hantaviruses, yellow fever, Rift Valley fever, and dengue.

LASSA FEVER

Lassa virus is known to cause endemic and epidemic disease in Nigeria, Sierra Leone, Guinea, and Liberia, although it is probably more widely distributed in West Africa. This virus and its relatives exist elsewhere in Africa, but their health significance is unknown. Like other arenaviruses, Lassa virus is spread to humans by

small-particle aerosols from chronically infected rodents and may also be acquired during the capture or eating of these animals. It can be transmitted by close person-to-person contact. The virus is often present in urine during convalescence and is suspected to be present in seminal fluid early in recovery. Nosocomial spread has occurred but is uncommon if proper sterile parenteral techniques are used. Individuals of all ages and both sexes are affected; the incidence of disease is highest in the dry season, but transmission takes place year-round. In countries where Lassa virus is endemic, Lassa fever can be a prominent cause of febrile disease. For example, in one hospital in Sierra Leone, laboratory-confirmed Lassa fever is consistently responsible for one-fifth of admissions to the medical wards. There are probably tens of thousands of Lassa fever cases annually in West Africa alone.

Among the HF agents, only the arenaviruses are typically associated with a gradual onset of illness. The average case of Lassa fever has a gradual onset that gives way to more severe constitutional symptoms and prostration. Bleeding is seen in only ~15–30% of cases. A maculopapular rash is often noted in light-skinned Lassa patients. Effusions are common, and male-dominant pericarditis may develop late. The fetal death rate is 92% in the last trimester, when the maternal mortality rate is also increased from the usual 15–30%; these figures suggest that interruption of the pregnancy of infected women should be considered. White blood cell counts are normal or slightly elevated, and platelet counts are normal or somewhat low. Deafness coincides with clinical improvement in ~20% of cases and is permanent and bilateral in some. Reinfection may occur but has not been associated with severe disease.

High-level viremia or a high serum concentration of AST statistically predicts a fatal outcome. Thus patients with an AST level of >150 IU/mL should be treated with IV ribavirin. This antiviral nucleoside analogue appears to be effective in reducing mortality rates from the levels documented among retrospective controls, and its only major side effect is reversible anemia that usually does not require transfusion. The drug should be given by slow IV infusion in a dose of 32 mg/kg; this dose should be followed by 16 mg/kg every 6 h for 4 days and then by 8 mg/kg every 8 h for 6 days.

SOUTH AMERICAN HF SYNDROMES (ARGENTINE, BOLIVIAN, VENEZUELAN, AND BRAZILIAN)

These diseases are similar to one another clinically, but their epidemiology differs with the habits of their rodent reservoirs and the interactions of these animals with humans. Person-to-person or nosocomial transmission is rare but has occurred.

The basic disease resembles Lassa fever, with two marked differences. First, thrombocytopenia—often marked—is the rule, and bleeding is quite common. Second, CNS dysfunction is much more common than in Lassa fever and is often manifested by marked confusion, tremors of the upper extremities and tongue, and cerebellar signs. Some cases follow a predominantly

neurologic course, with a poor prognosis. The clinical laboratory is helpful in diagnosis since thrombocytopenia, leukopenia, and proteinuria are typical findings.

Argentine HF is readily treated with convalescent-phase plasma given within the first 8 days of illness. In the absence of passive antibody therapy, IV ribavirin in the dose recommended for Lassa fever is likely to be effective in all the South American HF syndromes. The transmission of the disease from men convalescing from Argentine HF to their wives suggests the need for counseling of arenavirus HF patients concerning the avoidance of intimate contacts for several weeks after recovery. A safe, effective, live attenuated vaccine exists for Argentine HF. In experimental animals, this vaccine is cross-protective against the Bolivian HF virus.

RIFT VALLEY FEVER

The mosquito-borne Rift Valley fever virus is also a pathogen of domestic animals such as sheep, cattle, and goats. It is maintained in nature by transovarial transmission in floodwater *Aedes* mosquitoes and presumably also has a vertebrate amplifier. Epizootics and epidemics occur when sheep or cattle become infected during particularly heavy rains; developing high-level viremia, these animals infect many species of mosquitoes. Remote sensing via satellite can detect the ecologic changes associated with high rainfall that predict the likelihood of Rift Valley fever transmission; it can also detect the special depressions from which the floodwater *Aedes* mosquito vectors emerge. In addition, the virus is infectious when transmitted by contact with blood or aerosols from domestic animals or their abortuses. The slaughtered meat is not infectious; anaerobic glycolysis in postmortem tissues results in an acidic environment that rapidly inactivates Bunyaviridae such as Rift Valley fever virus and Crimean-Congo HF virus. The natural range of Rift Valley fever virus is confined to sub-Saharan Africa, where its circulation is markedly enhanced by substantial rainfall such as that which occurred during the El Niño phenomenon of 1997; subsequent spread to the Arabian Peninsula caused epidemic disease in 2000. The virus has also been found in Madagascar and has been introduced into Egypt, where it caused major epidemics in 1977–1979, 1993, and subsequently. Neither person-to-person nor nosocomial transmission has been documented.

Rift Valley fever virus is unusual in that it causes several clinical syndromes. Most infections are manifested as the febrile-myalgic syndrome. A small proportion of infections result in HF with especially prominent liver involvement. Renal failure and DIC are also common features. Perhaps 10% of otherwise mild infections lead to retinal vasculitis; funduscopic examination reveals edema, hemorrhages, and infarction, and some patients have permanently impaired vision. A small proportion of cases (<1 in 200) are followed by typical viral encephalitis. One of the complicated syndromes does not appear to predispose to another.

There is no proven therapy for any of the syndromes described above. Both retinal disease and encephalitis occur after the acute febrile syndrome has ended and

serum neutralizing antibody has developed—events suggesting that only supportive care need be given. Epidemic disease is best prevented by vaccination of livestock. The established ability of this virus to propagate after an introduction into Egypt suggests that other potentially receptive areas, including the United States, should have a response ready for such an eventuality. It seems likely that this disease, like Venezuelan equine encephalitis, can be controlled only with adequate stocks of an effective live attenuated vaccine, and there are no such global stocks. A formalin-inactivated vaccine confers immunity to humans, but quantities are limited and three injections are required; this vaccine is recommended for exposed laboratory workers and for veterinarians working in sub-Saharan Africa.

CRIMEAN-CONGO HF

This severe HF syndrome has a wide geographic distribution, potentially being found wherever ticks of the genus *Hyalomma* occur. The propensity of these ticks to feed on domestic livestock and certain wild mammals means that veterinary serosurveys are the most effective mechanism for the surveillance of virus circulation in a region. Human infection is acquired via a tick bite or during the crushing of infected ticks. Domestic animals do not become ill but do develop viremia; thus there is danger of infection at the time of slaughter and for a brief interval thereafter (through contact with hides or carcasses). Cases have followed sheep shearing. An epidemic in South Africa was associated with slaughter of tick-infested ostriches. Nosocomial epidemics are common and are usually related to extensive blood exposure or needle sticks.

Although generally similar to other HF syndromes, Crimean-Congo HF causes extensive liver damage, resulting in jaundice in some cases. Clinical laboratory values indicate DIC and show elevations in AST, creatine phosphokinase, and bilirubin. Patients with fatal cases generally have more marked changes, even in the early days of illness, and also develop leukocytosis rather than leukopenia. In addition, thrombocytopenia is more marked and develops earlier in cases with a fatal outcome.

No controlled trials have been performed with IV ribavirin, but clinical experience and retrospective comparison of patients with ominous clinical laboratory values suggest that ribavirin is efficacious and should be given. No human or veterinary vaccines are recommended.

HF WITH RENAL SYNDROME

This disease, the first to be identified as an HF, is widely distributed over Europe and Asia; the major causative viruses and their rodent reservoirs on these two continents are Puumala virus (bank vole, *Clethrionomys glareolus*) and Hantaan virus (striped field mouse, *Apodemus agrarius*), respectively. Other potential causative viruses exist, including Dobrava virus (yellow-necked field mouse, *A. flavicollis*), which causes severe HF with renal syndrome in the Balkans. Seoul virus is associated with the Norway or sewer rat, *Rattus norvegicus*, and has a

worldwide distribution through the migration of the rodent; it is associated with mild or moderate HF with renal syndrome in Asia, but in many areas of the world the human disease has been difficult to identify. Most cases occur in rural residents or vacationers; the exception is Seoul virus disease, which may be acquired in an urban or rural setting or from contaminated laboratory rat colonies. Classic Hantaan disease in Korea (Korean HF) and in rural China (epidemic HF) is most common in spring and fall and is related to rodent density and agricultural practices. Human infection is acquired primarily through aerosols of rodent urine, although virus is also present in saliva and feces. Patients with hantavirus diseases are not infectious. HF with renal syndrome is the most important form of HF today, with >100,000 cases of severe disease in Asia annually and milder Puumala infections numbering in the thousands as well.

Severe cases of HF with renal syndrome caused by Hantaan virus evolve in identifiable stages: the febrile stage with myalgia, lasting 3 or 4 days; the hypotensive stage, often associated with shock and lasting from a few hours to 48 h; the oliguric stage with renal failure, lasting 3–10 days; and the polyuric stage with diuresis and hyposthenuria.

The *febrile stage* is initiated by the abrupt onset of fever, headache, severe myalgia, thirst, anorexia, and often nausea and vomiting. Photophobia, retroorbital pain, and pain on ocular movement are common, and the vision may become blurred with ciliary body inflammation. Flushing over the face, the V area of the neck, and the back is characteristic, as are pharyngeal injection, periorbital edema, and conjunctival suffusion. Petechiae often develop in areas of pressure, the conjunctivae, and the axillae. Back pain and tenderness to percussion at the costovertebral angle reflect massive retroperitoneal edema. Laboratory evidence of mild to moderate DIC is present. Other laboratory findings include proteinuria and an active urinary sediment.

The *hypotensive stage* is ushered in by falling blood pressure and sometimes by shock. The relative bradycardia typical of the febrile phase is replaced by tachycardia. Kinin activation is marked. The rising hematocrit reflects increasing vascular leakage. Leukocytosis with a left shift develops, and thrombocytopenia continues. Atypical lymphocytes—which in fact are activated CD8+ (and, to a lesser extent, CD4+) T cells—circulate. Proteinuria is marked, and the urine's specific gravity falls to 1.010. The renal circulation is congested and compromised from local and systemic circulatory changes resulting in necrosis of tubules, particularly at the corticomedullary junction, and oliguria.

During the *oliguric stage*, hemorrhagic tendencies continue, probably in large part because of uremic bleeding defects. The oliguria persists for 3–10 days before the return of renal function marks the onset of the *polyuric stage*, which carries the danger of dehydration and electrolyte abnormalities.

Mild cases of HF with renal syndrome may be much less stereotypical. The presentation may include only fever, gastrointestinal abnormalities, and transient oliguria followed by hyposthenuria.

HF with renal syndrome should be suspected in patients with rural exposure in an endemic area. Prompt recognition of the disease permits rapid hospitalization and expectant management of shock and renal failure. Useful clinical laboratory parameters include leukocytosis, which may be leukemoid and is associated with a left shift; thrombocytopenia; and proteinuria. Mainstays of therapy are the management of shock, reliance on pressors, modest crystalloid infusion, IV use of human serum albumin, and treatment of renal failure with prompt dialysis for the usual indications. Hydration may result in pulmonary edema, and hypertension should be avoided because of the possibility of intracranial hemorrhage. Use of IV ribavirin has reduced mortality and morbidity in severe cases provided treatment is begun within the first 4 days of illness. The case-fatality ratio may be as high as 15% but with proper therapy should be <5%. Sequelae have not been definitively established, but there is a correlation in the United States between chronic hypertensive renal failure and the presence of antibodies to Seoul virus.

Infections with Puumala virus, the most common cause of HF with renal syndrome in Europe, result in a much attenuated picture but the same general presentation. The syndrome may be referred to by its former name, *nephropathia epidemica*. Bleeding manifestations are found in only 10% of cases, hypotension rather than shock is usually seen, and oliguria is present in only about half of patients. The dominant features may be fever, abdominal pain, proteinuria, mild oliguria, and sometimes blurred vision or glaucoma followed by polyuria and hypostenuria in recovery. The mortality rate is <1%.

The diagnosis is readily made by IgM-capture ELISA, which should be positive at admission or within 24–48 h thereafter. The isolation of virus is difficult, but RT-PCR of a blood clot collected early in the clinical course or of tissues obtained postmortem will give positive results. Such testing is usually undertaken only if definitive identification of the infecting viral species is required or if molecular epidemiologic questions exist.

HANTAVIRUS PULMONARY SYNDROME

Hantavirus pulmonary syndrome was discovered in 1993, but retrospective identification of cases by immunohistochemistry (1978) and serology (1959) support the idea that it is a newly discovered disease rather than a truly new disease. The causative agents are hantaviruses of a distinct phylogenetic lineage that is associated with the rodent subfamily Sigmodontinae. Sin Nombre virus, which chronically infects the deer mouse (*Peromyscus maniculatus*), is the most important agent of hantavirus pulmonary syndrome in the United States. The disease is also caused by a Sin Nombre virus variant from the white-footed mouse (*P. leucopus*), by Black Creek Canal virus (*Sigmodon hispidus*, the cotton rat), and by Bayou virus (*Oryzomys palustris*, the rice rat). Several other related viruses cause the disease in South America, but Andes virus is unusual in that it, alone among hantaviruses, has been implicated in human-to-human transmission. The disease is linked to rodent exposure and particularly affects rural residents living in dwellings permeable to rodent entry or working at occupations

that pose a risk of rodent exposure. Each rodent species has its own particular habits; in the case of the deer mouse, these behaviors include living in and around human habitation.

The disease begins with a prodrome of ~3–4 days (range, 1–11 days) comprising fever, myalgia, malaise, and often gastrointestinal disturbances such as nausea, vomiting, and abdominal pain. Dizziness is common and vertigo occasional. Severe prodromal symptoms bring some individuals to medical attention, but patients are usually recognized as the cardiopulmonary phase begins. Typically, there is slightly lowered blood pressure, tachycardia, tachypnea, mild hypoxemia, and early radiographic signs of pulmonary edema. Physical findings in the chest are often surprisingly scant. The conjunctival and cutaneous signs of vascular involvement seen in other types of HF are absent. During the next few hours, decompensation may progress rapidly to severe hypoxemia and respiratory failure. Most patients surviving the first 48 h of hospitalization are extubated and discharged within a few days, with no apparent residua.

Management during the first few hours after presentation is critical. The goal is to prevent severe hypoxemia by oxygen therapy, with intubation and intensive respiratory management if needed. During this period, hypotension and shock with increasing hematocrit invite aggressive fluid administration, but this intervention should be undertaken with great caution. Because of low cardiac output with myocardial depression and increased pulmonary vascular permeability, shock should be managed expectantly with pressors and modest infusion of fluid guided by the pulmonary capillary wedge pressure. Mild cases can be managed by frequent monitoring and oxygen administration without intubation. Many patients require intubation to manage hypoxemia and also develop shock. Mortality rates remain at ~30–40% even with good management. The antiviral drug ribavirin inhibits the virus *in vitro* but did not have a marked effect on patients treated in an open-label study.

During the prodrome, the differential diagnosis of hantavirus pulmonary syndrome is difficult, but by the time of presentation or within 24 h thereafter, a number of diagnostically helpful clinical features become apparent. Cough is not usually present at the outset but may develop later. Interstitial edema is evident on the chest x-ray. Later, bilateral alveolar edema with a central distribution develops in the setting of a normal-sized heart; occasionally, the edema is initially unilateral. Pleural effusions are often seen. Thrombocytopenia, circulating atypical lymphocytes, and a left shift (often with leukocytosis) are almost always evident; thrombocytopenia is a particularly important early clue. Hemoconcentration, proteinuria, and hypoalbuminemia should also be sought. Although thrombocytopenia virtually always develops and prolongation of the partial thromboplastin time is the rule, clinical evidence for coagulopathy or laboratory indications of DIC are found in only a minority of cases, usually in severely ill patients. Patients with severe illness also have acidosis and elevated serum levels of lactate. Mildly increased values in renal function tests are common, but patients with severe cases often have markedly

elevated concentrations of serum creatinine; some of the viruses other than Sin Nombre virus have been associated with more kidney involvement, but few such cases have been studied. The differential diagnosis includes abdominal surgical conditions and pyelonephritis as well as rickettsial disease, sepsis, meningococcemia, plague, tularemia, influenza, and relapsing fever.

A specific diagnosis is best made by IgM testing of acute-phase serum, which has yielded positive results even in the prodrome. Tests using a Sin Nombre virus antigen detect the related hantaviruses causing the pulmonary syndrome in the Americas. Occasionally, heterologous viruses will react only in the IgG ELISA, but this finding is highly suspicious given the very low seroprevalence of these viruses in normal populations. RT-PCR is usually positive when used to test blood clots obtained in the first 7–9 days of illness as well as tissues; this test is useful in identifying the infecting virus in areas outside the home range of the deer mouse and in atypical cases.

YELLOW FEVER

Yellow fever virus caused major epidemics in the Americas, Africa, and Europe before the discovery of mosquito transmission in 1900 led to its control through attacks on its urban vector, *A. aegypti*. Only then was it found that a jungle cycle also existed in Africa, involving other *Aedes* mosquitoes and monkeys, and that colonization of the New World with *A. aegypti*, originally an African species, had established urban yellow fever as well as an independent sylvatic yellow fever cycle involving *Haemagogus* mosquitoes and New World monkeys in American jungles. Today, urban yellow fever transmission occurs only in some African cities, but the threat exists in the great cities of South America, where reinfestation by *A. aegypti* has taken place and dengue transmission by the same mosquito is common. As late as 1905, New Orleans suffered >3000 cases with 452 deaths from “yellow jack.” Despite the existence of a highly effective and safe vaccine, several hundred jungle yellow fever cases occur annually in South America, and thousands of jungle and urban cases occur each year in Africa.

Yellow fever is a typical HF accompanied by prominent hepatic necrosis. A period of viremia, typically lasting 3 or 4 days, is followed by a period of “intoxication.” During the latter phase in severe cases, the characteristic jaundice, hemorrhages, black vomit, anuria, and terminal delirium occur, perhaps related in part to extensive hepatic involvement. Blood leukocyte counts may be normal or reduced and are often high in terminal stages. Albuminuria is usually noted and may be marked; as renal function fails in terminal or severe cases, the level of blood urea nitrogen rises proportionately. Abnormalities detected in liver function tests range from modest elevations of AST levels in mild cases to severe derangement.

Urban yellow fever can be prevented by the control of *A. aegypti*. The continuing sylvatic cycle requires vaccination of all visitors to areas of potential transmission. With few exceptions, reactions to vaccine are minimal; immunity is provided within 10 days and lasts for at least 10 years. An egg allergy dictates caution in vaccine

administration. Although there are no documented harmful effects of the vaccine on the fetus, pregnant women should be immunized only if they are definitely at risk of yellow fever exposure. Since vaccination has been associated with several cases of encephalitis in children <6 months of age, it should be delayed until after 12 months of age unless the risk of exposure is very high. Rare, serious, multisystemic adverse reactions (occasionally fatal) have been reported, particularly affecting the elderly; nevertheless, the number of deaths of unvaccinated travelers with yellow fever exceeds the number of deaths from vaccination, and a liberal vaccination policy for travelers to involved areas should be pursued. Timely information on changes in yellow fever distribution and yellow fever vaccine requirements can be obtained from Health Information for Travelers, Centers for Disease Control and Prevention, Atlanta, GA 30333; by fax request (404-332-4565; document number 220022); by phone (404-332-4559); or via the Internet (www.cdc.gov).

DENGUE HEMORRHAGIC FEVER/DENGUE SHOCK SYNDROME

A syndrome of HF noted in the 1950s among children in the Philippines and Southeast Asia was soon associated with dengue virus infections, particularly those occurring against a background of previous exposure to another dengue-virus serotype. The transient heterotypic protection after dengue virus infection is replaced within several weeks by the potential for heterotypic infection resulting in typical dengue fever (see above) or—uncommonly—in enhanced disease (secondary DHF/DSS). In rare instances, primary dengue infections lead to an HF syndrome, but much less is known about pathogenesis in this situation. In the past 20 years, *A. aegypti* has progressively reinvaded Latin America and other areas, and frequent travel by infected individuals has introduced multiple strains of dengue virus from many geographic areas. Thus the pattern of hyperendemic transmission of multiple dengue serotypes has now been established in the Americas and the Caribbean and has led to the emergence of DHF/DSS as a major problem there as well. Millions of dengue infections, including many thousands of cases of DHF/DSS, occur annually. The severe syndrome is unlikely to be seen in U.S. citizens since few children have the dengue antibodies that can trigger the pathogenetic cascade when a second infection is acquired.

Macrophage/monocyte infection is central to the pathogenesis of dengue fever and to the origin of DHF/DSS. Previous infection with a heterologous dengue-virus serotype may result in the production of nonprotective antiviral antibodies that nevertheless bind to the virion's surface and through interaction with the Fc receptor focus secondary dengue viruses on the target cell, the result being enhanced infection. The host is also primed for a secondary antibody response when viral antigens are released and immune complexes lead to activation of the classic complement pathway, with consequent phlogistic effects. Cross-reactivity at the T-cell level results in the release of physiologically active cytokines, including interferon γ and tumor necrosis

factor α . The induction of vascular permeability and shock depends on multiple factors, including the following:

1. *Presence of enhancing and nonneutralizing antibodies*—Transplacental maternal antibody may be present in infants <9 months old, or antibody elicited by previous heterologous dengue infection may be present in older individuals. T-cell reactivity is also intimately involved.
2. *Age*—Susceptibility to DHF/DSS drops considerably after 12 years of age.
3. *Sex*—Females are more often affected than males.
4. *Race*—Caucasians are more often affected than blacks.
5. *Nutritional status*—Malnutrition is protective.
6. *Sequence of infection*—For example, serotype 1 followed by serotype 2 seems to be more dangerous than serotype 4 followed by serotype 2.
7. *Infecting serotype*—Type 2 is apparently more dangerous than other serotypes.

In addition, there is considerable variation among strains of a given serotype, with Southeast Asian serotype 2 strains having more potential to cause DHF/DSS than others.

Dengue HF is identified by the detection of bleeding tendencies (tourniquet test, petechiae) or overt bleeding in the absence of underlying causes such as preexisting gastrointestinal lesions. Dengue shock syndrome, usually accompanied by hemorrhagic signs, is much more serious and results from increased vascular permeability leading to shock. In mild DHF/DSS, restlessness, lethargy, thrombocytopenia ($<100,000/\mu\text{L}$), and hemoconcentration are detected 2–5 days after the onset of typical dengue fever, usually at the time of defervescence. The maculopapular rash that often develops in dengue fever may also appear in DHF/DSS. In more severe cases, frank shock is apparent, with low pulse pressure, cyanosis, hepatomegaly, pleural effusions, ascites, and in some cases severe ecchymoses and gastrointestinal bleeding. The period of shock lasts only 1 or 2 days, and most patients respond promptly to close monitoring, oxygen administration, and infusion of crystalloid or—in severe cases—colloid. The case-fatality rates reported vary greatly with case ascertainment and the quality of treatment; however, most DHF/DSS patients respond well to supportive therapy, and the overall mortality rate at an experienced center in the tropics is probably as low as 1%.

A virologic diagnosis can be made by the usual means, although multiple flavivirus infections lead to a broad immune response to several members of the group, and this situation may result in a lack of virus specificity of the IgM and IgG immune responses. A secondary antibody response can be sought with tests against several flavivirus antigens to demonstrate the characteristic wide spectrum of reactivity.

The key to control of both dengue fever and DHF/DSS is the control of *A. aegypti*, which also reduces the risk of urban yellow fever and chikungunya virus circulation. Control efforts have been handicapped by the presence of nondegradable tires and long-lived

plastic containers in trash repositories, insecticide resistance, urban poverty, and an inability of the public health community to mobilize the populace to respond to the need to eliminate mosquito breeding sites. Live attenuated dengue vaccines are in the late stages of development and have produced promising results in early tests. Whether vaccines can provide safe, durable immunity to an immunopathologic disease such as DHF/DSS in endemic areas is an issue that will have to be tested, but it is hoped that vaccination will reduce transmission to negligible levels.

KYASANUR FOREST DISEASE AND OMSK HEMORRHAGIC FEVER

Kyasanur Forest virus and Omsk HF virus are geographically restricted, tick-borne flaviviruses that cause a syndrome of viral HF during a wave of viremia and that may also enter the CNS to cause subsequent viral encephalitis (see discussion of tick-borne encephalitis earlier in the chapter). There is no therapy for these infections, but an inactivated vaccine has been used in India against Kyasanur Forest disease. A new and related virus isolate has been obtained from butchers with HF in the Middle East; the implication is that there are more agents in this group.

CHAPTER 100

EBOLA AND MARBURG VIRUSES

Clarence J. Peters

DEFINITION

Both Marburg virus and Ebola virus cause an acute febrile illness associated with high mortality. This illness is characterized by multisystem involvement that begins with the abrupt onset of headache, myalgias, and fever and proceeds to prostration, rash, and shock and often to bleeding manifestations. Epidemics usually begin with a single case acquired from an unknown reservoir in nature and spread mainly through close contact with sick persons or their body fluids, either at home or in the hospital.

ETIOLOGY

The family Filoviridae (**Fig. 100-1**) comprises two antigenically and genetically distinct genera: *Marburgvirus* and *Ebolavirus*. *Ebolavirus* has four readily distinguishable species named for their original sites of recognition: Zaire, Sudan, Côte d'Ivoire, and Reston. Except for the Reston virus, all the Filoviridae are African viruses that cause severe and often fatal disease in humans. The Reston virus, which has been exported from the Philippines on several occasions, has caused fatal infections in monkeys but only subclinical infections in humans. Different strains of the four Ebola species, isolated over time and space, exhibit remarkable

sequence conservation, indicating marked genetic stability in their selective niche.

Typical filovirus particles contain a single linear, negative-sense, single-stranded RNA arranged in a helical nucleocapsid. The virions are 790–970 nm in length; they may also appear in elongated, contorted forms. The lipid envelope confers sensitivity to lipid solvents and common detergents. The viruses are largely destroyed by heat (60°C, 30 min) and by acidity but may persist for weeks in blood at room temperature. The surface glycoprotein self-associates to form the virion surface spikes, which presumably mediate attachment to cells and fusion. The glycoprotein's high sugar content may contribute to its low capacity to elicit neutralizing antibodies. A smaller form of the glycoprotein, bearing many of its antigenic determinants, is produced by in vitro–infected cells and is found in the circulation in human disease; it has been speculated that this circulating soluble protein may suppress the immune response to the virion surface protein or block antiviral effector mechanisms. Both Marburg virus and Ebola virus are biosafety level 4 pathogens because of their high associated mortality rate and aerosol infectivity.

EPIDEMIOLOGY

Marburg virus was first identified in Germany in 1967, when infected African green monkeys (*Cercopithecus aethiops*) imported from Uganda transmitted the agent to workers in a vaccine laboratory. Of the 25 human cases acquired from monkeys, seven ended in death. The six secondary cases were associated with close contact or parenteral exposure. Secondary spread to the wife of one patient was documented, and virus was isolated from the husband's semen despite the presence of circulating antibodies. Subsequently, isolated cases of Marburg virus infection have been reported from eastern and southern Africa, with limited spread.

In 1999, repeated transmission of Marburg virus to workers in a gold mine in eastern Democratic Republic of the Congo was documented. The secondary spread of the virus among patients' families was more extensive than previously noted, resembling that of Ebola virus and emphasizing the importance of hygiene and proper barrier nursing in the epidemiology of these viruses in Africa.

In 2004–2005, an alarming, massive Marburg virus epidemic, with >250 cases, occurred in Angola. The epidemiologic features resembled those of the Ebola virus epidemics described below, and the case-fatality

FIGURE 100-1

Ebola virions: diagnostic specimen from the first passage in Vero cells of a blood sample from a patient. Some of the filamentous (negatively stained) virions were fused together, end-to-end, giving the appearance of a “bowl of spaghetti.” This image was from the first isolation and visualization of Ebola virus in 1970. (Courtesy of Fredrick A. Murphy, MD, University of Texas Medical Branch, Galveston, Texas; with permission.)

rate was 90%. This high figure may have been due in part to poor conditions in African hospitals; however, the virus isolated in this epidemic was slightly different phylogenetically from other known strains and exhibited increased virulence in nonhuman primates.

In 1976, epidemics of severe hemorrhagic fever (550 human cases) occurred simultaneously in Zaire and Sudan, and Ebola virus was found to be the etiologic agent. Later, it was shown that different species of virus (with associated mortality rates of 90% and 50%, respectively) had caused the two epidemics. Both epidemics were associated with interhuman spread (particularly in the hospital setting) and the use of unsterilized needles and syringes—a common practice in developing-country hospitals. The epidemics dwindled as the clinics were closed and as people in the endemic area increasingly shunned affected persons and avoided traditional burial practices.

The Zaire Ebola virus recurred in a major epidemic (317 cases, 88% mortality rate) in the Democratic Republic of the Congo in 1995 and in smaller epidemics in Gabon in 1994–1996. Mortality rates were high, transmission to caregivers and others who had direct contact with body fluids was common, and poor hygiene in hospitals exacerbated spread. In the Congo epidemic, an index case was infected in Kikwit in January 1995. The epidemic smoldered until April, when intense nosocomial transmission forced closure of the hospitals; samples were finally sent to the laboratory for Ebola testing, which yielded positive results within a few hours. International assistance, with barrier nursing instruction and materials, was provided; nosocomial transmission ceased, hospitals reopened, and patients were segregated to prevent intrafamilial spread. The last case was reported in June 1995.

Separate emergences of Ebola virus (Zaire) were detected in Gabon in 1994–2003, usually in association with deep-forest exposure and subsequent familial and nosocomial transmission. Die-offs of nonhuman primates were sometimes documented, and Ebola infection was confirmed in at least some animals. In a 1996 episode, a physician exposed to Ebola-infected patients traveled to South Africa with a fever; a nurse who assisted in a cutdown on the physician developed Ebola hemorrhagic fever and died despite intensive care. The index patient was identified retrospectively on the basis of serum antibodies and virus isolation from semen. No additional cases were detected from care of the primary or secondary case, nor were there any secondary cases following care of an unsuspected Côte d'Ivoire Ebola case in Switzerland. Thus, distant transport of Ebola virus is an established risk, but limited nosocomial spread occurs under proper hygienic conditions.

In 2000–2001, an indolent outbreak of Sudan Ebola virus claimed the lives of 224 (53%) of 425 patients with presumptive cases in Uganda.

Reston Ebola virus was first seen in the United States in 1989, when it caused a fatal, highly transmissible disease among cynomolgus macaques imported from the Philippines and quarantined in Reston, Virginia, pending distribution to biomedical researchers. This and other appearances of the Reston virus have been traced to a single export facility in the Philippines, but no source in nature has been established.

Epidemiologic studies (including a specific search in the Kikwit epidemic) have failed to yield evidence for an important role of airborne particles in human disease. This lack of epidemiologic evidence is surprising and seems to conflict with the viruses' classification as biosafety level 4 pathogens (which is based in part on their aerosol infectivity) and with formal laboratory assessments showing a high degree of aerosol infectivity for monkeys. Sick humans apparently do not usually generate sufficient amounts of infectious aerosols to pose a significant hazard to those around them.

Although numerous die-offs have recently been reported among chimpanzees and gorillas (some even threatening the viability of these endangered species), these animals (like humans) appear to be sentinels for virus activity. Speculation about the true reservoirs has centered on bats, and preliminary evidence indicates that bats may indeed be the reservoirs of filoviruses. This evidence includes the detection of antibodies and reverse-transcriptase polymerase chain reaction (RT-PCR) products in bats, the epidemiologic findings in subterranean gold mines in Durba (Democratic Republic of the Congo) where Marburg transmission has occurred, and reported associations of human antibody production with the handling of bats.

PATHOLOGY AND PATHOGENESIS

In humans and in animal models, Ebola and Marburg viruses replicate well in virtually all cell types, including endothelial cells, macrophages, and parenchymal cells of multiple organs. The earliest involvement—that of the mononuclear phagocyte system—is responsible for initiation of the disease process. Viral replication is associated with cellular necrosis both *in vivo* and *in vitro*. Significant findings at the light-microscopic level include liver necrosis with Councilman bodies, intracellular inclusions that correlate with extensive collections of viral nucleocapsids, interstitial pneumonitis, cerebral glial nodules, and small infarcts. Antigen and virions are abundant in fibroblasts, interstitium, and (to a lesser extent) the appendages of the subcutaneous tissues in fatal cases; escape through small breaks in the skin or possibly through sweat glands may occur and, if so, may be correlated with the established epidemiologic risk of close contact with patients and the touching of the deceased. Inflammatory cells are not prominent, even in necrotic areas.

In addition to sustaining direct damage from viral infection, patients infected with Ebola virus (Zaire) have high circulating levels of proinflammatory cytokines, which presumably contribute to the severity of the illness. In fact, the virus interacts intimately with the cellular cytokine system. It is resistant to the antiviral effects of interferon α , although this mediator is amply induced. Viral infection of endothelial cells selectively inhibits the expression of major histocompatibility complex class I molecules and blocks the induction of several genes by the interferons. In addition, glycoprotein expression inhibits αV integrin expression, an effect that has been shown to lead to detachment and subsequent death of endothelial cells *in vitro*.

Acute infection is associated with high levels of circulating virus and viral antigen. Clinical improvement takes place when viral titers decrease concomitantly with the

onset of a virus-specific immune response, as detected by enzyme-linked immunosorbent assay (ELISA) or fluorescent antibody testing. In fatal cases, there is usually little evidence of an antibody response, and there is extensive depletion of spleen and lymph nodes. Recovery is apparently mediated by the cellular immune response: convalescent-phase plasma has little in vitro virus-neutralizing capacity and is not protective in passive transfer experiments in monkey and guinea pig models.

CLINICAL MANIFESTATIONS

After an incubation period of ~7–10 days (range, 3–16 days), the patient abruptly develops fever, severe headache, malaise, myalgia, nausea, and vomiting. Continued fever is joined by diarrhea (often severe), chest pain (accompanied by cough), prostration, and depressed mentation. In light-skinned patients (and less often in dark-skinned individuals), a maculopapular rash appears around day 5–7 and is followed by desquamation. Bleeding may begin about this time and is apparent from any mucosal site and into the skin. In some epidemics, fewer than half of patients have had overt bleeding, and this manifestation has been absent even in some fatal cases. Additional findings include edema of the face, neck, and/or scrotum; hepatomegaly; flushing; conjunctival injection; and pharyngitis. Around 10–12 days after the onset of disease, the sustained fever may break, with improvement and eventual recovery of the patient. Recrudescence of fever may be associated with secondary bacterial infections or possibly with localized virus persistence. Late hepatitis, uveitis, and orchitis have been reported, with isolation of virus from semen or detection of PCR products in vaginal secretions for several weeks.

LABORATORY FINDINGS

Leukopenia is common early on; neutrophilia has its onset later. Platelet counts fall below (sometimes much below) 50,000/ μ L. Laboratory evidence of disseminated intravascular coagulation is found, but its clinical significance and the need for therapy are controversial. Serum levels of alanine and aspartate aminotransferases (particularly the latter) rise progressively, and jaundice develops in some cases. The serum amylase level may be elevated, and this elevation may be associated with abdominal pain, suggesting pancreatitis. Proteinuria is usual; decreased kidney function is proportional to shock.

DIAGNOSIS

Most patients acutely ill as a result of infection with Ebola or Marburg virus have high concentrations of virus in blood. Antigen-detection ELISA is a sensitive, robust diagnostic modality. Virus isolation and RT-PCR are also effective and provide additional sensitivity in some cases. Patients who are recovering develop IgM and IgG antibodies that are best detected by ELISA but are also reactive in the less specific fluorescent antibody test. Skin biopsies are an extremely useful adjunct in postmortem diagnosis of infection with Ebola virus (and, to a lesser extent, Marburg virus) because of the presence of large amounts of viral antigen, the relatively

low risk posed by sample collection, and the lack of cold-chain requirements for formalin-fixed tissues.

Rx Treatment: EBOLA AND MARBURG VIRUS INFECTIONS

No virus-specific therapy is available, and—given the extensive viral involvement in fatal cases—supportive treatment may not be as useful as was once hoped. However, recent studies in rhesus monkeys have shown improved survival among animals treated with an inhibitor of factor VIIa/tissue factor or with activated protein C. Vigorous treatment of shock should take into account the likelihood of vascular leak in the pulmonary and systemic circulation and of myocardial functional compromise. The membrane fusion mechanism of Ebola virus resembles that of retroviruses, and the identification of “fusogenic” sequences suggests that inhibitors of cell entry may be developed. Despite the poor neutralizing capacity of polyclonal convalescent-phase sera, phage display of immunoglobulin mRNA from convalescent-phase bone marrow has yielded monoclonal antibodies that have in vitro neutralizing capacity and mediate protection in guinea pig models (but, unfortunately, not in monkey models).

PREVENTION

No vaccine or antiviral drug is currently available, but barrier nursing precautions in African hospitals can greatly decrease the spread of the virus beyond the index case and thus prevent epidemics of infection with filoviruses and with other agents as well. An adenovirus-vectored Ebola glycoprotein gene has proved protective in nonhuman primates and is undergoing phase 1 trials in humans.

SECTION VI

PRION DISEASES

CHAPTER 101

PRION DISEASES

Stanley B. Prusiner ■ Bruce L. Miller

Prions are infectious proteins that cause degeneration of the central nervous system (CNS). Prion diseases are disorders of protein conformation, the most common of which in humans is called Creutzfeldt-Jakob disease (CJD). CJD typically presents with dementia and myoclonus, is relentlessly progressive, and generally causes death within a year of onset. Most CJD patients are between 50 and 75 years of age; however, patients as young as 17 and as old as 83 have been recorded.

In mammals, prions reproduce by binding to the normal, cellular isoform of the prion protein (PrP^{C}) and stimulating conversion of PrP^{C} into the disease-causing isoform (PrP^{Sc}). PrP^{C} is rich in α -helix and has little β -structure, while PrP^{Sc} has less α -helix and a high amount of β -structure (Fig. 101-1). This α -to- β structural transition in the prion protein (PrP) is the fundamental event underlying prion diseases (Table 101-1).

FIGURE 101-1

Structures of prion proteins. **A.** NMR structure of Syrian hamster recombinant (rec) PrP(90–231). Presumably, the structure of the α -helical form of recPrP(90–231) resembles that of PrP^{C} . recPrP(90–231) is viewed from the interface where PrP^{Sc} is thought to bind to PrP^{C} . Shown are: α -helices A (residues 144–157), B (172–193), and C (200–227). Flat ribbons depict β -strands S1 (129–131) and S2 (161–163). (**A**, from SB Prusiner: *N Engl J Med* 344:1516, 2006; with permission.) **B.** Structural model of PrP^{Sc} . The 90–160 region has been modeled onto a β -helical architecture while the COOH terminal helices B and C are preserved as in PrP^{C} . (Image prepared by C. Govaerts.)

Four new concepts have emerged from studies of prions: (1) Prions are the only known infectious pathogens that are devoid of nucleic acid; all other infectious agents possess genomes composed of either RNA or DNA that direct the synthesis of their progeny. (2) Prion diseases may be manifest as infectious, genetic, and sporadic disorders; no other group of illnesses with a single etiology presents with such a wide spectrum of clinical manifestations. (3) Prion diseases result from the accumulation of PrP^{Sc} , the conformation of which differs substantially from that of its precursor, PrP^{C} . (4) PrP^{Sc} can exist in a variety of different conformations, each of which seems to specify a particular disease phenotype. How a specific conformation of a PrP^{Sc} molecule is imparted to PrP^{C} during prion replication to produce nascent PrP^{Sc} with

TABLE 101-1

GLOSSARY OF PRION TERMINOLOGY

| | |
|--------------------------|--|
| Prion | Proteinaceous infectious particle that lacks nucleic acid. Prions are composed largely, if not entirely, of PrP^{Sc} molecules. They can cause scrapie in sheep and goats, and related neurodegenerative diseases of humans such as Creutzfeldt-Jakob disease (CJD). |
| PrP^{Sc} | Disease-causing isoform of the prion protein. This protein is the only identifiable macromolecule in purified preparations of scrapie prions. |
| PrP^{C} | Cellular isoform of the prion protein. PrP^{C} is the precursor of PrP^{Sc} . |
| PrP 27-30 | A fragment of PrP^{Sc} , generated by truncation of the NH_2 -terminus by limited digestion with proteinase K. PrP 27-30 retains prion infectivity and polymerizes into amyloid. |
| PRNP | PrP gene located on human chromosome 20. |
| Prion rod | An aggregate of prions composed largely of PrP 27-30 molecules. Created by detergent extraction and limited proteolysis of PrP^{Sc} . Morphologically and histochemically indistinguishable from many amyloids. |
| PrP amyloid | Amyloid containing PrP in the brains of animals or humans with prion disease; often accumulates as plaques. |

TABLE 101-2

THE PRION DISEASES

| DISEASE | HOST | MECHANISM OF PATHOGENESIS |
|--------------------------------|------------------------------|---|
| Human | | |
| Kuru | Fore people | Infection through ritualistic cannibalism |
| iCJD | Humans | Infection from prion-contaminated hGH, dura mater grafts, etc. |
| vCJD | Humans | Infection from bovine prions |
| fCJD | Humans | Germ-line mutations in <i>PRNP</i> |
| GSS | Humans | Germ-line mutations in <i>PRNP</i> |
| FFI | Humans | Germ-line mutation in <i>PRNP</i> (D178N, M129) |
| sCJD | Humans | Somatic mutation or spontaneous conversion of PrP ^C into PrP ^{Sc} ? |
| sFI | Humans | Somatic mutation or spontaneous conversion of PrP ^C into PrP ^{Sc} ? |
| Animal | | |
| Scrapie | Sheep, goats | Infection in genetically susceptible sheep |
| BSE | Cattle | Infection with prion-contaminated MBM |
| TME | Mink | Infection with prions from sheep or cattle |
| CWD | Mule deer, elk | Unknown |
| FSE | Cats | Infection with prion-contaminated beef |
| Exotic ungulate encephalopathy | Greater kudu, nyala, or oryx | Infection with prion-contaminated MBM |

Note: BSE, bovine spongiform encephalopathy; CJD, Creutzfeldt-Jakob disease; fCJD, familial Creutzfeldt-Jakob disease; iCJD, iatrogenic Creutzfeldt-Jakob disease; sCJD, sporadic Creutzfeldt-Jakob disease; vCJD, variant Creutzfeldt-Jakob disease; CWD, chronic wasting disease; FFI, fatal familial insomnia; sFI, sporadic fatal insomnia; FSE, feline spongiform encephalopathy; GSS, Gerstmann-Sträussler-Scheinker disease; hGH, human growth hormone; MBM, meat and bone meal; TME, transmissible mink encephalopathy.

the same conformation is unknown. Additionally, it is unclear what factors determine where in the CNS a particular PrP^{Sc} molecule will be deposited.

SPECTRUM OF PRION DISEASES

The sporadic form of CJD is the most common prion disorder in humans. Sporadic CJD (sCJD) accounts for ~85% of all cases of human prion disease, while inherited prion diseases account for 10–15% of all cases (Table 101-2). Familial CJD (fCJD), Gerstmann-Sträussler-Scheinker (GSS) disease, and fatal familial insomnia (FFI) are all dominantly inherited prion diseases that are caused by mutations in the PrP gene.

Although infectious prion diseases account for <1% of all cases and infection does not seem to play an important role in the natural history of these illnesses, the transmissibility of prions is an important biologic feature. *Kuru* of the Fore people of New Guinea is thought to have resulted from the consumption of brains from dead relatives during ritualistic cannibalism. With the cessation of ritualistic cannibalism in the late 1950s, *kuru* has nearly disappeared, with the exception of a few recent patients exhibiting incubation periods of >40 years. Iatrogenic CJD (iCJD) seems to be the result of the accidental inoculation of patients with prions. Variant CJD (vCJD) in teenagers and young adults in Europe is the result of exposure to tainted beef from cattle with bovine spongiform encephalopathy (BSE).

Six diseases of animals are caused by prions (Table 101-2). Scrapie of sheep and goats is the prototypic prion disease. Mink encephalopathy, BSE, feline spongiform

encephalopathy, and exotic ungulate encephalopathy are all thought to occur after the consumption of prion-infected foodstuffs. The BSE epidemic emerged in Britain in the late 1980s and was shown to be due to industrial cannibalism. Whether BSE began as a sporadic case of BSE in a cow or started with scrapie in sheep is unknown. The origin of chronic wasting disease (CWD), a prion disease endemic in deer and elk in regions of North America, is uncertain.

EPIDEMIOLOGY

CJD is found throughout the world. The incidence of sCJD is approximately one case per million population, and thus it accounts for about one in every 10,000 deaths. Because sCJD is an age-dependent neurodegenerative disease, its incidence is expected to increase steadily as older segments of populations in developed and developing countries continue to expand. Although many geographic clusters of CJD have been reported, each has been shown to segregate with a PrP gene mutation. Attempts to identify common exposure to some etiologic agent have been unsuccessful for both the sporadic and familial cases. Ingestion of scrapie-infected sheep or goat meat as a cause of CJD in humans has not been demonstrated by epidemiologic studies, although speculation about this potential route of inoculation continues. Of particular interest are deer hunters who develop CJD, because up to 90% of culled deer in some game herds have been shown to harbor CWD prions. Whether prion disease in deer or elk can be passed to cows, sheep, or directly to humans remains unknown. Studies with Syrian hamsters demonstrate

PATHOGENESIS

The human prion diseases were initially classified as neurodegenerative disorders of unknown etiology on the basis of pathologic changes being confined to the CNS. With the transmission of kuru and CJD to apes, investigators began to view these diseases as infectious CNS illnesses caused by slow viruses. Even though the familial nature of a subset of CJD cases was well described, the significance of this observation became more obscure with the transmission of CJD to animals. Eventually the meaning of heritable CJD became clear with the discovery of mutations in the PRNP gene of these patients. The prion concept explains how a disease can manifest as a heritable as well as an infectious illness. Moreover, the hallmark of all prion diseases, whether sporadic, dominantly inherited, or acquired by infection, is that they involve the aberrant metabolism of PrP.

A major feature that distinguishes prions from viruses is the finding that both PrP isoforms are encoded by a chromosomal gene. In humans, the PrP gene is designated *PRNP* and is located on the short arm of chromosome 20. Limited proteolysis of PrP^{Sc} produces a smaller, protease-resistant molecule of ~142 amino acids designated PrP 27–30; PrP^C is completely hydrolyzed under the same conditions (Fig. 101-2). In the presence of detergent, PrP 27–30 polymerizes into amyloid. Prion rods formed by limited proteolysis and detergent extraction are indistinguishable from the filaments that aggregate to form PrP amyloid plaques in the CNS. Both the rods and the PrP amyloid filaments found in brain tissue exhibit similar ultrastructural morphology and green-gold birefringence after staining with Congo red dye.

Prion Strains

The existence of prion strains raised the question of how heritable biologic information can be enciphered in a molecule other than nucleic acid. Various strains of prions have been defined by incubation times and the distribution of neuronal vacuolation. Subsequently, the

FIGURE 101-2
Prion protein isoforms. Bar diagram of Syrian hamster PrP, which consists of 254 amino acids. After processing of the NH₂ and COOH termini, both PrP^C and PrP^{Sc} consist of 209 residues. After limited proteolysis, the NH₂ terminus of PrP^{Sc} is truncated to form PrP 27–30 composed of ~142 amino acids.

patterns of PrP^{Sc} deposition were found to correlate with vacuolation profiles, and these patterns were also used to characterize prion strains.

Persuasive evidence that strain-specific information is enciphered in the tertiary structure of PrP^{Sc} comes from transmission of two different inherited human prion diseases to mice expressing a chimeric human-mouse PrP transgene. In FFI, the protease-resistant fragment of PrP^{Sc} after deglycosylation has a molecular mass of 19 kDa, whereas in fCJD and most sporadic prion diseases, it is 21 kDa (Table 101-3). This difference in molecular mass was shown to be due to different sites of proteolytic cleavage at the NH₂ termini of the two human PrP^{Sc} molecules, reflecting different tertiary structures. These distinct conformations were not unexpected because the amino acid sequences of the PrPs differ.

Extracts from the brains of patients with FFI transmitted disease into mice expressing a chimeric human-mouse PrP transgene and induced formation of the 19-kDa PrP^{Sc}, whereas brain extracts from fCJD and sCJD patients produced the 21-kDa PrP^{Sc} in mice expressing the same transgene. On second passage, these differences were maintained, demonstrating that chimeric PrP^{Sc} can

^aTg(MHu2M) mice express a chimeric mouse-human PrP gene.
Note: Clinicopathologic phenotype is determined by the conformation of PrP^{Sc} in accord with the results of the transmission of human prions from patients with FFI to transgenic mice. FFI, fatal familial insomnia; fCJD, familial Creutzfeldt-Jakob disease.

exist in two different conformations based on the sizes of the protease-resistant fragments, even though the amino acid sequence of PrP^{Sc} is invariant.

This analysis was extended when patients with sporadic fatal insomnia (sFI) were identified. Although they did not carry a *PRNP* gene mutation, the patients demonstrated a clinical and pathologic phenotype that was indistinguishable from that of patients with FFI. Furthermore, 19-kDa PrP^{Sc} was found in their brains, and on passage of prion disease to mice expressing a chimeric human-mouse PrP transgene, 19-kDa PrP^{Sc} was also found. These findings indicate that the disease phenotype is dictated by the conformation of PrP^{Sc} and not the amino acid sequence. PrP^{Sc} acts as a template for the conversion of PrP^C into nascent PrP^{Sc}. On the passage of prions into mice expressing a chimeric hamster-mouse PrP transgene, a change in the conformation of PrP^{Sc} was accompanied by the emergence of a new strain of prions.

New strains of prions were also generated from recombinant (rec) PrP produced in bacteria. In these studies, recPrP was polymerized into amyloid fibrils and inoculated into transgenic mice expressing very high levels of truncated mouse PrP^C; about 500 days later, the mice died of prion disease. These “synthetic prions” were found to be much more stable than any prions previously isolated from animals or humans with naturally occurring prion diseases. Surprisingly, studies of synthetic and naturally occurring prions indicate that the incubation time is directly proportional to the stability of the prion. As the stability increases, the incubation time lengthens; thus, less-stable prions replicate more rapidly. These studies also showed that PrP^{Sc} can adopt a continuum of conformational states, each of which enciphers a distinct incubation-time phenotype.

Species Barrier

Studies on the role of the primary and tertiary structures of PrP in the transmission of prion disease have given new insights into the pathogenesis of these maladies. The amino acid sequence of PrP encodes the species of the prion, and the prion derives its PrP^{Sc} sequence from the last mammal in which it was passaged. While the primary structure of PrP is likely to be the most important or even sole determinant of the tertiary structure of PrP^C, PrP^{Sc} seems to function as a template in determining the tertiary structure of nascent PrP^{Sc} molecules as they are formed from PrP^C. In turn, prion diversity appears to be enciphered in the conformation of PrP^{Sc}, and thus prion strains seem to represent different conformers of PrP^{Sc}.

In general, transmission of prion disease from one species to another is inefficient, in that not all intracerebrally inoculated animals develop disease, and those that fall ill do so only after long incubation times that can approach the natural life span of the animal. This “species barrier” to transmission is correlated with the degree of similarity between the amino acid sequences of PrP^C in the inoculated host and of PrP^{Sc} in the prion inoculum. The importance of sequence similarity between the host

and donor PrP argues that PrP^C directly interacts with PrP^{Sc} in the prion conversion process.

SPORADIC AND INHERITED PRION DISEASES

Several different scenarios might explain the initiation of sporadic prion disease: (1) A somatic mutation may be the cause and thus follow a path similar to that for germline mutations in inherited disease. In this situation, the mutant PrP^{Sc} must be capable of targeting wild-type PrP^C, a process known to be possible for some mutations but less likely for others. (2) The activation barrier separating wild-type PrP^C from PrP^{Sc} could be crossed on rare occasions when viewed in the context of a population. Most individuals would be spared while presentations in the elderly with an incidence of ~1 per million would be seen. (3) PrP^{Sc} may be present at very low levels in some normal cells, where it performs some important, as yet unknown, function. The level of PrP^{Sc} in such cells is hypothesized to be sufficiently low as to be not detected by bioassay. In some altered metabolic states, the cellular mechanisms for clearing PrP^{Sc} might become compromised and the rate of PrP^{Sc} formation would then begin to exceed the capacity of the cell to clear it. The third possible mechanism is attractive since it suggests PrP^{Sc} is not simply a misfolded protein, as proposed for the first and second mechanisms, but that it is an alternatively folded molecule with a function. Moreover, the multitude of conformational states that PrP^{Sc} can adopt, as described above, raises the possibility that PrP^{Sc} or another prion-like protein might function in a process like short-term memory where information storage occurs in the absence of new protein synthesis.

More than 30 different mutations resulting in non-conservative substitutions in the human *PRNP* gene have been found to segregate with inherited human prion diseases. Missense mutations and expansions in the octapeptide repeat region of the gene are responsible for familial forms of prion disease. Five different mutations of the *PRNP* gene have been linked genetically to heritable prion disease.

Although phenotypes may vary dramatically within families, specific phenotypes tend to be observed with certain mutations. A clinical phenotype indistinguishable from typical sCJD is usually seen with substitutions at codons 180, 183, 200, 208, 210, and 232. Substitutions at codons 102, 105, 117, 198, and 217 are associated with the GSS variant of prion disease. The normal human PrP sequence contains five repeats of an eight-amino-acid sequence. Insertions from two to nine extra octapeptides frequently cause variable phenotypes ranging from a condition indistinguishable from sCJD to a slowly progressive dementing illness of many years' duration to an early-age-of-onset disorder that is similar to Alzheimer's disease. A mutation at codon 178 resulting in substitution of asparagine for aspartic acid produces FFI if a methionine is encoded at the polymorphic 129 residue on the same allele. Typical CJD is seen if a valine is encoded at position 129 of the same allele.

HUMAN PRNP GENE POLYMORPHISMS

Polymorphisms influence the susceptibility to sporadic, inherited, and infectious forms of prion disease. The methionine/valine polymorphism at position 129 not only modulates the age of onset of some inherited prion diseases but can also determine the clinical phenotype. The finding that homozygosity at codon 129 predisposes to sCJD supports a model of prion production that favors PrP interactions between homologous proteins.

Substitution of the basic residue lysine at position 218 in mouse PrP produced dominant-negative inhibition of prion replication in transgenic mice. This same lysine at position 219 in human PrP has been found in 12% of the Japanese population, and this group appears to be resistant to prion disease. Dominant-negative inhibition of prion replication was also found with substitution of the basic residue arginine at position 171; sheep with arginine are resistant to scrapie prions but are susceptible to BSE prions that were inoculated intracerebrally.

INFECTIOUS PRION DISEASES

IATROGENIC CJD

Accidental transmission of CJD to humans appears to have occurred with corneal transplantation, contaminated electroencephalogram (EEG) electrode implantation, and surgical procedures. Corneas from donors with inapparent CJD have been transplanted to apparently healthy recipients who developed CJD after prolonged incubation periods. The same improperly decontaminated EEG electrodes that caused CJD in two young patients with intractable epilepsy caused CJD in a chimpanzee 18 months after their experimental implantation.

Surgical procedures may have resulted in accidental inoculation of patients with prions, presumably because some instrument or apparatus in the operating theater became contaminated when a CJD patient underwent surgery. Although the epidemiology of these studies is highly suggestive, no proof for such episodes exists.

Dura Mater Grafts

More than 160 cases of CJD after implantation of dura mater grafts have been recorded. All of the grafts were thought to have been acquired from a single manufacturer whose preparative procedures were inadequate to inactivate human prions. One case of CJD occurred after repair of an eardrum perforation with a pericardium graft.

Human Growth Hormone and Pituitary Gonadotropin Therapy

The possibility of transmission of CJD from contaminated human growth hormone (hGH) preparations derived from human pituitaries has been raised by the occurrence of fatal cerebellar disorders with dementia in >180 patients ranging in age from 10 to 41 years. These patients received injections of hGH every 2–4 days for 4–12 years. If it is assumed that these patients developed CJD from injections of prion-contaminated hGH preparations, the possible incubation periods range from

4 to 30 years. Even though several investigations argue for the efficacy of inactivating prions in hGH fractions prepared from human pituitaries with 6 M urea, it seems doubtful that such protocols will be used for purifying hGH because recombinant hGH is available. Four cases of CJD have occurred in women receiving human pituitary gonadotropin.

VARIANT CJD

The restricted geographic occurrence and chronology of vCJD raised the possibility that BSE prions have been transmitted to humans through the consumption of tainted beef. More than 190 cases of vCJD have occurred, with >90% of these in Britain. vCJD has also been reported in people either living in or originating from France, Ireland, Italy, the Netherlands, Portugal, Spain, Saudi Arabia, United States, Canada, and Japan.

Because the number of vCJD cases is still small, it is not possible to decide if we are at the beginning of a prion disease epidemic in Europe, similar to those seen for BSE and kuru, or if the number of vCJD cases will remain small. What is certain is that prion-tainted meat should be prevented from entering the human food supply.

The most compelling evidence that vCJD is caused by BSE prions was obtained from experiments in mice expressing the bovine PrP transgene. Both BSE and vCJD prions were efficiently transmitted to these transgenic mice and with similar incubation periods. In contrast to sCJD prions, vCJD prions did not transmit disease efficiently to mice expressing a chimeric human-mouse PrP transgene. Earlier studies with nontransgenic mice suggested that vCJD and BSE might be derived from the same source because both inocula transmitted disease with similar but very long incubation periods.

Attempts to determine the origin of BSE and vCJD prions have relied on passaging studies in mice, some of which are described above, as well as studies of the conformation and glycosylation of PrP^{Sc}. One scenario suggests that a particular conformation of bovine PrP^{Sc} was selected for heat resistance during the rendering process and was then reselected multiple times as cattle infected by ingesting prion-contaminated meat and bone meal (MBM) were slaughtered and their offal rendered into more MBM.

NEUROPATHOLOGY

Frequently the brains of patients with CJD have no recognizable abnormalities on gross examination. Patients who survive for several years have variable degrees of cerebral atrophy.

On light microscopy, the pathologic hallmarks of CJD are spongiform degeneration and astrocytic gliosis. The lack of an inflammatory response in CJD and other prion diseases is an important pathologic feature of these degenerative disorders. Spongiform degeneration is characterized by many 1- to 5- μ m vacuoles in the neuropil between nerve cell bodies. Generally the spongiform changes occur in the cerebral cortex, putamen, caudate nucleus, thalamus, and molecular layer of the

cerebellum. Astrocytic gliosis is a constant but nonspecific feature of prion diseases. Widespread proliferation of fibrous astrocytes is found throughout the gray matter of brains infected with CJD prions. Astrocytic processes filled with glial filaments form extensive networks.

Amyloid plaques have been found in ~10% of CJD cases. Purified CJD prions from humans and animals exhibit the ultrastructural and histochemical characteristics of amyloid when treated with detergents during limited proteolysis. In first passage from some human Japanese CJD cases, amyloid plaques have been found in mouse brains. These plaques stain with antibodies raised against PrP.

The amyloid plaques of GSS disease are morphologically distinct from those seen in kuru or scrapie. GSS plaques consist of a central dense core of amyloid surrounded by smaller globules of amyloid. Ultrastructurally, they consist of a radiating fibrillar network of amyloid fibrils, with scant or no neuritic degeneration. The plaques can be distributed throughout the brain but are most frequently found in the cerebellum. They are often located adjacent to blood vessels. Congophilic angiopathy has been noted in some cases of GSS disease.

In vCJD, a characteristic feature is the presence of “florid plaques.” These are composed of a central core of PrP amyloid, surrounded by vacuoles in a pattern suggesting petals on a flower.

CLINICAL FEATURES

Nonspecific prodromal symptoms occur in about a third of patients with CJD and may include fatigue, sleep disturbance, weight loss, headache, malaise, and ill-defined pain. Most patients with CJD present with deficits in higher cortical function. These deficits almost always progress over weeks or months to a state of profound dementia characterized by memory loss, impaired judgment, and a decline in virtually all aspects of intellectual function. A few patients present with either visual impairment or cerebellar gait and coordination deficits. Frequently the cerebellar deficits are rapidly followed by progressive dementia. Visual problems often begin with blurred vision and diminished acuity, rapidly followed by dementia.

Other symptoms and signs include extrapyramidal dysfunction manifested as rigidity, masklike facies, or choreoathetoid movements; pyramidal signs (usually mild); seizures (usually major motor) and, less commonly, hypoesthesia; supranuclear gaze palsy; optic atrophy; and vegetative signs such as changes in weight, temperature, sweating, or menstruation.

Myoclonus

Most patients (~90%) with CJD exhibit myoclonus that appears at various times throughout the illness. Unlike other involuntary movements, myoclonus persists during sleep. Startle myoclonus elicited by loud sounds or bright lights is frequent. It is important to stress that myoclonus is neither specific nor confined to CJD. Dementia with myoclonus can also be due to Alzheimer’s disease (AD), dementia with Lewy bodies, cryptococcal

encephalitis (Chap. 106), or the myoclonic epilepsy disorder Unverricht-Lundborg disease.

Clinical Course

In documented cases of accidental transmission of CJD to humans, an incubation period of 1.5–2.0 years preceded the development of clinical disease. In other cases, incubation periods of up to 30 years have been suggested. Most patients with CJD live 6–12 months after the onset of clinical signs and symptoms, whereas some live for up to 5 years.

DIAGNOSIS

The constellation of dementia, myoclonus, and periodic electrical bursts in an afebrile 60-year-old patient generally indicates CJD. Clinical abnormalities in CJD are confined to the CNS. Fever, elevated sedimentation rate, leukocytosis in blood, or a pleocytosis in cerebrospinal fluid (CSF) should alert the physician to another etiology to explain the patient’s CNS dysfunction.

Variations in the typical course appear in inherited and transmitted forms of the disease. fCJD has an earlier mean age of onset than sCJD. In GSS disease, ataxia is usually a prominent and presenting feature, with dementia occurring late in the disease course. GSS disease typically presents earlier than CJD (mean age 43 years) and is typically more slowly progressive than CJD; death usually occurs within 5 years of onset. FFI is characterized by insomnia and dysautonomia; dementia occurs only in the terminal phase of the illness. Rare sporadic cases have been identified. vCJD has an unusual clinical course, with a prominent psychiatric prodrome that may include visual hallucinations and early ataxia, while frank dementia is usually a late sign of vCJD.

DIFFERENTIAL DIAGNOSIS

Many conditions may mimic CJD superficially. Dementia with Lewy bodies is the most common disorder to be mistaken for CJD. It can present in a subacute fashion with delirium, myoclonus, and extrapyramidal features. Other neurodegenerative disorders to consider include AD, frontotemporal dementia, progressive supranuclear palsy, ceroid lipofuscinosis, and myoclonic epilepsy with Lafora bodies. The absence of abnormalities on diffusion-weighted and FLAIR MRI will usually distinguish these dementing conditions from CJD.

Hashimoto’s encephalopathy, which presents as a subacute progressive encephalopathy with myoclonus and periodic triphasic complexes on the EEG, should be excluded in every case of suspected CJD. It is diagnosed by the finding of high titers of antithyroglobulin or antithyroid peroxidase (antimicrosomal) antibodies in the blood and improves with glucocorticoid therapy. Unlike CJD, fluctuations in severity typically occur in Hashimoto’s encephalopathy.

Intracranial vasculitides may produce nearly all of the symptoms and signs associated with CJD, sometimes without systemic abnormalities. Myoclonus is exceptional with cerebral vasculitis, but focal seizures may

confuse the picture. Prominent headache, absence of myoclonus, stepwise change in deficits, abnormal CSF, and focal white matter changes on MRI or angiographic abnormalities all favor vasculitis.

Paraneoplastic conditions, particularly limbic encephalitis and cortical encephalitis, can also mimic CJD. In many of these patients, dementia appears prior to the diagnosis of a tumor, and in some, no tumor is ever found. Detection of the paraneoplastic antibodies is often the only way to distinguish these cases from CJD.

Other diseases that can simulate CJD include neurosyphilis (Chap. 70), AIDS dementia complex (Chap. 90), progressive multifocal leukoencephalopathy (Chap. 29), subacute sclerosing panencephalitis, progressive rubella panencephalitis, herpes simplex encephalitis, diffuse intracranial tumor (gliomatosis cerebri), anoxic encephalopathy, dialysis dementia, uremia, hepatic encephalopathy, and lithium or bismuth intoxication.

LABORATORY TESTS

The only specific diagnostic tests for CJD and other human prion diseases measure PrP^{Sc}. The most widely used method involves limited proteolysis that generates PrP 27–30, which is detected by immunoassay after denaturation. The conformation-dependent immunoassay (CDI) is based on immunoreactive epitopes that are exposed in PrP^C but buried in PrP^{Sc}. The CDI is extremely sensitive and quantitative and is likely to find wide application in both the post- and antemortem detection of prions. In humans, the diagnosis of CJD can be established by brain biopsy if PrP^{Sc} is detected. If no attempt is made to measure PrP^{Sc}, but the constellation of pathologic changes frequently found in CJD is seen in a brain biopsy, then the diagnosis is reasonably secure (see “Neuropathology” earlier in the chapter). Because PrP^{Sc} is not uniformly distributed throughout the CNS, the apparent absence of PrP^{Sc} in a limited sample such as a biopsy does not rule out prion disease. At autopsy, sufficient brain samples should be taken for both PrP^{Sc} immunoassay, preferably by CDI, and immunohistochemistry of tissue sections.

To establish the diagnosis of either sCJD or familial prion disease, sequencing the *PRNP* gene must be performed. Finding the wild-type *PRNP* gene sequence permits the diagnosis of sCJD if there is no history to suggest infection from an exogenous source of prions. The identification of a mutation in the *PRNP* gene sequence that encodes a nonconservative amino acid substitution argues for familial prion disease.

CT may be normal or show cortical atrophy. MRI is valuable for distinguishing sCJD from most other conditions. On FLAIR sequences and diffusion-weighted imaging, ~90% of patients show increased intensity in the basal ganglia and cortical ribboning (Fig. 101-3). This pattern is not seen with other neurodegenerative disorders but has been seen infrequently with viral encephalitis, paraneoplastic syndromes, or seizures. When the typical MRI pattern is present, in the proper clinical setting, diagnosis is facilitated. However, some cases of sCJD do not show this typical pattern, and other early diagnostic approaches are still needed.

FIGURE 101-3

T2-weighted (FLAIR) MRI showing hyperintensity in the cortex in a patient with sporadic CJD. This so-called “cortical ribboning” along with increased intensity in the basal ganglia on T2 or diffusion-weighted imaging can aid in the diagnosis of CJD.

CSF is nearly always normal but may show protein elevation and, rarely, mild pleocytosis. Although the stress protein 14-3-3 is elevated in the CSF of some patients with CJD, similar elevations of 14-3-3 are found in patients with other disorders; thus this elevation is not specific.

The EEG is often useful in the diagnosis of CJD, although only about 60% of individuals show the typical pattern. During the early phase of CJD, the EEG is usually normal or shows only scattered theta activity. In most advanced cases, repetitive, high-voltage, triphasic, and polyphasic sharp discharges are seen, but in many cases their presence is transient. The presence of these stereotyped periodic bursts of <200 ms duration, occurring every 1–2 s, makes the diagnosis of CJD very likely. These discharges are frequently but not always symmetric; there may be a one-sided predominance in amplitude. As CJD progresses, normal background rhythms become fragmentary and slower.

CARE OF CJD PATIENTS

Although CJD should not be considered either contagious or communicable, it is transmissible. The risk of accidental inoculation by aerosols is very small; nonetheless, procedures producing aerosols should be performed in certified biosafety cabinets. Biosafety level 2 practices, containment equipment, and facilities are recommended by the Centers for Disease Control and Prevention and the National Institutes of Health. The primary problem in caring for patients with CJD is the inadvertent infection

of health care workers by needle and stab wounds. The transmission of prions through the air has never been documented. Electroencephalographic and electromyographic needles should not be reused after studies on patients with CJD have been performed.

There is no reason for pathologists or other morgue employees to resist performing autopsies on patients whose clinical diagnosis was CJD. Standard microbiologic practices outlined here, along with specific recommendations for decontamination, seem to be adequate precautions for the care of patients with CJD and the handling of infected specimens.

DECONTAMINATION OF CJD PRIONS

Prions are extremely resistant to common inactivation procedures, and there is some disagreement about the optimal conditions for sterilization. Some investigators recommend treating CJD-contaminated materials once with 1 N NaOH at room temperature, but we believe this procedure may be inadequate for sterilization. Autoclaving at 134°C for 5 h or treatment with 2 N NaOH for several hours is recommended for sterilization of prions. The term *sterilization* implies complete destruction of prions; any residual infectivity can be hazardous. Recent studies show that sCJD prions bound to stainless steel surfaces are resistant to inactivation by autoclaving at 134°C for 2 h; exposure of bound prions to an acidic detergent solution prior to autoclaving rendered prions susceptible to inactivation.

PREVENTION AND THERAPEUTICS

There is no known effective therapy for preventing or treating CJD. The finding that phenothiazines and acridines inhibit PrP^{Sc} formation in cultured cells led to clinical studies of quinacrine in CJD patients. Although quinacrine seems to slow the rate of decline in some CJD patients, no cure of the disease has been observed. In wild-type mice, quinacrine treatment has been

ineffective. Recent studies indicate that inhibition of the P-glycoprotein (Pgp) transport system results in substantially increased quinacrine levels in the brains of mice. Whether such an approach can be used to treat CJD remains to be established.

Like the acridines, anti-PrP antibodies have been shown to eliminate PrP^{Sc} from cultured cells. Additionally, such antibodies in mice, either administered by injection or produced from a transgene, have been shown to prevent prion disease when prions are introduced by a peripheral route, such as intraperitoneal inoculation. Unfortunately, the antibodies were ineffective in mice inoculated intracerebrally with prions. Several drugs, including pentosan polysulfate and porphyrin derivatives, delay the onset of disease in animals inoculated intracerebrally with prions if the drugs are given intracerebrally beginning soon after inoculation.

Structure-based drug design predicated on dominant-negative inhibition of prion formation has produced several promising compounds. Modified quinacrine compounds that are more potent than the parent drug have been found. Whether improving the efficacy of such small molecules will provide general methods for developing novel therapeutics for other neurodegenerative disorders, including AD and Parkinson's disease as well as amyotrophic lateral sclerosis (ALS), remains to be established.

SECTION VII

FUNGAL AND ALGAL INFECTIONS

CHAPTER 102

DIAGNOSIS AND TREATMENT OF FUNGAL INFECTIONS

John E. Edwards, Jr.

TERMINOLOGY AND MICROBIOLOGY

Traditionally, fungal infections have been classified into specific categories based on both anatomic location and epidemiology. The most common general anatomic categories are mucocutaneous and deep organ infection; the most common general epidemiologic categories are endemic and opportunistic. Although *mucocutaneous infections* can cause serious morbidity, they are rarely fatal. *Deep organ infections* also cause severe illness in many cases but, in contrast to mucocutaneous infections, are often fatal. The *endemic mycoses* (e.g., coccidioidomycosis) are infections caused by fungal organisms that are not part of the normal human microbial flora and are acquired from environmental sources. In contrast, *opportunistic mycoses* are caused by organisms (e.g., *Candida* and *Aspergillus*) that frequently are components of the normal human flora and whose ubiquity in nature renders them easily acquired by the immunocompromised host. Opportunistic fungi cause serious infections when the immunologic response of the host becomes ineffective, allowing the organisms to transition from harmless commensals to invasive pathogens. Frequently, the diminished effectiveness of the immune system is a result of advanced modern therapies that coincidentally either unbalance the host's microflora or directly interfere with immunologic responses. Endemic mycoses cause more severe illness in immunocompromised patients than in immunocompetent individuals.

Patients acquire infection with endemic fungi almost exclusively by inhalation. The soil is the natural reservoir for the vast majority of endemic mycoses. The dermatophytic fungi may be acquired by human-to-human transmission, but the majority of infections result from environmental contact. In contrast, the opportunistic fungus *Candida* invades the host from normal sites of colonization, usually the mucous membranes of the gastrointestinal tract. In general, innate immunity is the primary defense mechanism against fungi. Although antibodies are formed during many fungal infections (and even during commensalism), they generally do not constitute the primary mode of defense. Nevertheless, in selected infections, as discussed below, measurement of antibody titers may be a useful diagnostic test.

Three other terms frequently used in clinical discussions of fungal infections are *yeast*, *mold*, and *dimorphic fungus*. *Yeasts* are seen as rounded single cells or as budding organisms. *Candida* and *Cryptococcus* are traditionally

classified as yeasts. Molds grow as filamentous forms called *hyphae* both at room temperature and when they invade tissue. *Aspergillus*, *Rhizopus* [the species that causes mucormycosis (zygomycosis)], and fungi commonly infecting the skin to cause ringworm and related cutaneous conditions are classified as molds. Variations occur within this classification of yeasts and molds. For instance, when *Candida* infects tissue, both yeasts and filamentous forms may occur (except with *C. glabrata*, which forms only yeasts in tissue); in contrast, *Cryptococcus* exists only in yeast form. *Dimorphic* is the term used to describe fungi that grow as yeasts or large spherical structures in tissue but as filamentous forms at room temperature in the environment. Classified in this group are the organisms causing blastomycosis, paracoccidioidomycosis, coccidioidomycosis, histoplasmosis, blastomycosis, and sporotrichosis.

The incidence of fungal infections has risen substantially over the past several decades. Opportunistic infections have increased in frequency as a consequence of intentional immunosuppression in organ and stem cell transplantation and many other diseases, the administration of cytotoxic chemotherapy for cancers, and the liberal use of antibacterial agents. The incidence of endemic mycoses has increased in geographic locations where there has been substantial population growth.

DIAGNOSIS

The definitive diagnosis of any fungal infection requires histopathologic identification of the fungus invading tissue, accompanied by evidence of an inflammatory response. The identification of an inflammatory response has been especially important with regard to *Aspergillus* infection. *Aspergillus* is ubiquitous and can float from the air onto biopsy material. Therefore, in rare but important instances, this fungus is an ex vivo contaminant during processing of a specimen for microscopy, with a consequent incorrect diagnosis. The stains most commonly used to identify fungi are periodic acid-Schiff and Gomori methenamine silver. *Candida*, unlike other fungi, is visible on gram-stained tissue smears. Hematoxylin and eosin stain is not sufficient to identify *Candida* in tissue specimens. When positive, an India ink preparation of cerebrospinal fluid (CSF) is diagnostic for cryptococcosis. Most laboratories now use calcofluor

white staining coupled with fluorescent microscopy to identify fungi in fluid specimens.

Extensive investigations of the diagnosis of deep organ fungal infections have yielded a variety of tests with different degrees of specificity and sensitivity. The most reliable tests are the detection of antibody to *Coccidioides immitis* and *Histoplasma capsulatum* in serum and CSF, the detection of cryptococcal polysaccharide antigen in serum and CSF, and the detection of *Histoplasma* antigen in urine or serum. The test for galactomannan has been used extensively in Europe and is now approved in the United States for diagnosis of aspergillosis. This test requires additional validation before its true usefulness can be determined. Sources of concern are the incidence of false-negative results and the need for multiple serial tests to reduce this incidence. The β -glucan test for *Candida* is also under evaluation but, like the galactomannan test, requires additional validation. Numerous polymerase chain reaction assays to detect antigens are in the developmental stages, as are nucleic acid hybridization techniques; however, these methods are not currently used on a widespread basis in major medical centers.

Of the fungal organisms, *Candida* is by far most frequently recovered from blood. Although *Candida* species can be detected with any of the automated blood culture systems widely used at present, the lysis-centrifugation technique increases the sensitivity of blood cultures for less common organisms (e.g., *H. capsulatum*) and should be used when disseminated fungal infection is suspected.

Except in the cases of coccidioidomycosis, cryptococcosis, and histoplasmosis, there are no fully validated and widely used tests for serodiagnosis of disseminated fungal infection. Skin tests for the endemic mycoses are no longer available.

Rx Treatment: **FUNGAL INFECTIONS**

This discussion is intended as a brief overview of general strategies for the use of antifungal agents in the treatment of fungal infections. Details on regimens, schedules, and strategies are discussed in the chapters on specific mycoses that follow in this section.

Since fungal organisms are eukaryotic cells that contain most of the same organelles (with many of the same physiologic functions) as human cells, the identification of drugs that selectively kill or inhibit fungi but are not toxic to human cells has been highly problematic. Far fewer antifungal than antibacterial agents have been introduced into clinical medicine.

AMPHOTERICIN B (AmB) The introduction of AmB in the late 1950s revolutionized the treatment of fungal infections in deep organs. Before AmB became available, cryptococcal meningitis and other disseminated fungal infections were nearly always fatal. For nearly a decade after AmB was introduced, it was the only effective agent for the treatment of life-threatening fungal infections. AmB remains the broadest-spectrum

antifungal agent but carries several disadvantages, including significant nephrotoxicity, lack of an oral preparation, and unpleasant side effects (fever, chills, and nausea) during treatment. To circumvent nephrotoxicity and infusion side effects, lipid formulations of AmB were developed and have virtually replaced the original colloidal deoxycholate formulation in clinical use (although the older formulation is still available). The lipid formulations include liposomal AmB (L-AB; 435 mg/kg per day) and AmB lipid complex (ABLC; 5 mg/kg per day). A third preparation, AmB colloidal dispersion (ABCD; 3–4 mg/kg per day), is rarely used because of the high incidence of side effects associated with infusion. (The doses listed are standard doses for adults with invasive infection.)

The lipid formulations of AmB have the disadvantage of being considerably more expensive than the deoxycholate formulation. Experience is still accumulating on the comparative efficacy, toxicity, and advantages of the different formulations for specific clinical fungal infections [e.g., central nervous system (CNS) infection]. Whether there is a clinically significant difference in these drugs with respect to CNS penetration or nephrotoxicity remains controversial. Despite these issues and despite the expense, the lipid formulations are now much more commonly used than AmB deoxycholate in the United States.

AZOLES This class of antifungal drugs offers important advantages over AmB: the azoles cause little or no nephrotoxicity and are available in oral preparations. Early azoles included ketoconazole and miconazole, which have been replaced by newer agents for the treatment of deep organ fungal infections. The azoles' mechanism of action is inhibition of ergosterol synthesis in the fungal cell wall. Unlike AmB, these drugs are considered fungistatic, not cidal.

Fluconazole Since its introduction, fluconazole has played an extremely important role in the treatment of a wide variety of serious fungal infections. Its major advantages are the availability of both oral and IV formulations, a long half-life, satisfactory penetration of most body fluids (including ocular fluid and CSF), and minimal toxicity (especially relative to AmB). Its disadvantages include (usually reversible) hepatotoxicity and—at high doses—alopecia, muscle weakness, and dry mouth with a metallic taste. Fluconazole is not effective for the treatment of aspergillosis, mucormycosis, or *Scedosporium apiospermum* infections. It is less effective than the newer azoles against *C. glabrata* and *C. krusei*.

Fluconazole has become the agent of choice for the treatment of coccidioidal meningitis, although relapses have followed therapy with this drug. In addition, fluconazole is useful for both consolidation and maintenance therapy for cryptococcal meningitis. This agent has been shown to be as efficacious as AmB in the treatment of candidemia. The effectiveness of fluconazole in candidemia and the drug's relatively minimal toxicity, in conjunction with the inadequacy of diagnostic tests for widespread hematogenously disseminated candidiasis, have led to a change in the paradigm for candidemia

management. The standard of care is now to treat all candidemic patients with an antifungal agent and to change all their intravascular lines, if feasible, rather than merely to remove a singular suspect intravascular line and then observe the patient. The usual fluconazole regimen for treatment of candidemia is 400 mg/d given until 2 weeks after the last positive blood culture.

Fluconazole is considered effective as fungal prophylaxis in bone marrow transplant recipients and high-risk liver transplant patients. Its use for prophylaxis in patients with leukemia, in AIDS patients with low CD4+ T-cell counts, and in patients on surgical intensive care units remains controversial.

Voriconazole Like fluconazole, voriconazole is available in both oral and IV formulations. Voriconazole has a broader spectrum than fluconazole against *Candida* species (including *C. glabrata* and *C. krusei*) and is active against *Aspergillus*, *Scedosporium*, and *Fusarium*. It is generally considered the first-line drug of choice for treatment of aspergillosis. A few case reports have shown voriconazole to be effective in individual patients with coccidioidomycosis, blastomycosis, and histoplasmosis, but (because of limited data) this agent is not recommended for treatment of the endemic mycoses. Among the disadvantages of voriconazole (compared with fluconazole) are its more numerous interactions with many of the drugs used in patients predisposed to fungal infections. Hepatotoxicity, skin rashes (including photosensitivity), and visual disturbances are relatively common. Voriconazole is also considerably more expensive than fluconazole. Moreover, it is advisable to monitor voriconazole levels in certain patients since (1) this drug is completely metabolized in the liver by CYP2C9, CYP3A4, and CYP2C19; and (2) human genetic variability in CYP2C19 activity exists. Dosages should be reduced accordingly in those patients with liver failure. Dose adjustments for renal insufficiency are not necessary; however, because the IV formulation is prepared in cyclodextrin, it should not be given to patients with severe renal insufficiency.

Itraconazole Itraconazole is available in IV and oral (capsule and suspension) formulations. Varying blood levels among patients taking oral itraconazole reflect a disadvantage compared with the other azoles. Itraconazole is the drug of choice for mild to moderate histoplasmosis and blastomycosis and has often been used for chronic mucocutaneous candidiasis. It has been approved by the U.S. Food and Drug Administration (FDA) for use in febrile neutropenic patients. Itraconazole has also proven useful for the treatment of chronic coccidioidomycosis, sporotrichosis, and *S. apiospermum* infection. The mucocutaneous and cutaneous fungal infections that have been treated successfully with itraconazole include oropharyngeal candidiasis (especially in AIDS patients), tinea versicolor, tinea capitis, and onychomycosis. Disadvantages of itraconazole include its poor penetration into the CSF, the use of cyclodextrin in both the oral suspension and the IV preparation, the variable absorption of the capsules, and the need for

monitoring of blood levels in patients taking capsules for disseminated mycoses. In recent years, reported cases of severe congestive heart failure in patients taking itraconazole have been a source of concern. Like the other azoles, itraconazole can cause hepatic toxicity.

Posaconazole Posaconazole is approved by the FDA for prophylaxis of aspergillosis and candidiasis in patients at high risk for developing these infections because of severe immunocompromise. This drug has also been evaluated for the treatment of zygomycosis, fusariosis, aspergillosis, and oropharyngeal candidiasis. The relevant studies of posaconazole in zygomycosis, fusariosis, and aspergillosis have examined salvage therapy. A study of >90 patients whose zygomycosis was refractory to other therapy yielded encouraging results. No trials of posaconazole for the treatment of candidemia have yet been reported. Case reports have described the drug's efficacy in coccidioidomycosis and histoplasmosis. Controlled trials have shown its effectiveness as a prophylactic agent in patients with acute leukemia and in bone marrow transplant recipients. In addition, posaconazole has been found to be effective against fluconazole-resistant *Candida* species. The results of a large-scale study of the use of posaconazole as salvage therapy for aspergillosis have been promising but, as of this writing, have not been published in a peer-reviewed format.

ECHINOCANDINS The echinocandins, including the approved drugs caspofungin, anidulafungin, and micafungin, have added considerably to the antifungal armamentarium. All three of these agents inhibit β -1,3-glucan synthase, which is necessary for cell wall synthesis in fungi and is not a component of human cells. None of these agents is available in an oral formulation. The echinocandins are considered fungicidal for *Candida* and fungistatic for *Aspergillus*. Their greatest use to date is against candidal infections. They offer two advantages: broad-spectrum activity against all *Candida* species and relatively low toxicity. The minimum inhibitory concentrations (MICs) of all the echinocandins are highest against *C. parapsilosis*; it is not clear whether these higher MIC values represent less clinical effectiveness against this species. The echinocandins are among the safest antifungal agents.

In controlled trials, *caspofungin* has been at least as efficacious as AmB for the treatment of candidemia and invasive candidiasis and as efficacious as fluconazole for the treatment of candidal esophagitis. In addition, caspofungin has been efficacious as salvage therapy for aspergillosis. At present, it is used most extensively for the treatment of candidemic patients, especially before the infecting species is precisely identified.

Anidulafungin has been approved by the FDA as therapy for candidemia in nonneutropenic patients and for *Candida* esophagitis, intraabdominal infection, and peritonitis. In controlled trials, anidulafungin has been more efficacious than fluconazole against candidemia and invasive candidiasis and as efficacious as fluconazole against candidal esophagitis. When anidulafungin is used with

cyclosporine, tacrolimus, or voriconazole, no dosage adjustment is required for either drug in the combination.

Micafungin has been approved for the treatment of esophageal candidiasis and for prophylaxis in patients receiving stem cell transplants. Studies thus far have shown that coadministration of micafungin and cyclosporine does not require dose adjustments for either drug. When micafungin is given with sirolimus, the AUC rises for sirolimus, usually necessitating a reduction in its dose. In open-label trials, favorable results have been obtained with micafungin for the treatment of deep-seated *Aspergillus* and *Candida* infections.

FLUCYTOSINE (5-FLUOROCYTOSINE) The use of flucytosine has diminished in recent years as newer antifungal drugs have been developed. Flucytosine has a unique mechanism of action based on intra-fungal conversion to 5-fluorouracil, which is toxic to the cell. Development of resistance to the compound has limited its use as a single agent. Flucytosine is nearly always used in combination with AmB. Its good penetration into the CSF makes it attractive for use with AmB for treatment of cryptococcal meningitis. Flucytosine has also been recommended for the treatment of candidal meningitis in combination with AmB; comparative trials with AmB alone have not been done. Significant and frequent bone marrow depression is seen with flucytosine when this drug is used with AmB.

GRISEOFULVIN AND TERBINAFINE Historically, griseofulvin has been useful primarily for ringworm infection. This agent is usually given for relatively long periods. Terbinafine has been used primarily for onychomycosis but also for ringworm. In comparative studies, terbinafine has been as effective as itraconazole and more effective than griseofulvin for both conditions.

TOPICAL ANTIFUNGAL AGENTS A detailed discussion of the agents used for the treatment of cutaneous fungal infections and onychomycosis is beyond the scope of this chapter; the reader is referred to the

dermatology literature. Many classes of compounds have been used to treat the common fungal infections of the skin. Among the azoles used are clotrimazole, econazole, miconazole, oxiconazole, sulconazole, ketoconazole, tioconazole, butoconazole, and terconazole. In general, topical treatment of vaginal candidiasis has been successful. Since there is considered to be little difference in the efficacy of the various vaginal preparations, the choice of agent is made by the physician and/or the patient on the basis of preference and availability. Fluconazole given orally at 150 mg has the advantage of not requiring repeated intravaginal application. Nystatin is a polyene that has been used for both oropharyngeal thrush and vaginal candidiasis. Useful agents in other classes include ciclopirox olamine, haloprogin, terbinafine, naftifine, tolnaftate, and undecylenic acid.

CHAPTER 103

HISTOPLASMOSIS

Chadi A. Hage ■ L. Joseph Wheat

ETIOLOGY

Histoplasma capsulatum, a thermal dimorphic fungus, is the etiologic agent of histoplasmosis. In most endemic areas, *H. capsulatum* var. *capsulatum* is the causative agent; in Africa, *H. capsulatum* var. *duboisii* is also found.

Mycelia—the naturally infectious form of *Histoplasma*—have a characteristic appearance, with microconidial and macroconidial forms. Microconidia are oval and are small enough (2–5 µm) to reach the terminal bronchioles and alveoli. Shortly after infecting the host, mycelia transform

into the yeasts that are found inside macrophages and other phagocytes. The yeast forms are characteristically small (2–5 μm), with occasional narrow budding. In the laboratory, mycelia are best grown at room temperature, whereas yeasts are grown at 37°C on enriched media.

EPIDEMIOLOGY

Histoplasmosis is the most prevalent endemic mycosis in North America. Although this fungal disease has been reported throughout the world, its endemicity is particularly notable in certain parts of North, Central, and South America; Africa; and Asia. In the United States, the endemic areas spread over the Ohio and Mississippi river valleys. This pattern is related to the humid and acidic nature of the soil in these areas. Soil enriched with bird or bat droppings promotes the growth and sporulation of *Histoplasma*. Disruption of soil containing the organism leads to aerosolization of the microconidia and exposure of humans nearby. Activities associated with high-level exposure include spelunking, excavation, cleaning of chicken coops, demolition and remodeling of old buildings, and cutting of dead trees. Most cases seen outside of highly endemic areas represent imported disease—e.g., cases reported in Europe after travel to the Americas, Africa, or Asia.

PATHOGENESIS AND PATHOLOGY

Infection follows inhalation of microconidia (Fig. 103-1). Once they reach the alveolar spaces, microconidia are rapidly recognized and engulfed by alveolar macrophages. At this point, the microconidia transform into budding yeasts (Fig. 103-2), a process that is integral to the pathogenesis of histoplasmosis and is dependent on the availability of calcium and iron inside the phagocytes. The yeasts are capable of growing and multiplying inside resting macrophages. Neutrophils and then lymphocytes are attracted to the site of infection. Before the development of cellular immunity, yeasts use the phagosomes as a vehicle for translocation to local draining lymph nodes,

FIGURE 103-1

whence they spread hematogenously throughout the reticuloendothelial system. Adequate cellular immunity develops ~2 weeks after infection. T cells produce interferon γ to assist the macrophages in killing the organism and controlling the progression of disease. Interleukin 12 and tumor necrosis factor α (TNF- α) play an essential role in cellular immunity to *H. capsulatum*. In the immunocompetent host, macrophages, lymphocytes, and epithelial cells eventually organize and form granulomas that contain the organisms. These granulomas typically fibrose and calcify; calcified mediastinal lymph nodes and hepatosplenic calcifications are frequently found in healthy individuals from endemic areas. In immunocompetent hosts, infection with *H. capsulatum* confers some immunity to reinfection. In patients with impaired cellular immunity, the infection is not contained and can disseminate. Progressive disseminated histoplasmosis (PDH) can involve multiple organs, most commonly the bone marrow, spleen, liver (Fig. 103-3), adrenal glands, and mucocutaneous membranes. Unlike latent tuberculosis, latent histoplasmosis is rarely reactivated.

Structural lung disease (e.g., emphysema) impairs the clearance of pulmonary histoplasmosis, and chronic pulmonary disease can result. This chronic process is characterized by progressive inflammation, tissue necrosis, and fibrosis mimicking cavitary tuberculosis.

CLINICAL MANIFESTATIONS

The clinical spectrum of histoplasmosis ranges from asymptomatic infection to life-threatening illness. The attack rate and the extent and severity of the disease depend on the intensity of exposure, the immune status

FIGURE 103-3

Intracellular yeasts (arrows) of *H. capsulatum* in a liver biopsy specimen (hematoxylin and eosin stain).

of the exposed individual, and the underlying lung architecture of the host.

In immunocompetent individuals with low-level exposure, most *Histoplasma* infections are either asymptomatic or mild and self-limited. Of adults residing in endemic areas, 50–80% have skin-test and/or radiographic evidence of previous infection without clinical manifestations. When symptoms do develop, they usually appear 2–4 weeks after exposure. Heavy exposure leads to a flulike illness with fever, chills, sweats, headache, myalgia, anorexia, cough, dyspnea, and chest pain. Chest radiographs usually show signs of pneumonitis with hilar or mediastinal adenopathy. Pulmonary infiltrates may be focal with light exposure or diffuse with heavy exposure. Rheumatologic symptoms of arthralgia or arthritis, often associated with erythema nodosum, occur in 5–10% of patients with acute histoplasmosis. Pericarditis may also develop. These manifestations represent inflammatory responses to the acute infection rather than its direct effects. Hilar or mediastinal lymph nodes may undergo necrosis and coalesce to form large mediastinal masses that can cause compression of great vessels, proximal airways, and the esophagus. These necrotic lymph nodes also may rupture and create fistulas between mediastinal structures (e.g., bronchoesophageal fistulas).

PDH is typically seen in immunocompromised individuals, who account for ~70% of cases. Common risk factors include AIDS (CD4+ T-cell count, <200/μL), extremes of age, and the use of immunosuppressive medications such as prednisone, methotrexate, and anti-TNF-α agents. The spectrum of PDH ranges from an acute, rapidly fatal course—with diffuse interstitial or reticulonodular lung infiltrates causing respiratory failure, shock, coagulopathy, and multiorgan failure—to a more subacute course with a focal organ distribution. Common manifestations include fever and weight loss. Hepatosplenomegaly is also common. Other findings may include meningitis or focal brain lesions, ulcerations of

the oral mucosa, gastrointestinal ulcerations, and adrenal insufficiency. Prompt recognition of this devastating illness is of paramount importance in patients with more severe manifestations or with underlying immunosuppression, especially AIDS (Chap. 90).

Chronic cavitary histoplasmosis is seen in smokers who have structural lung disease (e.g., bullous emphysema). This chronic illness is characterized by productive cough, dyspnea, low-grade fever, night sweats, and weight loss. Chest radiographs usually show upper-lobe infiltrates, cavitation, and pleural thickening—findings resembling those of tuberculosis. Without treatment, the course is slowly progressive.

Fibrosing mediastinitis is an uncommon and serious complication of histoplasmosis. In certain patients, acute infection is followed for unknown reasons by progressive fibrosis around the hilar and mediastinal lymph nodes. Involvement may be unilateral or bilateral; bilateral involvement carries a worse prognosis. Major manifestations include superior vena cava syndrome, obstruction of pulmonary vessels, and recurrent airway obstruction. Patients may experience recurrent pneumonia, hemoptysis, or respiratory failure. Fibrosing mediastinitis is fatal in up to one-third of cases.

In healed histoplasmosis, calcified mediastinal nodes or lung parenchyma may erode through the walls of the airways and cause hemoptysis. This condition is called *broncholithiasis*.

African histoplasmosis caused by *H. capsulatum* var. *duboisii* is clinically distinct and is characterized by frequent skin and bone involvement.

DIAGNOSIS

Fungal culture remains the gold standard diagnostic test for histoplasmosis. However, culture results may not be known for up to 1 month, and cultures are often negative in less severe cases. Cultures are positive in ~75% of cases of PDH and chronic pulmonary histoplasmosis. Cultures of bronchoalveolar lavage (BAL) fluid are positive in about half of patients with acute pulmonary histoplasmosis causing diffuse infiltrates with hypoxemia. In PDH, the culture yield is highest for BAL fluid, bone marrow aspirate, and blood. Cultures of sputum or bronchial washings are usually positive in chronic pulmonary histoplasmosis. Cultures are typically negative, however, in other forms of histoplasmosis.

Fungal stains of cytopathology or biopsy materials showing structures resembling *Histoplasma* yeasts are helpful in the diagnosis of PDH, yielding positive results in about half of cases. Yeasts can be seen in BAL fluid (Fig. 103-2) from patients with diffuse pulmonary infiltrates, in bone marrow biopsy samples, and in biopsy specimens of other involved organs (e.g., the adrenal glands). Occasionally, yeasts are seen in blood smears from patients with severe PDH. However, staining artifacts and other fungal elements may be misidentified as *Histoplasma* yeasts.

The detection of *Histoplasma* antigen in body fluids is extremely useful in the diagnosis of PDH and acute diffuse pulmonary histoplasmosis. The sensitivity of this

technique is >90% for urine and 80% for serum from patients with PDH and ~75% for urine from patients with acute pulmonary histoplasmosis. Antigen can be detected in cerebrospinal fluid from patients with meningitis and in BAL fluid from those with pneumonia. Cross-reactivity occurs with African histoplasmosis, blastomycosis, coccidioidomycosis, paracoccidioidomycosis, and *Penicillium marneffe*i infection.

Serologic tests, including immunodiffusion and complement fixation, are especially useful for the diagnosis of self-limited acute pulmonary histoplasmosis; however, at least 1 month is required for the production of antibodies after acute infection. A fourfold rise in antibody titer may be seen in patients with acute pulmonary histoplasmosis. Serologic tests are also useful for the diagnosis of chronic pulmonary histoplasmosis. Limitations of serology, however, include insensitivity early in the course of infection in immunosuppressed patients and the persistence of detectable antibody for several years after infection. Positive results from past infection may lead to a misdiagnosis of active histoplasmosis in a patient with another disease process.

Rx Treatment: HISTOPLASMOSIS

Treatment recommendations for histoplasmosis are summarized in [Table 103-1](#).

Treatment is indicated for all patients with PDH or chronic pulmonary histoplasmosis as well as for symptomatic patients with acute pulmonary histoplasmosis causing diffuse infiltrates, especially with hypoxemia. In the vast majority of cases, however, acute pulmonary histoplasmosis resolves without therapy, and treatment is not recommended.

The preferred treatments for histoplasmosis include the lipid formulations of amphotericin B in more severe

cases and itraconazole in others. Liposomal amphotericin B has been more effective than the deoxycholate formulation for treatment of PDH in patients with AIDS. The deoxycholate formulation of amphotericin B is an alternative to a lipid formulation in patients who are at a low risk for nephrotoxicity. Posaconazole, voriconazole, and fluconazole are alternatives for patients who cannot take itraconazole.

In severe cases requiring hospitalization, a lipid formulation of amphotericin B is followed by itraconazole. In patients with meningitis, a lipid formulation of amphotericin B should be given for 4–6 weeks before the switch to itraconazole. In immunosuppressed patients, the degree of immunosuppression should be reduced if possible. Antiretroviral treatment improves the outcome of PDH in patients with AIDS and is recommended.

Blood levels of itraconazole should be monitored to ensure adequate drug exposure, and drug interactions should be carefully assessed: itraconazole not only is cleared by cytochrome P450 metabolism but also inhibits cytochrome P450. This profile causes interactions with many other medications.

The duration of treatment for acute pulmonary histoplasmosis is 6–12 weeks, while that for PDH and chronic pulmonary histoplasmosis is ≥1 year. Antigen levels in urine and serum should be monitored during and for at least 1 year after therapy for PDH. Stable or rising antigen levels suggest treatment failure or relapse.

Previously, lifelong itraconazole maintenance therapy was recommended for patients with AIDS once histoplasmosis was diagnosed. Today, however, maintenance therapy is not required for patients who respond well to antiretroviral therapy, with CD4+ T-cell counts of at least 150/μL (preferably >250/μL); who complete at least 1 year of itraconazole therapy; and who exhibit

TABLE 103-1
RECOMMENDATIONS FOR THE TREATMENT OF HISTOPLASMOSIS

| TYPE OF HISTOPLASMOSIS | TREATMENT RECOMMENDATIONS | COMMENTS |
|---|---|---|
| Acute pulmonary, moderate to severe illness with diffuse infiltrates and/or hypoxemia | Lipid amphotericin B (3–5 mg/kg per day) ± glucocorticoids for 1–2 weeks; then itraconazole (200 mg twice daily) for 12 weeks. Monitor renal and hepatic function. | Patients with mild cases usually recover without therapy, but itraconazole should be considered if the patient's condition has not improved after 1 month. |
| Chronic/cavitary pulmonary | Itraconazole (200 mg once or twice daily) for at least 12 months. Monitor hepatic function. | Continue treatment until radiographic findings show no further improvement. Monitor for relapse after treatment is stopped. |
| Progressive disseminated | Lipid amphotericin B (3–5 mg/kg per day) for 1–2 weeks; then itraconazole (200 mg twice daily) for at least 12 months. Monitor renal and hepatic function. | Liposomal amphotericin B is preferred, but the amphotericin B lipid complex may be used because of cost. Chronic maintenance therapy may be necessary if the degree of immunosuppression cannot be reduced. |
| Central nervous system | Liposomal amphotericin B (5 mg/kg per day) for 4–6 weeks; then itraconazole (200 mg 2 or 3 times daily) for at least 12 months. Monitor renal and hepatic function. | A longer course of lipid amphotericin B is recommended because of the high risk of relapse. Itraconazole should be continued until cerebrospinal fluid or CT abnormalities clear. |

neither clinical evidence of active histoplasmosis nor an antigenuria level of >4 ng/mL.

Fibrosing mediastinitis, which represents a chronic fibrotic reaction to past mediastinal histoplasmosis rather than an active infection, does not respond to antifungal therapy. While treatment is often prescribed for patients with acute pulmonary histoplasmosis who have not recovered within 1 month and for those with persistent mediastinal lymphadenopathy, the effectiveness of antifungal therapy in these situations is unknown.

CHAPTER 104

COCCIDIOIDOMYCOSIS

Neil M. Ampel

DEFINITION AND ETIOLOGY

Coccidioidomycosis, commonly known as valley fever, is caused by the dimorphic soil-dwelling fungus *Coccidioides*. Genetic analysis has demonstrated the existence of two species, *C. immitis* and *C. posadasii*. These species are indistinguishable with regard to the clinical disease they cause as well as in routine laboratory tests. Thus, the organism will be referred to simply as *Coccidioides* for the remainder of this chapter.

EPIDEMIOLOGY

Coccidioidomycosis is confined to the Western Hemisphere between the latitudes of 40°N and 40°S. In the United States, areas of high endemicity include the southern portion of the San Joaquin Valley of California, the south-central region of Arizona, and the southwestern Rio Grande Valley. However, infection may be acquired in other areas of the southwestern United States, including the southern coastal counties in California, southern Nevada, and southwestern Utah. Outside the United States, coccidioidomycosis is endemic to

northern Mexico as well as to localized regions of Central America. In South America, there are endemic foci in Colombia, Venezuela, northeastern Brazil, Paraguay, Bolivia, and north-central Argentina.

The risk of infection is increased by direct exposure to soil harboring *Coccidioides*. Because of difficulty in isolating *Coccidioides* from the soil, the precise characteristics of potentially infectious soil are not known. In general, *Coccidioides* appears to be supported in previously uncultivated desert soil, such as that found in the Lower Sonoran Life Zone. However, several outbreaks have been associated with soil from archaeological excavations of Amerindian sites both within and outside of the recognized endemic region.

In endemic areas, many cases of *Coccidioides* infection occur without obvious soil or dust exposure. Climatic factors appear to increase the infection rate in these regions. In particular, periods of dryness after rainy seasons have been associated with marked increases in the number of cases.

Recently, the number of cases of symptomatic coccidioidomycosis has increased dramatically in south-central

Arizona, where most of the state's population resides. The factors causing this increase have not been fully elucidated; however, an influx of older, susceptible individuals into the region as well as increased construction in previously undeveloped desert appear to be involved.

PATHOGENESIS, PATHOLOGY, AND IMMUNE RESPONSE

On agar media and in the soil, *Coccidioides* exists as a filamentous mold. Within this mycelial structure, individual filaments (*hyphae*) elongate and branch, some growing upward. Cells within the hyphae degenerate, leaving alternating barrel-shaped viable cells called *arthroconidia*. Measuring only $\sim 2 \times 5 \mu\text{m}$, arthroconidia may become airborne for extended periods. The small size of the arthroconidia also allows them to evade initial mechanical mucosal defenses and reach the alveolus, where infection is initiated in the nonimmune host.

Once in a susceptible host, the arthroconidia enlarge, become rounded, and develop internal septations. The resulting structures, called *spherules* (Fig. 104-1), may attain sizes of $80 \mu\text{m}$ and are unique to *Coccidioides*. The septations encompass uninuclear elements called *endospores*. Spherules may rupture and release packets of endospores.

FIGURE 104-1

Life cycle of *Coccidioides*. (From Kirkland TN, Fierer J: *Coccidioidomycosis: A reemerging infectious disease. Emerg Infect Dis* 2:192, 1996.)

that can themselves develop into spherules, thus propagating infection locally. If returned to artificial media or the soil, the fungus reverts to its mycelial stage.

Clinical observations and data from studies of animals strongly support the critical role of a robust cellular immune response in the host's control of coccidioidomycosis. Necrotizing granulomas containing spherules are typically identified in patients with resolved pulmonary infection. In disseminated disease, granulomas are generally poorly formed or do not develop at all, and a polymorphonuclear leukocyte response occurs frequently. In patients who are asymptomatic or in whom the initial pulmonary infection resolves, delayed-type hypersensitivity to coccidioidal antigens is routinely documented.

CLINICAL AND LABORATORY MANIFESTATIONS

Coccidioidomycosis is protean in its manifestations. Of infected individuals, 60% are completely asymptomatic, and the remaining 40% have symptoms that are related principally to pulmonary infection, including fever, cough, and pleuritic chest pain. The risk of symptomatic illness increases with age. Coccidioidomycosis is commonly misdiagnosed as community-acquired bacterial pneumonia.

There are several cutaneous manifestations of primary pulmonary coccidioidomycosis. Toxic erythema consisting of a maculopapular rash has been noted in some cases. Erythema nodosum (typically over the lower extremities) or erythema multiforme (usually in a necklace distribution) may occur; these manifestations are seen particularly often in women. Arthralgias and arthritis may develop. The diagnosis of primary pulmonary coccidioidomycosis is suggested by a history of night sweats or profound fatigue as well as by peripheral-blood eosinophilia or hilar or mediastinal lymphadenopathy on chest radiography. While pleuritic chest pain is common, pleural effusion is less so, occurring in fewer than 10% of cases. Such effusions are invariably associated with a pulmonary infiltrate on the same side. The cellular content of these effusions is mononuclear in nature; *Coccidioides* is rarely grown from effusions.

Although primary pulmonary coccidioidomycosis usually resolves without sequelae, several complications may ensue. Pulmonary nodules are residua of primary pneumonia. Generally single, located in the upper lobes, and $\leq 4 \text{ cm}$ in diameter, nodules are often discovered on a routine chest radiograph in an asymptomatic patient. Calcification is uncommon.

Pulmonary cavities occur when a nodule extrudes its contents into the bronchus, resulting in a thin-walled shell. These cavities can be associated with persistent cough, hemoptysis, and pleuritic chest pain. Rarely, a cavity may rupture into the pleural space, causing pyopneumothorax. In such cases, patients present with acute dyspnea, and the chest radiograph reveals a collapsed lung with a pleural air-fluid level. Chronic or persistent pulmonary coccidioidomycosis manifests with prolonged symptoms of fever, cough, and weight loss and is radiographically associated with pulmonary scarring, fibrosis, and cavities. It occurs in

fewer than 1% of patients, many of whom already have chronic lung disease of other etiologies.

In some cases, primary pneumonia presents as a diffuse reticulonodular pulmonary process (detected by plain chest radiography) in association with dyspnea and fever. Primary diffuse coccidioidal pneumonia may occur in settings of intense environmental exposure or profoundly suppressed cellular immunity, with unrestrained fungal growth that is frequently associated with fungemia.

Dissemination outside the thoracic cavity occurs in fewer than 1% of infected individuals. Dissemination is more likely to occur in males, particularly those of African-American or Filipino ancestry, and in persons with depressed cellular immunity, including patients with HIV infection and peripheral-blood CD4⁺ T-cell counts of <250/ μ L; those receiving chronic glucocorticoid therapy; those with allogeneic solid-organ transplants; and those being treated with tumor necrosis factor α antagonists. Women who acquire infection during the second or third trimester of pregnancy are also at risk for disseminated disease. Common sites for dissemination include the skin, bone, joints, soft tissues, and meninges. Dissemination may follow symptomatic or asymptomatic pulmonary infection and may involve only one site or multiple anatomic foci. When it occurs, clinical dissemination is usually evident within the first few months after primary pulmonary infection.

Meningitis, if untreated, is uniformly fatal. Patients usually present with a persistent headache, which is occasionally accompanied by lethargy and confusion. Nuchal rigidity, if present, is not severe. Examination of cerebrospinal fluid (CSF) demonstrates lymphocytic pleocytosis with profound hypoglycorrhachia and elevated protein levels. CSF eosinophilia is occasionally documented. With or without appropriate therapy, patients may develop hydrocephalus, which presents clinically as a marked decline in mental status, often with gait disturbances.

DIAGNOSIS

As mentioned above, coccidioidomycosis is often misdiagnosed as community-acquired bacterial pneumonia. Serology plays an important role in establishing the diagnosis of coccidioidomycosis. Several techniques are available, including the traditional tube-precipitin (TP) and complement-fixation (CF) assays, immunodiffusion (IDTP and IDCF), and enzyme immunoassay (EIA) to detect IgM and IgG antibodies. TP antibody is found in serum soon after infection and persists for weeks. TP titers are not useful for gauging disease progression, and this antibody is not found in the CSF. Titers of CF antibody generally rise later than do those of TP antibody, and CF antibody usually persists longer. Rising CF titers are associated with clinical progression, and the presence of CF antibody in CSF is an indicator for coccidioidal meningitis.

Because of its commercial availability, the coccidioidal EIA is frequently used as a screening tool for coccidioidal serology. However, the frequent false-positive results obtained with the IgM EIA make this test unreliable. Instead, the traditional TP or IDTP should be used. In addition, while the sensitivity and specificity of the

IgG EIA appear to be high when compared with those of the CF and IDCF assays, the optical density obtained in the EIA does not correlate with the serologic titer of either of the latter tests.

Coccidioides grows within 3–7 days at 37°C on a variety of artificial media, including blood agar. Therefore, it is always useful to obtain samples of sputum or other respiratory fluids and tissues for culture in suspected cases of coccidioidomycosis. The clinical laboratory should be alerted to the possibility of this diagnosis, since *Coccidioides* can pose a significant hazard to laboratory workers if it is inadvertently inhaled. *Coccidioides* can also be identified directly. While treatment of samples with potassium hydroxide is rarely fruitful in establishing the diagnosis, examination of sputum or other respiratory fluids after Papanicolaou or Gomori methenamine silver staining reveals spherules in a significant proportion of patients with pulmonary coccidioidomycosis. For fixed tissues (e.g., those obtained from biopsy specimens), spherules with surrounding inflammation can be demonstrated with hematoxylin-eosin or Gomori methenamine silver staining.

Rx Treatment: COCCIDIOIDOMYCOSIS

(Table 104-1) Currently, there are two main classes of antifungals useful for the treatment of coccidioidomycosis. While once routinely prescribed, amphotericin B in all its formulations is now reserved for only the most severe cases of dissemination and for intrathecal or intraventricular administration to patients with coccidioidal meningitis in whom triazole therapy has failed. The original formulation of amphotericin B, which is dispersed with deoxycholate, is usually administered intravenously in doses of 0.7–1.0 mg/kg either daily or three times per week. The newer lipid-based formulations—amphotericin B lipid complex (ABLC), amphotericin B colloidal dispersion (ABCD), and amphotericin B liposomal complex—appear to offer no therapeutic advantage over the deoxycholate formulation but are associated with less renal toxicity. The lipid dispersions are administered intravenously at doses of 5 mg/kg daily or three times per week.

Triazole antifungals are the principal drugs now used to treat most cases of coccidioidomycosis. Clinical trials have demonstrated the usefulness of both fluconazole and itraconazole, and evidence indicates that itraconazole may be more efficacious against bone and joint disease. Because of its demonstrated penetration into CSF, fluconazole is the azole of choice for the treatment of coccidioidal meningitis. For both drugs, a minimal oral adult dosage of 400 mg/d should be used. The maximal dose of itraconazole is 200 mg three times daily, but higher doses of fluconazole may be given. Two newer triazole antifungals, posaconazole and voriconazole, are now available. However, given the paucity of clinical data, the high cost, and (particularly for voriconazole) the potential toxicity, these agents should be reserved for

CLINICAL PRESENTATIONS OF COCCIDIOIDOMYCOSIS, THEIR FREQUENCY, AND RECOMMENDED INITIAL THERAPY FOR THE IMMUNOCOMPETENT HOST

| CLINICAL PRESENTATION | FREQUENCY, % | RECOMMENDED THERAPY |
|--------------------------------|--------------|--|
| Asymptomatic | 60 | None |
| Primary | 40 | In most cases, none ^a |
| pneumonia (focal) | | |
| Diffuse pneumonia | <1 | Amphotericin B followed by prolonged oral triazole therapy |
| Pulmonary sequelae | 5 | |
| Nodule | — | None |
| Cavity | — | In most cases, none ^b |
| Chronic pneumonia | — | Prolonged triazole therapy |
| Disseminated disease | ≤1 | |
| Skin, bone, joint, soft tissue | — | Prolonged triazole therapy ^c |
| Meningitis | — | Life-long triazole therapy ^d |

^aTreatment is indicated for hosts with depressed cellular immunity as well as for those with prolonged symptoms and signs of increased severity, including night sweats for >3 weeks, weight loss of >10%, a complement-fixation titer of >16, and extensive pulmonary involvement on chest radiography.

^bTreatment (usually the oral triazoles fluconazole and itraconazole) is recommended for persistent symptoms.

^cIn severe cases, some clinicians would use amphotericin B as initial therapy.

^dIntraventricular or intrathecal amphotericin B is recommended in cases of triazole failure. Hydrocephalus may occur, requiring a CSF shunt.

cases that remain recalcitrant when treated with fluconazole or itraconazole. High-dose triazole therapy may be teratogenic; thus, amphotericin B should be considered as therapy for coccidioidomycosis in pregnant women.

Most patients with focal primary pulmonary coccidioidomycosis require no therapy. Patients for whom antifungal therapy should be considered include those with underlying cellular immunodeficiencies and those with prolonged symptoms and signs of extensive disease. Specific criteria include symptoms persisting for ≥2 months, night sweats occurring for >3 weeks, weight loss of >10%, a serum CF antibody titer of >1:16, and extensive pulmonary involvement apparent on chest radiograph.

Diffuse pulmonary coccidioidomycosis represents a special situation. Because most patients with this form of disease are profoundly hypoxemic and critically ill, many clinicians favor beginning therapy with amphotericin B and switching to an oral triazole once clinical improvement occurs.

The nodules that may follow primary pulmonary coccidioidomycosis do not require treatment. However, nodules are not easily distinguished from pulmonary malignancies by means of radiographic imaging (including positron emission tomography scans). Close clinical follow-up and biopsy may be required to distinguish these two entities. Most pulmonary cavities do not require therapy. Antifungal treatment should be considered in patients with persistent cough, pleuritic chest pain, and hemoptysis. Occasionally, pulmonary coccidioidal cavities become secondarily infected. This development is usually manifested by an air-fluid level within the cavity. Bacterial flora or *Aspergillus* species are commonly involved, and therapy directed at these organisms should be considered. Surgery is rarely required except in cases of persistent hemoptysis or pyopneumothorax. For chronic pulmonary coccidioidomycosis, prolonged antifungal therapy—lasting for at least 1 year—is usually required, with monitoring of symptoms, radiographic changes, sputum cultures, and serologic titers.

Most cases of disseminated coccidioidomycosis require prolonged antifungal therapy. Duration of treatment is based on resolution of the signs and symptoms of the lesion in conjunction with a significant decline in serum CF antibody titer. Such therapy routinely is continued for at least several years. Relapse occurs in 15–30% of individuals once therapy is discontinued.

Coccidioidal meningitis poses a special challenge. While most patients with this form of disease respond to treatment with oral triazoles, 80% experience relapse when therapy is stopped. Thus, life-long therapy is recommended. In cases of triazole failure, intrathecal or intraventricular amphotericin B may be used. Installation requires considerable expertise and should be performed only by an experienced health care provider. Shunting of CSF in addition to appropriate antifungal therapy is required in cases of meningitis complicated by hydrocephalus. It is prudent to obtain expert consultation in all cases of coccidioidal meningitis.

PREVENTION

There are no proven methods to reduce the risk of acquiring coccidioidomycosis among residents of an endemic region. Avoidance of direct contact with uncultivated soil or with visible dust containing soil presumably reduces the risk. Prophylactic antifungal therapy may be useful in patients who have evidence of active or recent coccidioidomycosis and are about to undergo allogeneic solid-organ transplantation. Data on the use of antifungal agents for prophylaxis in other situations are scanty and do not suggest efficacy.

CHAPTER 105

BLASTOMYCOSIS

Stanley W. Chapman ■ Donna C. Sullivan

Blastomycosis is a systemic pyogranulomatous infection, primarily involving the lungs, which arises after inhalation of the conidia of *Blastomyces dermatitidis*. Pulmonary blastomycosis varies from an asymptomatic infection to acute or chronic pneumonia. Hematogenous dissemination occurs frequently. Extrapulmonary disease of the skin, bones, and genitourinary system is common, but almost any organ can be infected.

ETIOLOGIC AGENT

B. dermatitidis is the asexual state of *Ajellomyces dermatitidis*. Two serotypes have been identified on the basis of the presence or absence of the A antigen. *B. dermatitidis* exhibits thermal dimorphism, growing as the mycelial phase at room temperature and as the yeast phase at 37°C. Primary isolation is most dependable for the mycelial phase incubated at 30°C. Definitive identification usually requires conversion to the yeast phase at 37°C or, more commonly, the use of nucleic acid amplification techniques (e.g., AccuProbe, Gen-Probe, San Diego, CA) that detect mycelial-phase growth. Yeast cells are usually 8–15 µm in diameter, have thick refractile cell walls, are multinucleate, and reproduce by a single, large, broad-based bud.

EPIDEMIOLOGY

Most cases of blastomycosis have been reported in North America. Endemic areas include the southeastern and south-central states bordering the Mississippi and Ohio river basins, the midwestern states and Canadian provinces bordering the Great Lakes, and a small area in New York and Canada along the St. Lawrence River. Outside North America, blastomycosis has been reported most frequently in Africa.

Early studies of endemic cases indicated that middle-aged men with outdoor occupations were at greatest risk. Reported outbreaks, however, do not suggest a predilection according to sex, age, race, occupation, or season. *B. dermatitidis* probably grows as microfoci in the warm, moist soil of wooded areas rich in organic debris. Exposure to soil, whether related to work or recreation, appears to be the common factor associated with infection.

PATHOGENESIS

After inhalation, the conidia of *B. dermatitidis* are susceptible to phagocytosis and killing in the lungs by polymorphonuclear leukocytes, monocytes, and alveolar macrophages. This phagocytic response represents innate immunity and probably explains the high frequency of asymptomatic infections in outbreaks. Conidia that escape phagocytosis rapidly convert to the yeast phase in tissue. The greater resistance of the thick-walled yeast form to phagocytosis and killing probably contributes to infection. This yeast-phase conversion also induces the expression of the 120-kDa glycoprotein BAD-1, which is an adhesin, an essential virulence factor, and the major epitope for humoral and cellular immunity. The primary acquired host defense against *B. dermatitidis* is cellular immunity mediated by antigen-specific T cells and lymphokine-activated macrophages.

Approach to the Patient: BLASTOMYCOSIS

Whether acute or chronic, blastomycosis mimics many other disease processes. For example, acute pulmonary blastomycosis may present with signs and

symptoms indistinguishable from those of bacterial pneumonia or influenza. Chronic pulmonary blastomycosis most commonly mimics malignancy or tuberculosis. Skin lesions are often misdiagnosed as basal cell or squamous cell carcinoma, pyoderma gangrenosum, or keratoacanthoma. Laryngeal lesions are frequently mistaken for squamous cell carcinoma. Thus, the clinician must maintain a high index of suspicion and perform a careful histologic evaluation of secretions or biopsy material from patients who live in or have visited regions endemic for blastomycosis.

CLINICAL MANIFESTATIONS

Acute pulmonary infection is usually diagnosed in association with point-source outbreaks and is accompanied by the abrupt onset of fever, chills, pleuritic chest pain, arthralgias, and myalgias. Cough is initially nonproductive but frequently becomes purulent as disease progresses. Chest radiographs usually reveal alveolar infiltrates with consolidation. Pleural effusions and hilar adenopathy are uncommon. Most patients diagnosed with pulmonary blastomycosis have chronic indolent pneumonia with signs and symptoms of fever, weight loss, productive cough, and hemoptysis. The most common radiologic findings are alveolar infiltrates with or without cavitation, mass lesions that mimic bronchogenic carcinoma, and fibronodular infiltrates. Respiratory failure (adult respiratory distress syndrome) associated with miliary disease or diffuse pulmonary infiltrates is more common among immunocompromised patients, especially those in the late stages of AIDS (Chap. 90). Mortality rates are $\geq 50\%$ among these patients, and most deaths occur within the first few days of therapy.

Skin disease is the most common extrapulmonary manifestation of blastomycosis. Two types of skin lesions occur: verrucous (more common) and ulcerative. Osteomyelitis is associated with as many as one-fourth of *B. dermatitidis* infections. The vertebrae, pelvis, sacrum, skull, ribs, or long bones are most frequently involved. Patients with *B. dermatitidis* osteomyelitis often present with contiguous soft-tissue abscesses or chronic draining sinuses. In men, blastomycosis may involve the prostate and epididymis. Central nervous system (CNS) disease occurs in $<5\%$ of immunocompetent patients with blastomycosis. In AIDS patients, however, CNS disease has been reported in $\sim 40\%$ of cases, usually presenting as a brain abscess. Less common forms of CNS disease are cranial or spinal epidural abscess and meningitis.

DIAGNOSIS

Definitive diagnosis of blastomycosis requires growth of the organism from sputum, pus, or biopsy material. A presumptive diagnosis is made by visualization of the characteristic broad-based budding yeast in clinical specimens. Serologic diagnosis of blastomycosis is of limited

usefulness because of cross-reactivity with other fungal antigens.

A *Blastomyces* antigen assay that detects antigen in urine and serum is commercially available (Mira Vista Diagnostics, Indianapolis, IN). Antigen detection in urine appears to be more sensitive than serum antigen detection. This antigen test may be useful for monitoring of patients during therapy or for early detection of relapse.

Rx Treatment: BLASTOMYCOSIS

The Infectious Diseases Society of America has published guidelines for the treatment of blastomycosis. Selection of an appropriate therapeutic regimen must be based on the clinical form and severity of the disease, the immune status of the patient, and the toxicity of the antifungal agent (Table 105-1). Although spontaneous cures of acute pulmonary infection have been well documented, there are no criteria by which to distinguish patients whose disease will progress or disseminate. Thus, almost all patients with blastomycosis should be treated.

Itraconazole is the agent of choice for immunocompetent patients with mild to moderate pulmonary or non-CNS extrapulmonary disease. Therapy is continued for 6–12 months. Amphotericin B is the preferred initial treatment for patients who are severely immunocompromised, who have life-threatening disease or CNS disease, or whose disease progresses during treatment with itraconazole. Although not rigorously studied, lipid formulations of amphotericin B can provide an alternative for patients who cannot tolerate amphotericin B deoxycholate. Most patients with non-CNS disease whose clinical condition improves after an initial course of amphotericin B (usually 2 weeks in duration) can be switched to itraconazole to complete 6–12 months of therapy. Fluconazole, because of its excellent penetration of the CNS, may have a role in the treatment of patients with brain abscess or meningitis after an initial course of amphotericin B.

The newer triazoles voriconazole and posaconazole have not been studied extensively in human cases of blastomycosis. The echinocandins have variable activity against *B. dermatitidis* and have no place in the treatment of blastomycosis.

PROGNOSIS

Clinical and mycologic response rates are 90–95% among compliant immunocompetent patients given itraconazole for mild to moderate pulmonary and extrapulmonary disease without CNS involvement. Bone and joint disease usually requires 12 months of therapy. The $<5\%$ of infections that relapse after an initial course of itraconazole usually respond well to a second treatment course.

TABLE 105-1

TREATMENT OF BLASTOMYCOSIS

| DISEASE | PRIMARY THERAPY | ALTERNATIVE THERAPY |
|---|--|--|
| Immunocompetent Patient/Life-Threatening Disease | | |
| Pulmonary | AmB, ^a 0.7–1.0 mg/kg qd (total dose: 1.5–2.5 g) | Itraconazole, 200–400 mg/d (once patient's condition has stabilized) |
| Disseminated CNS | AmB, 0.7–1.0 mg/kg qd (total dose: at least 2 g) | Fluconazole, 800 mg/d (if patient is intolerant to full course of AmB) |
| Non-CNS | AmB, 0.7–1.0 mg/kg qd (total dose: 1.5–2.5 g) | Itraconazole, 200–400 mg/d (once patient's condition has stabilized) |
| Immunocompetent Patient/Non-Life-Threatening Disease | | |
| Pulmonary or disseminated (non-CNS) | Itraconazole, 200–400 mg/d or AmB, 0.5–0.7 mg/kg qd (in patients intolerant to itraconazole or whose disease progresses despite therapy) | Fluconazole, 400–800 mg/d or Ketoconazole, 400–800 mg/d |
| Immunocompromised Patient^b | | |
| All infections | AmB, 0.7–1.0 mg/kg qd (total dose: 1.5–2.5 g) | Itraconazole, 200–400 mg/d (non-CNS disease, once clinically improved) |

^aIn all regimens listed, an AmB lipid formulation (3.0–5.0 mg/kg qd) can be substituted for AmB deoxycholate.

^bSuppressive therapy with itraconazole may be considered for patients whose immunocompromised state continues. Fluconazole (800 mg/d) may be useful for patients who have CNS disease or are intolerant to itraconazole.

Note: AmB, amphotericin B; CNS, central nervous system.

CHAPTER 106

CRYPTOCOCOCCOSIS

Arturo Casadevall

DEFINITION AND ETIOLOGY

Cryptococcus neoformans, a yeast-like fungus, is the etiologic agent of cryptococcosis. Cryptococcal strains are antigenically and genetically diverse. Both *C. neoformans* and *C. gattii* are pathogenic for humans and can cause cryptococcosis. *C. neoformans* consists of serotypes A and D, and

C. gattii consists of serotypes B and C. Currently, most authorities further subdivide *C. neoformans* into two varieties: *grubii* (serotype A) and *neoformans* (serotype D). Most clinical microbiology laboratories do not routinely distinguish among cryptococcal species and varieties but rather identify all isolates simply as *C. neoformans*.

Cryptococcosis was first described in the 1890s but remained relatively rare until the mid-twentieth century, when advances in diagnosis and increases in the number of immunosuppressed individuals markedly raised its reported prevalence. The spectrum of disease caused by *C. neoformans* consists predominantly of meningoencephalitis and pneumonia, but skin and soft tissue infections also occur. Serologic studies have shown that, although cryptococcal infection is common among immunocompetent individuals, cryptococcal disease (cryptococcosis) is relatively rare in the absence of impaired immunity. Individuals at high risk for cryptococcosis include patients with hematologic malignancies, recipients of solid organ transplants who require ongoing immunosuppressive therapy, persons whose medical conditions necessitate glucocorticoid therapy, and patients with advanced HIV infection and CD4+ T-lymphocyte counts of <200/μL. Since the onset of the HIV pandemic in the early 1980s, the overwhelming majority of cryptococcosis cases have occurred in patients with AIDS (Chap. 90). To understand the impact of HIV infection on the epidemiology of cryptococcosis, it is instructive to note that in the early 1990s there were >1000 cases of cryptococcal meningitis each year in New York City—a figure far exceeding that for all cases of bacterial meningitis. With the advent of effective antiretroviral therapy, the incidence of AIDS-related cryptococcosis has been sharply reduced among treated individuals; however, the disease remains distressingly common in regions where antiretroviral therapy is not readily available, such as Africa and Asia, where up to one-third of patients with AIDS have cryptococcosis.

Cryptococcal infection is acquired from the environment. *C. neoformans* and *C. gattii* inhabit different ecologic niches. *C. neoformans* is frequently found in soils contaminated with avian excreta and can easily be recovered from shaded and humid soils contaminated with pigeon droppings. In contrast, *C. gattii* is not found in bird feces. Instead, it inhabits a variety of arboreal species, including several types of eucalyptus tree. *C. neoformans* strains are found throughout the world; however, var. *grubii* (serotype A) strains are far more common than var. *neoformans* (serotype D) strains among both clinical and environmental isolates. The geographic distribution of *C. gattii* was thought to be largely limited to tropical regions until an outbreak of cryptococcosis caused by a new serotype B strain began in Vancouver in 1999. In addition to the different geographic distributions of the two cryptococcal species, individual susceptibility to these species affects epidemiology. Cryptococcosis caused by the *C. neoformans* varieties occurs mostly in individuals with AIDS (Chap. 90) and other forms of impaired immunity. In contrast, *C. gattii*-related disease is not associated with specific immune deficits and often occurs in immunocompetent individuals.

PATHOGENESIS

Cryptococcal infection is acquired by inhalation of aerosolized infectious particles. The exact nature of these particles is not known; the two leading candidate forms

are small desiccated yeast cells and basidiospores. Little is known about the pathogenesis of initial infection. Serologic studies have shown that cryptococcal infection is acquired in childhood, but it is not known whether the initial infection is symptomatic. Given serologic documentation that cryptococcal infection is common yet cryptococcal disease is rare, the consensus is that pulmonary defense mechanisms in immunologically intact individuals are highly effective at containing *C. neoformans*. It is not clear whether initial infection leads to a state of immunity or whether most individuals are subject throughout life to frequent and recurrent infections that resolve without clinical disease. However, evidence indicates that some human cryptococcal infections lead to a state of latency in which viable organisms are harbored for prolonged periods, possibly in granulomas. Thus the inhalation of *C. neoformans* can be followed by clearance of the organism or establishment of the latent state. The consequences of prolonged harboring of *C. neoformans* in the lung are not known, but evidence from animal studies indicates that the organism's prolonged presence could alter the immunologic milieu in the lung and predispose to allergic airway disease.

Cryptococcosis usually presents clinically as chronic meningoencephalitis. The mechanisms by which *C. neoformans* undergoes extrapulmonary dissemination and enters the central nervous system (CNS) remain poorly understood. There is evidence that yeast cells can migrate directly across the endothelium by a mechanism that may be associated with changes in polysaccharide structure. *C. neoformans* has well-defined virulence factors that include the polysaccharide capsule, the ability to make melanin, and the elaboration of enzymes (e.g., phospholipase and urease) that enhance the survival of fungal cells in tissue. Among these virulence factors, the capsule and melanin production have been most extensively studied. The *C. neoformans* capsule is antiphagocytic, and the capsular polysaccharide has been associated with numerous deleterious effects on host immune function. Cryptococcal infections elicit little or no tissue inflammatory response. The immune dysfunction seen in cryptococcosis has been attributed to the release of copious amounts of capsular polysaccharide into tissues, where it probably interferes with local immune responses (Fig. 106-1). In clinical practice, the cryptococcal polysaccharide is the antigen that is measured as a diagnostic marker of *C. neoformans* infection.

Approach to the Patient: CRYPTOCOCCOSIS

Cryptococcosis should be included in the differential diagnosis when any patient presents with findings suggestive of chronic meningitis. Concern about cryptococcosis is heightened by a history of headache and neurologic symptoms in a patient with an underlying immunosuppressive disorder or state that is associated with an increased incidence of cryptococcosis, such as advanced HIV infection or solid organ transplantation.

**FIGURE 106-1**

Cryptococcal antigen in human brain tissue, as revealed by immunohistochemical staining. Brown areas show polysaccharide deposits in the midbrain of a patient who died of cryptococcal meningitis. (Reprinted with permission from SC Lee et al: *Hum Pathol* 27:839, 1996.)

CLINICAL MANIFESTATIONS

The clinical manifestations of cryptococcosis reflect the site of fungal infection. *C. neoformans* infection can affect any tissue or organ, but the majority of cases that come to clinical attention involve the CNS and/or the lungs. CNS involvement usually presents as signs and symptoms of chronic meningitis, such as headache, fever, lethargy, sensorium deficits, memory deficits, cranial nerve paresis, vision deficits, and meningismus. Cryptococcal meningitis differs from bacterial meningitis in that many *Cryptococcus*-infected patients present with symptoms of several weeks' duration. In addition, classic characteristics of meningeal irritation, such as meningismus, may be absent in cryptococcal meningitis. Indolent cases can present as subacute dementia. Meningeal cryptococcosis can lead to sudden catastrophic vision loss.

Pulmonary cryptococcosis usually presents as cough, increased sputum production, and chest pain. Patients infected with *C. gattii* can present with granulomatous pulmonary masses known as *cryptococcomas*. Fever develops in a minority of cases. Like CNS disease, pulmonary cryptococcosis can follow an indolent course, and the majority of cases probably do not come to clinical attention. In fact, many cases are discovered incidentally during the workup of an abnormal chest radiograph obtained for other diagnostic purposes. Pulmonary cryptococcosis is often associated with antecedent diseases such as malignancy, diabetes, and tuberculosis.

Skin lesions are common in patients with disseminated cryptococcosis and can be highly variable, including papules, plaques, purpura, vesicles, tumor-like lesions, and rashes. The spectrum of cryptococcosis in HIV-infected patients is so varied and has changed so much since the advent of antiretroviral therapy that a distinction between HIV-related and HIV-unrelated cryptococcosis is no longer pertinent. In patients with

**FIGURE 106-2**

Disseminated fungal infection. A liver transplant recipient developed six cutaneous lesions similar to the one shown. Biopsy and serum antigen testing demonstrated *Cryptococcus*. Important features of the lesion include a benign-appearing fleshy papule with central umbilication resembling molluscum contagiosum. (Photo courtesy of Dr. Lindsey Baden; with permission.)

AIDS and solid organ transplant recipients, the lesions of cutaneous cryptococcosis often resemble those of molluscum contagiosum (Fig. 106-2; Chaps. 84 and 90).

DIAGNOSIS

A diagnosis of cryptococcosis requires the demonstration of *C. neoformans* in normally sterile tissues. Visualization of the capsule of fungal cells in cerebrospinal fluid (CSF) mixed with India ink is a useful rapid diagnostic technique. *C. neoformans* cells in India ink have a distinctive appearance because their capsules exclude ink particles. However, the CSF India ink examination may yield negative results in patients with a low fungal burden. This examination should be performed by a trained individual, since leukocytes and fat globules can sometimes be mistaken for fungal cells. Cultures of CSF and blood that are positive for *C. neoformans* are diagnostic for cryptococcosis. In cryptococcal meningitis, CSF examination usually reveals evidence of chronic meningitis with mononuclear cell pleocytosis and increased protein levels. A particularly useful test is cryptococcal antigen (CRAg) detection in CSF and blood. The assay is based on serologic detection of cryptococcal polysaccharide and is both sensitive and specific. A positive cryptococcal antigen test provides strong presumptive evidence for cryptococcosis; however, because the result is often negative in pulmonary cryptococcosis, the test is less useful in the diagnosis of pulmonary disease.

R_x Treatment: **CRYPTOCOCCOSIS**

Both the site of infection and the immune status of the host must be considered in the selection of therapy for cryptococcosis. The disease has two general patterns of manifestation: (1) pulmonary cryptococcosis, with no evidence of extrapulmonary dissemination; and (2) extrapulmonary (systemic) cryptococcosis, with or without meningoencephalitis. Pulmonary cryptococcosis in an immunocompetent host sometimes resolves without therapy. However, given the propensity of *C. neoformans* to disseminate from the lung, the inability to gauge the host's immune status precisely, and the availability of low-toxicity therapy in the form of fluconazole, the current recommendation is for pulmonary cryptococcosis in an immunocompetent individual to be treated with fluconazole (200–400 mg/d for 3–6 months). Extrapulmonary cryptococcosis without CNS involvement in an immunocompetent host can be treated with the same regimen, although amphotericin B (AmB; 0.5–1.0 mg/kg daily for 4–6 weeks) may be required for more severe cases. In general, extrapulmonary cryptococcosis without CNS involvement requires less intensive therapy—with the caveat that morbidity and death in cryptococcosis are associated with meningeal involvement. Thus the decision to categorize cryptococcosis as “extrapulmonary without CNS involvement” should be made only after careful evaluation of the CSF reveals no evidence of *C. neoformans* infection. For CNS involvement in a host without AIDS or obvious immune impairment, most authorities recommend initial therapy with AmB (0.5–1.0 mg/kg daily) during an induction phase, which is followed by prolonged therapy with fluconazole (400 mg/d) during a consolidation phase. For cryptococcal meningoencephalitis without a concomitant immunosuppressive condition, the recommended regimen is AmB (0.5–1.0 mg/kg) plus flucytosine (100 mg/kg) daily for 6–10 weeks. Alternatively, patients can be treated with AmB (0.5–1.0 mg/kg) plus flucytosine (100 mg/kg) daily for 2 weeks and then with fluconazole (400 mg/d) for at least 10 weeks. Patients with immunosuppression are treated with the same initial regimens except that consolidation therapy with fluconazole is given for a prolonged period to prevent relapse.

Cryptococcosis in patients with HIV infection always requires aggressive therapy and is considered incurable unless immune function improves. Consequently, therapy for cryptococcosis in the setting of AIDS has two phases: induction therapy (intended to reduce the fungal burden and alleviate symptoms) and lifelong maintenance therapy (to prevent a symptomatic clinical relapse). Pulmonary and extrapulmonary cryptococcosis without evidence of CNS involvement can be treated with fluconazole (200–400 mg/d). In patients who have more extensive disease, flucytosine (100 mg/d) may be added to the fluconazole regimen for 10 weeks, with lifelong fluconazole maintenance therapy thereafter.

For HIV-infected patients with evidence of CNS involvement, most authorities recommend induction therapy with AmB. An acceptable regimen is AmB (0.7–1.0 mg/kg) plus flucytosine (100 mg) daily for 2 weeks followed by fluconazole (400 mg/d) for at least 10 weeks and then by lifelong maintenance therapy with fluconazole (200 mg/d). Fluconazole (400–800 mg/d) plus flucytosine (150–100 mg/d) for 6–10 weeks followed by fluconazole (200 mg/d) as maintenance therapy can be used as an alternative. Lipid formulations of AmB can be substituted for AmB deoxycholate in patients with renal impairment. Neither caspofungin nor mycofungin is effective against *C. neoformans*, and neither drug has a role in the treatment of cryptococcosis. Cryptococcal meningoencephalitis is often associated with increased intracranial pressure, which is believed to be responsible for damage to the brain and cranial nerves. Appropriate management of CNS cryptococcosis requires careful attention to the management of intracranial pressure, including the reduction of pressure by repeated therapeutic lumbar puncture and the placement of shunts.

In HIV-infected patients with previously treated cryptococcosis who are receiving fluconazole maintenance therapy, it may be possible to discontinue antifungal drug treatment if antiretroviral therapy results in immunologic improvement. However, certain recipients of maintenance therapy who have a history of successfully treated cryptococcosis can develop a troublesome immune reconstitution syndrome when antiretroviral therapy produces a rebound in immunologic function.

PROGNOSIS AND COMPLICATIONS

Even with antifungal therapy, cryptococcosis is associated with high rates of morbidity and death. For the majority of patients with cryptococcosis, the most important prognostic factor is the extent and the duration of the underlying immunologic deficits that predisposed them to develop the disease. Therefore, cryptococcosis is often curable with antifungal therapy in individuals with no apparent immunologic dysfunction, but, in patients with severe immunosuppression (e.g., those with AIDS), the best that can be hoped for is that antifungal therapy will induce remission, which can then be maintained with lifelong suppressive therapy. Before the advent of antiretroviral therapy, the median overall survival period for AIDS patients with cryptococcosis was <1 year. Cryptococcosis in patients with underlying neoplastic disease has a particularly poor prognosis. For CNS cryptococcosis, poor prognostic markers are a positive CSF assay for yeast cells by initial India ink examination (evidence of a heavy fungal burden), high CSF pressure, low CSF glucose levels, low CSF pleocytosis (<2/μL), recovery of yeast cells from extraneural sites, the absence of antibody to *C. neoformans*, a CSF or serum cryptococcal antigen level of ≥1:32, and concomitant glucocorticoid therapy or hematologic malignancy. A response to treatment does not guarantee cure since relapse of cryptococcosis is common even among

patients with relatively intact immune systems. Complications of CNS cryptococcosis include cranial nerve deficits, vision loss, and cognitive impairment.

PREVENTION

No vaccine is available for cryptococcosis. In patients at high risk (e.g., those with advanced HIV infection and CD4+ T lymphocyte counts of <200/ μ L), primary prophylaxis with fluconazole (200 mg/d) is effective in reducing the prevalence of disease. Since antiretroviral therapy raises the CD4+ T lymphocyte count, it constitutes an immunologic form of prophylaxis. However, cryptococcosis in the setting of immune reconstitution has been reported in patients with HIV infection and recipients of solid organ transplants.

CHAPTER 107

CANDIDIASIS

John E. Edwards, Jr.

The genus *Candida* encompasses more than 150 species, only a few of which cause disease in humans. With rare exceptions, the human pathogens are *C. albicans*, *C. guilliermondii*, *C. krusei*, *C. parapsilosis*, *C. tropicalis*, *C. kefyr*, *C. lusitanae*, *C. dubliniensis*, and *C. glabrata*. Ubiquitous in nature, these organisms are found on inanimate objects, in foods, and on animals and are normal commensals of humans. They inhabit the gastrointestinal tract (including the mouth and oropharynx), the female genital tract, and the skin. Although cases of candidiasis have been described since antiquity in debilitated patients, the advent of *Candida* species as common human pathogens dates to the introduction of modern therapeutic approaches that suppress normal host defense mechanisms. Of these relatively recent advances, the most important is the use of antibacterial agents that alter the normal human microbial flora and allow nonbacterial species to become more prevalent in the commensal flora. With the introduction of antifungal agents, the causes of *Candida* infections shifted from an almost complete dominance of *C. albicans* to the common involvement of *C. glabrata* and the other species listed above. The non-*albicans* species now account for approximately half of all cases of candidemia and hematogenously disseminated candidiasis. Recognition of this change is

clinically important, since the various species differ in susceptibility to the newer antifungal agents. In developed countries, where medical therapeutics are commonly used, *Candida* species are now among the most common nosocomial pathogens. In the United States, these species are the fourth most common isolates from the blood of hospitalized patients.

Candida is a small, thin-walled, ovoid yeast that measures 4–6 μ m in diameter and reproduces by budding. Organisms of this genus occur in three forms in tissue: blastospores, pseudohyphae, and hyphae. *Candida* grows readily on simple medium; lysis centrifugation enhances its recovery from blood. Species are identified by biochemical testing (currently with automated devices) or on special agar.

PATHOGENESIS

In the most serious form of *Candida* infection, the organisms disseminate hematogenously and form microabscesses and small macroabscesses in major organs. Although the exact mechanism is not known, *Candida* probably enters the bloodstream from mucosal surfaces after growing to large numbers as a consequence of bacterial suppression by

antibacterial drugs; alternatively, in some instances, the organism may enter from the skin. A change from the blastospore stage to the pseudohyphal and hyphal stages is generally considered integral to the organism's penetration into tissue. However, *C. glabrata* can cause extensive infection even though it does not transform into pseudohyphae or hyphae. Numerous reviews of cases of hematogenously disseminated candidiasis have identified the following predisposing factors or conditions: antibacterial agents, indwelling intravascular catheters, hyperalimentation fluids, indwelling urinary catheters, parenteral glucocorticoids, respirators, neutropenia, abdominal and thoracic surgery, cytotoxic chemotherapy, and immunosuppressive agents for organ transplantation. Patients with severe burns, low-birth-weight neonates, and persons using illicit IV drugs are also susceptible. HIV-infected patients with low CD4+ T cell counts and patients with diabetes are susceptible to mucocutaneous infection, which may eventually develop into the disseminated form when other predisposing factors are encountered. Women who receive antibacterial agents may develop vaginal candidiasis.

Innate immunity is the most important defense mechanism against hematogenously disseminated candidiasis, and the neutrophil is the most important component of this defense. Although many immunocompetent individuals have antibodies to *Candida*, the role of these antibodies in defense against the organism is not clear.

CLINICAL MANIFESTATIONS

Mucocutaneous Candidiasis

Thrush is characterized by white, adherent, painless, discrete or confluent patches in the mouth, tongue, or esophagus, occasionally with fissuring at the corners of the mouth. This form of *Candida* disease may also occur at points of contact with dentures. Organisms are identifiable in gram-stained scrapings from lesions. The occurrence of thrush in a young, otherwise healthy-appearing person should prompt an investigation for underlying HIV infection. More commonly, thrush is seen as a nonspecific manifestation of severe debilitating illness. Vulvovaginal candidiasis is accompanied by pruritus, pain, and vaginal discharge that is usually thin but may contain whitish "curds" in severe cases.

Other *Candida* skin infections include paronychia, a painful swelling at the nail-skin interface; onychomycosis, a fungal nail infection rarely caused by this genus; intertrigo, an erythematous irritation with redness and pustules in the skin folds; balanitis, an erythematous-pustular infection of the glans penis; erosio interdigitalis blastomycetica, an infection between the digits of the hands or toes; folliculitis, with pustules developing most frequently in the area of the beard; perianal candidiasis, a pruritic, erythematous, pustular infection surrounding the anus; and diaper rash, a common erythematous-pustular perineal infection in infants. Generalized disseminated cutaneous candidiasis, another form of infection that occurs primarily in infants, is characterized by widespread eruptions over the trunk, thorax, and extremities. The diagnostic macronodular lesions of hematogenously disseminated candidiasis (Fig. 107-1) indicate a high probability for

FIGURE 107-1

Macronodular skin lesions associated with hematogenously disseminated candidiasis. *Candida* organisms are usually but not always visible on histopathologic examination. The fungi grow when a portion of the biopsied specimen is cultured. Therefore, for optimal identification, both histopathology and culture should be performed. (Image courtesy of Dr. Noah Craft and the Victor Newcomer collection at UCLA, archived by Logical Images, Inc.; with permission.)

dissemination to multiple organs as well as the skin. While the lesions are seen predominantly in immunocompromised patients treated with cytotoxic drugs, they may also develop in patients without neutropenia.

Chronic mucocutaneous candidiasis is a heterogeneous infection of the hair, nails, skin, and mucous membranes that persists despite intermittent therapy. The onset of disease usually comes in infancy or within the first two decades of life but in rare cases can come in later life. The condition may be mild and limited to a specific area of the skin or nails, or it may take a severely disfiguring form (*Candida* granuloma) characterized by exophytic outgrowths on the skin. The condition is usually associated with specific immunologic dysfunction; most frequently reported is a failure of T lymphocytes to proliferate or to stimulate cytokines in response to stimulation by *Candida* antigens in vitro. Approximately half of patients have associated endocrine abnormalities that together are designated the autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome. This syndrome is due to mutations in the autoimmune regulator (*AIRE*) gene and is most prevalent among Finns, Iranian Jews, Sardinians, northern Italians, and Swedes. Conditions that usually follow the onset of the disease include hypoparathyroidism, adrenal insufficiency, autoimmune thyroiditis, Graves' disease, chronic active hepatitis, alopecia, juvenile-onset pernicious anemia, malabsorption, and primary hypogonadism. In addition, dental enamel dysplasia, vitiligo, pitted nail dystrophy, and calcification of the tympanic membranes may occur. Patients with chronic mucocutaneous candidiasis rarely develop hematogenously

disseminated candidiasis, probably because their neutrophil function remains intact.

Deeply Invasive Candidiasis

Deeply invasive *Candida* infections may or may not be due to hematogenous seeding. Deep esophageal infection may result from penetration by organisms from superficial esophageal erosions; joint or deep wound infection from contiguous spread of organisms from the skin; kidney infection from catheter-initiated spread of organisms through the urinary tract; infection of intraabdominal organs and the peritoneum from perforation of the gastrointestinal tract; and gallbladder infection from retrograde migration of organisms from the gastrointestinal tract into the biliary drainage system.

However, far more commonly, deeply invasive candidiasis is a result of hematogenous seeding of various organs as a complication of candidemia. Once the organism gains access to the intravascular compartment (either from the gastrointestinal tract or, less often, from the skin through the site of an indwelling intravascular catheter), it may spread hematogenously to a variety of deep organs. The brain, chorioretina (Fig. 107-2), heart, and kidneys are most commonly infected and the liver and spleen less commonly so (most often in neutropenic patients). In fact, nearly any organ can become involved, including the endocrine glands, pancreas, heart valves (native or prosthetic), skeletal muscle, joints (native or prosthetic), bone, and meninges. *Candida* organisms may also spread hematogenously to the skin and cause classic macronodular lesions (Fig. 107-1). Frequently, painful muscular involvement is also evident beneath the area of

affected skin. Chorioretinal involvement and skin involvement are highly significant, since both findings are associated with a very high probability of abscess formation in multiple deep organs as a result of generalized hematogenous seeding. Ocular involvement (Fig. 107-2) may require specific treatment, such as partial vitrectomy to prevent permanent blindness. An ocular examination is indicated for all patients with candidemia, whether or not they have ocular manifestations.

DIAGNOSIS

The diagnosis of *Candida* infection is established by visualization of pseudohyphae or hyphae on wet mount (saline and 10% KOH), tissue Gram's stain, periodic acid-Schiff stain, or methenamine silver stain in the presence of inflammation. Absence of organisms on hematoxylin-eosin staining does not reliably exclude *Candida* infection. The most challenging aspect of diagnosis is determining which patients with *Candida* isolates have hematogenously disseminated candidiasis. For instance, recovery of *Candida* from sputum, urine, or peritoneal catheters may indicate mere colonization rather than deep-seated infection, and *Candida* isolation from the blood of patients with indwelling intravascular catheters may reflect inconsequential seeding of the blood from or growth of the organisms on the catheter. Despite extensive research into both antigen and antibody detection systems, there is currently no widely available and validated diagnostic test to distinguish patients with inconsequential seeding of the blood from those whose positive blood cultures represent hematogenous dissemination to multiple organs. Many studies are under way to establish the utility of the β -glucan test. Meanwhile, the presence of ocular or macronodular skin lesions is highly suggestive of widespread infection of multiple deep organs.

FIGURE 107-2

Hematogenous *Candida* endophthalmitis. A classic off-white lesion projecting from the chorioretina into the vitreous causes the surrounding haze. The lesion is composed primarily of inflammatory cells rather than organisms. Lesions of this type may progress to cause extensive vitreal inflammation and eventual loss of the eye. Partial vitrectomy, combined with IV and possibly intravitreal antifungal therapy, may be helpful in controlling the lesions. (Image courtesy of Dr. Gary Holland; with permission.)

Treatment:

CANDIDA INFECTIONS

MUCOCUTANEOUS CANDIDA INFECTION

The treatment of mucocutaneous candidiasis is summarized in [Table 107-1](#).

CANDIDEMIA AND SUSPECTED HEMATOGENOUSLY DISSEMINATED CANDIDIASIS

All patients with candidemia are now treated with a systemic antifungal agent. A certain percentage of patients, including many of those who have candidemia associated with an indwelling intravascular catheter, probably have “benign” candidemia rather than deep-organ seeding. However, because there is no reliable way to distinguish benign candidemia from deep-organ infection, and because antifungal drugs less toxic than amphotericin B are available, it has become the standard of practice to treat all patients with candidemia, whether or not there is clinical evidence of deep-organ involvement. In addition, if an indwelling intravascular catheter may be involved, it is best to remove or replace the device whenever possible.

TABLE 107-1
TREATMENT OF MUCOCUTANEOUS CANDIDAL INFECTIONS

| DISEASE | PREFERRED TREATMENT | ALTERNATIVES |
|--------------|--|--|
| Cutaneous | Topical azole | Topical nystatin |
| Vulvovaginal | Oral fluconazole (150 mg) or azole cream or suppository | Nystatin suppository |
| Thrush | Clotrimazole troches | Nystatin |
| Esophageal | Fluconazole tablets (100–200 mg/d) or itraconazole solution (200 mg/d) | Caspofungin, micafungin, or amphotericin B |

The drugs used for the treatment of candidemia and suspected disseminated candidiasis are listed in [Table 107-2](#). Various lipid formulations of amphotericin B, three echinocandins, and the azoles fluconazole and voriconazole are used; no agent within a given class has been clearly identified as superior to the others. Most institutions choose an agent from each class on the basis of their own specific microbial epidemiology, strategies to minimize toxicities, and cost considerations. Unless azole resistance is considered likely, fluconazole is the agent of choice for the treatment of candidemia and suspected disseminated candidiasis in nonneutropenic, hemodynamically stable patients. Initial treatment in the context of likely azole resistance depends, as mentioned above, on the epidemiology of the individual hospital. For example, certain hospitals have a high rate of recovery of *C. glabrata*, while others do not. For hemodynamically unstable or neutropenic patients, initial treatment with broader-spectrum agents is desirable; these drugs include polyenes, echinocandins, or later-generation azoles such as voriconazole. Once the clinical response

has been assessed and the pathogen specifically identified, the regimen can be altered accordingly. At present, the vast majority of *C. albicans* isolates are sensitive to fluconazole. Isolates of *C. glabrata* and *C. krusei* are less sensitive to fluconazole and more sensitive to polyenes and echinocandins. *C. parapsilosis* is less sensitive to echinocandins in vitro, although the clinical significance of this finding is not known.

Some generalizations about the management of specific *Candida* infections are possible. Recovery of *Candida* from sputum is almost never indicative of underlying pulmonary candidiasis and does not by itself warrant antifungal treatment. Similarly, *Candida* in the urine of a patient with an indwelling bladder catheter may represent colonization only rather than bladder or kidney infection; however, the threshold for systemic treatment is lower in severely ill patients in this category since it is not possible to distinguish colonization from lower or upper urinary tract infection. If the isolate is *C. albicans*, most clinicians use oral fluconazole rather than a bladder washout with amphotericin, which was more commonly used in the past. The significance of the recovery of *Candida* from abdominal drains in postoperative patients is also unclear, but again, the threshold for treatment is generally low because most of the affected patients have been subjected to factors predisposing to disseminated candidiasis.

Removal of the infected valve and long-term antifungal therapy constitute appropriate treatment for *Candida* endocarditis. Although definitive studies are not available, patients usually are treated for weeks with a systemic antifungal agent and then given chronic suppressive therapy for months or years (and sometimes indefinitely) with an oral azole.

Hematogenous *Candida* endophthalmitis is a special problem requiring ophthalmologic consultation. In lesions that are expanding or that threaten the macula, an IV polyene combined with flucytosine has been the regimen of choice. However, as more data on the azoles

TABLE 107-2
AVAILABLE AGENTS FOR THE TREATMENT OF DISSEMINATED CANDIDIASIS

| AGENT | ROUTE OF ADMINISTRATION | COMMENT |
|-----------------------------------|-------------------------|--|
| Amphotericin B deoxycholate | IV only | Being replaced by lipid formulations |
| Amphotericin B lipid formulations | | Not FDA approved as primary therapy, but used commonly because less toxic than amphotericin B deoxycholate; ABCD associated with frequent infusion reactions |
| Liposomal (AmBisome, Abelcet) | IV only | |
| Lipid complex (ABLC) | IV only | |
| Colloidal dispersion (ABCD) | IV only | |
| Azoles | | |
| Fluconazole | IV and oral | Most commonly used |
| Voriconazole | IV and oral | Multiple drug interactions |
| Echinocandins | | Broad spectrum against <i>Candida</i> species |
| Caspofungin | IV only | Approved for disseminated candidiasis |
| Anidulafungin | IV only | Approved for disseminated candidiasis |
| Micafungin | IV only | Under evaluation for disseminated candidiasis |

Note: Although ketoconazole is approved for the treatment of disseminated candidiasis, it has been replaced by the newer agents listed in this table.
FDA, U.S. Food and Drug Administration.

and echinocandins become available, new strategies may evolve. Of paramount importance is the decision to perform a partial vitrectomy. This procedure debulks the infection and can preserve sight, which may otherwise be lost as a result of vitreal scarring. All patients with candidemia should undergo ophthalmologic examination because of the relatively high frequency of this ocular complication. Not only can this examination detect a developing eye lesion early in its course; in addition, identification of a lesion signifies a probability of ~90% of deep-organ abscesses and may prompt prolongation of therapy for candidemia beyond the recommended 2 weeks after the last positive blood culture.

Although the basis for the consensus is a very small data set, the recommended treatment for *Candida* meningitis is a polyene plus flucytosine. Successful treatment of *Candida*-infected prosthetic material (e.g., an artificial joint) nearly always requires removal of the infected material followed by long-term administration of an antifungal agent selected on the basis of the isolate's sensitivity and the logistics of administration.

PROPHYLAXIS

The use of antifungal agents to prevent *Candida* infections has been controversial, but some general principles have emerged. Most centers administer prophylactic fluconazole (400 mg/d) to recipients of allogeneic stem cell transplants. High-risk liver transplant recipients are also given fluconazole prophylaxis in most centers. The use of prophylaxis for neutropenic patients has varied considerably from center to center; most centers that elect to give prophylaxis to this population use either fluconazole or a comparatively low dose of an IV polyene—either amphotericin B deoxycholate or a lipid formulation of this agent. Some centers have used itraconazole suspension.

Prophylaxis is sometimes given to surgical patients at very high risk. The widespread use of prophylaxis in

general surgical or medical intensive care units is not—and should not be—a common practice for three reasons: (1) the incidence of disseminated candidiasis is relatively low, (2) the cost-benefit ratio is suboptimal, and (3) increased resistance with widespread prophylaxis is a valid concern.

Prophylaxis for oropharyngeal or esophageal candidiasis in HIV-infected patients is not recommended unless there are frequent recurrences.

CHAPTER 108

ASPERGILLOSIS

David W. Denning

Aspergillosis is the collective term used to describe all disease entities caused by any one of ~35 pathogenic and allergenic species of *Aspergillus*. Only those species that grow at 37°C can cause invasive infection, although some species without

this capability can cause allergic syndromes. *A. fumigatus* is responsible for most cases of invasive aspergillosis, almost all cases of chronic aspergillosis, and most allergic syndromes. *A. flavus* is more prevalent in some hospitals and causes a

higher proportion of cases of sinus and cutaneous infection and keratitis than *A. fumigatus*. *A. niger* can cause invasive infection but more commonly colonizes the respiratory tract and causes external otitis. *A. terreus* causes only invasive disease, usually with a poor prognosis. *A. nidulans* occasionally causes invasive infection, primarily in patients with chronic granulomatous disease.

EPIDEMIOLOGY AND ECOLOGY

Aspergillus has a worldwide distribution, most commonly growing in decomposing plant materials (i.e., compost) and in bedding. This hyaline (nonpigmented), septate, branching mold produces vast numbers of conidia (spores) on stalks above the surface of mycelial growth. Aspergilli are found in indoor and outdoor air, on surfaces, and in water from surface reservoirs. Daily exposures vary from a few to many millions of conidia; the latter high numbers of conidia are encountered in hay barns and other very dusty environments. The required size of the infecting inoculum is uncertain; however, only intense exposures (e.g., during construction work, handling of moldy bark or hay, or composting) are sufficient to cause disease in healthy immunocompetent individuals. Allergic syndromes may be exacerbated by continuous antigenic exposure arising from sinus or airway colonization or from nail infection. High-efficiency particulate air (HEPA) filtration is often protective against infection; thus HEPA filters should be installed and monitored for efficiency in operating rooms and in hospital environments that house very-high-risk patients.

The incubation period of invasive aspergillosis after exposure is highly variable, extending in documented cases from 2 to 90 days. Thus community-acquired acquisition of an infecting strain frequently manifests as invasive infection during hospitalization, although nosocomial acquisition is also common. Outbreaks usually are directly related to a contaminated air source in the hospital.

RISK FACTORS AND PATHOGENESIS

The primary risk factors for invasive aspergillosis are profound neutropenia and glucocorticoid use; risk increases with longer duration of these conditions. Higher doses of glucocorticoids increase the risk of both acquisition of invasive aspergillosis and death from the infection. Neutrophil and/or phagocyte dysfunction is also an important risk factor, as evidenced by aspergillosis in chronic granulomatous disease, advanced HIV infection, and relapsed leukemia. An increasing incidence of invasive aspergillosis in medical intensive care units suggests that, in patients who are not immunocompromised, temporary abrogation of protective responses as a result of glucocorticoid use or a general anti-inflammatory state is a significant risk factor. Many patients have some evidence of prior pulmonary disease—typically, a history of pneumonia or chronic obstructive pulmonary disease. Glucocorticoid use does not appear to predispose to invasive *Aspergillus* sinusitis but probably increases the risk of dissemination after pulmonary infection.

Patients with chronic pulmonary aspergillosis have a wide spectrum of underlying pulmonary disease, often tuberculosis or sarcoidosis. Patients are immunocompetent except that a genetic defect in mannose-binding protein is common, as are some cytokine regulation defects, most of which are consistent with an inability to mount an inflammatory immune (T_H1 -like) response. Glucocorticoids accelerate disease progression.

Allergic bronchopulmonary aspergillosis (ABPA) is associated with certain HLA class II types; polymorphisms of interleukin (IL) 4Ra, IL-10, and SPA2 genes; and heterozygosity of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene. These associations suggest a strong genetic basis for the development of a T_H2 -like and “allergic” response to *A. fumigatus*; this response probably is also protective against invasive disease, since high-dose glucocorticoid treatment for exacerbations of ABPA almost never leads to invasive aspergillosis.

CLINICAL FEATURES AND APPROACH TO THE PATIENT

(Table 108-1)

Invasive Pulmonary Aspergillosis

Both the frequency of invasive disease and the pace of its progression increase with greater degrees of immunocompromise (Fig. 108-1). Invasive aspergillosis is arbitrarily divided into acute and subacute forms that have courses of ≤ 1 month and 1–3 months, respectively. More than 80% of cases of invasive aspergillosis involve the lungs. The most common clinical features are no symptoms at all, fever, cough (sometimes productive), nondescript chest discomfort, trivial hemoptysis, and shortness of breath. Although the fever often responds to glucocorticoids, the disease progresses. The keys to early diagnosis in at-risk patients are a high index of suspicion, screening for circulating antigen, and urgent CT of the thorax.

Invasive Sinusitis

The sinuses are involved in 5–10% of cases of invasive aspergillosis, especially in patients with leukemia and recipients of hematopoietic stem cell transplants. In addition to fever, the most common features are nasal or facial discomfort, blocked nose, and nasal discharge (sometimes bloody). Direct examination of the interior of the nose reveals dusky or necrotic-looking tissue in any location. CT or MRI of the sinuses is essential but does not distinguish invasive *Aspergillus* sinusitis from pre-existing allergic sinusitis, bacterial sinusitis, or other fungal sinusitis early in the disease process.

Disseminated Aspergillosis

In the most severely immunocompromised patients, *Aspergillus* disseminates from the lungs to multiple organs—most often to the brain but also to the skin, thyroid, bone, kidney, liver, gastrointestinal tract, eye, and heart valve. Aside from cutaneous lesions, the most common features are gradual clinical deterioration over 1–3 days, with

TABLE 108-1

MAJOR MANIFESTATIONS OF ASPERGILLOSIS

| MAJOR MANIFESTATIONS IN INDICATED TYPE OF DISEASE | | | | |
|---|--|---|--|---|
| ORGAN | INVASIVE (ACUTE AND SUBACUTE) | CHRONIC | SAPROPHYTIC | ALLERGIC |
| Lung | Angioinvasive in neutropenia, non-angioinvasive, granulomatous | Chronic cavitary, chronic fibrosing | Aspergilloma (single), airway colonization | Allergic bronchopulmonary, severe asthma with fungal sensitization, extrinsic allergic alveolitis |
| Sinus | Acute invasive | Chronic invasive, chronic granulomatous | Maxillary fungal ball | Allergic fungal sinusitis, eosinophilic fungal rhinosinusitis |
| Brain | Abscess, hemorrhagic infarction, meningitis, mycotic cerebral aneurysm | Granulomatous, meningitis | None | None |
| Skin | Acute disseminated, locally invasive (trauma, burns, IV access) | External otitis, onychomycosis | None | None |
| Heart | Endocarditis (native or prosthetic), pericarditis | None | None | None |
| Eye | Keratitis, endophthalmitis (postoperative and disseminated) | None | None | None described |

low-grade fever and features of mild sepsis, and multiple nonspecific abnormalities in laboratory tests. In most cases, at least one localization becomes apparent. Blood cultures are not helpful since they are almost always negative.

Cerebral Aspergillosis

Hematogenous dissemination to the brain is a devastating complication of invasive aspergillosis. Single or multiple lesions may develop. In acute disease, hemorrhagic

infarction is most typical, and cerebral abscess is common. Rarer manifestations include meningitis, mycotic aneurysm, and cerebral granuloma. Local spread also occurs, resulting in a single abscess. Postoperative infection from cranial sinuses is occasionally recorded and is exacerbated by glucocorticoid use after neurosurgery. The presentation can be either acute or subacute, with mood changes, focal signs, seizures, and decline in mental status. Cerebral granuloma can mimic a primary or secondary tumor. MRI is the most useful immediate

FIGURE 108-1
Invasive aspergillosis: conditions placing patients at elevated risk of acquisition and relatively rapid progression. ICU, intensive care unit; COPD, chronic obstructive pulmonary disease; CMV, cytomegalovirus; GVHD, graft-versus-host disease.

1024 investigation; unenhanced CT of the brain is usually nonspecific, and contrast is often contraindicated in the affected patients because of poor renal function.

Endocarditis

Most cases of *Aspergillus* endocarditis are prosthetic valve infections resulting from contamination during surgery. Native valve disease is reported, especially as a feature of disseminated infection and in persons using illicit IV drugs. Culture-negative endocarditis with large vegetations is the most common presentation, but embolectomy reveals the diagnosis in a few cases.

Cutaneous Aspergillosis

Dissemination of *Aspergillus* occasionally results in cutaneous features, usually an erythematous or purplish non-tender area that progresses to a necrotic eschar. Direct invasion of the skin occurs in neutropenic patients at the site of IV catheter insertion and in burn patients. Rapidly progressive local aspergillosis of the skin and underlying tissue may follow trauma, and wounds may become infected with *Aspergillus* after surgery.

Chronic Pulmonary Aspergillosis

The hallmark of chronic cavitary pulmonary aspergillosis (also called semi-invasive aspergillosis, chronic necrotizing aspergillosis, or complex aspergilloma) (Fig. 108-2) is one or more pulmonary cavities expanding over a period of months or years in association with pulmonary symptoms

and systemic manifestations such as fatigue and weight loss. (Pulmonary aspergillosis developing over <3 months is better classified as subacute invasive aspergillosis.) Often mistaken initially for tuberculosis, almost all cases occur in patients with prior pulmonary disease (e.g., tuberculosis, atypical mycobacterial infection, sarcoidosis, ankylosing spondylitis, rheumatoid lung disease, pneumothorax, bullae) or prior lung surgery. The onset is insidious, and systemic features are sometimes more prominent than pulmonary symptoms. Cavities may have a fluid level or a well-formed fungal ball, but pericavitary infiltrates and multiple cavities—with or without pleural thickening—are typical. Antibodies to *Aspergillus* are almost always detectable in blood, usually as precipitating antibody and sometimes at high titers. Some patients have concurrent infections—even without a fungal ball—with atypical mycobacteria and/or other bacterial pathogens, such as *Staphylococcus aureus* or *Pseudomonas aeruginosa*. If untreated, chronic pulmonary aspergillosis typically progresses (sometimes relatively rapidly) to unilateral or upper-lobe fibrosis. This end-stage entity is termed *chronic fibrosing pulmonary aspergillosis*.

Aspergilloma

Aspergilloma (fungal ball) occurs in up to 20% of residual chest cavities ≥ 2 cm in diameter. Some fungal balls remain stable in a single cavity for many years, and 10% resolve spontaneously. However, aspergillomas are often a feature of chronic pulmonary aspergillosis with its associated features. Signs and symptoms associated with single (simple) aspergillomas are minor, including a cough (sometimes productive), hemoptysis, wheezing, and mild fatigue. More significant signs and symptoms are associated with chronic cavitary pulmonary aspergillosis. The vast majority of fungal balls are caused by *A. fumigatus*, but *A. niger* has been implicated, particularly in diabetic patients; aspergillomas due to *A. niger* can lead to oxalosis with renal dysfunction. The most significant complication of aspergilloma is life-threatening hemoptysis, which may be the presenting manifestation.

Chronic Sinusitis

Three entities are subsumed under this broad label: sinus aspergilloma, chronic invasive sinusitis, and chronic granulomatous sinusitis. *Sinus aspergilloma* is limited to the maxillary sinus and consists of a chronic saprophytic entity in which the sinus cavity is filled with a fungal ball. This form of disease is associated with prior upper-jaw root canal work and chronic (bacterial) sinusitis. About 90% of CT scans show focal hyperattenuation related to concretions; on MRI scans, the T2-weighted signal is decreased, whereas that of bacterial sinusitis is increased. Removal of the fungal ball is curative. No tissue invasion is demonstrable histologically or radiologically.

In contrast, *chronic invasive sinusitis* is a slowly destructive process that most commonly affects the ethmoid and sphenoid sinuses but can involve any sinus. Patients are usually but not always immunocompromised to some degree (e.g., as a result of diabetes or HIV infection). Imaging of the cranial sinuses shows opacification

FIGURE 108-2

CT scan image of the chest in a patient with longstanding bilateral chronic cavitary pulmonary aspergillosis. He had a prior history of several bilateral pneumothoraces and required bilateral pleurodesis (1990). CT scan then demonstrated multiple bullae, and sputum cultures grew *A. fumigatus*. The patient had initially weakly and later strongly positive serum *Aspergillus* antibody tests (precipitins). This scan (2003) shows a mixture of thick- and thin-walled cavities in both lungs, with a large cavity containing a probable fungal ball protruding into the large cavity on the right. There is also considerable pleural thickening bilaterally.

of one or more sinuses, local bone destruction, and invasion of local structures. The differential diagnosis is wide, as numerous other fungi may cause a similar disease and sphenoid sinusitis is often caused by bacteria. Apart from a history of chronic nasal discharge and blockage, loss of the sense of smell, and persistent headache, the usual presenting features are related to local involvement of critical structures. The orbital apex syndrome (blindness and proptosis) is characteristic. Facial swelling, cavernous sinus thrombosis, carotid artery occlusion, pituitary fossa, and brain and skull base invasion have been described.

Chronic granulomatous sinusitis due to *Aspergillus* is most commonly seen in the Middle East and India and is often caused by *A. flavus*. It typically presents late, with facial swelling and unilateral proptosis. The prominent granulomatous reaction histologically distinguishes this disease from chronic invasive sinusitis, in which tissue necrosis with a low-grade mixed-cell infiltrate is typical.

Allergic Bronchopulmonary Aspergillosis

In almost all cases, ABPA represents a hypersensitivity reaction to *A. fumigatus*; rare cases are due to other aspergilli and other fungi. ABPA occurs in ~1% of patients with asthma and in up to 15% of adults with cystic fibrosis, and occasional cases are reported in patients without either of these diseases. Episodes of bronchial obstruction with mucous plugs leading to coughing fits, “pneumonia,” consolidation, and breathlessness are typical. Many patients report coughing up thick sputum casts, usually brown or clear. Eosinophilia commonly develops before systemic glucocorticoids are given. The cardinal diagnostic tests include an elevated serum level of total IgE (usually >1000 IU/mL), a positive skin-prick test to *A. fumigatus* extract, or detection of *Aspergillus*-specific IgE and IgG (precipitating) antibodies. Central bronchiectasis is characteristic, but patients may present before it becomes apparent.

Severe Asthma with Fungal Sensitization (SAFS)

Many adults with severe asthma do not fulfill the criteria for ABPA and yet are allergic to fungi. Although *A. fumigatus* is a common allergen, numerous other fungi (e.g., *Cladosporium* and *Alternaria* spp.) are implicated by skin-prick testing and/or specific IgE radioallergosorbent (RAST) testing.

Allergic Sinusitis

Like the lungs, the sinuses manifest allergic responses to *Aspergillus* and other fungi. The affected patients present with chronic (i.e., perennial) sinusitis typically requiring multiple course of antibiotics that are of only limited benefit. Many of these patients have nasal polyps, and all have congested nasal mucosa and sinuses full of mucoid material. The histologic hallmark of allergic fungal sinusitis is local eosinophilia and the breakdown products of eosinophils, Charcot-Leyden crystals. Removal of abnormal mucus and polyps, with local and occasionally systemic administration of glucocorticoids, usually leads to resolution. Persistent or recurrent signs and

symptoms may require more extensive surgery (ethmoidectomy) and possibly local antifungal therapy.

Superficial Aspergillosis

Aspergillus can cause keratitis and otitis externa. The former may be difficult to diagnose early enough to save the patient's sight. Treatment requires local surgical debridement as well as both systemic and topical antifungal therapy. Otitis externa is a common problem for which local debridement and local application of antifungal agents constitute the most common approach to treatment.

DIAGNOSIS

Several techniques are required to establish the diagnosis of any form of aspergillosis with confidence. Patients with acute invasive aspergillosis have a relatively heavy load of fungus in the affected organ; thus culture, molecular diagnosis, antigen detection, and histopathology usually confirm the diagnosis. However, the pace of progression leaves only a narrow window for making the diagnosis without losing the patient, and some invasive procedures are not possible because of coagulopathy, respiratory compromise, and other factors. Currently, ~40% of cases of invasive aspergillosis are missed clinically and are diagnosed only at autopsy. Histologic examination of affected tissue reveals either infarction, with invasion of blood vessels by many fungal hyphae, or acute necrosis, with limited inflammation and hyphae. *Aspergillus* hyphae are hyaline, narrow, and septate, with branching at 45°; no yeast forms are present in infected tissue. Hyphae can be seen in cytology or microscopy preparations, which therefore provide a rapid means of presumptive diagnosis.

Culture is important in confirming the diagnosis, given that multiple other (rarer) fungi can mimic *Aspergillus* spp. histologically. Bacterial agar is less sensitive than fungal media for culture. Thus, if physicians do not request fungal culture, the diagnosis may be missed. Culture may be falsely positive (e.g., in patients whose airways are colonized by *Aspergillus*) or falsely negative. Only 10–30% of patients with invasive aspergillosis have a positive culture at any time. Molecular diagnostic techniques promise to be both faster and more sensitive than culture.

The *Aspergillus* antigen test relies on detection of galactomannan release from *Aspergillus* spp. during growth. Antigen testing in high-risk patients is best done prospectively, as positive results usually precede clinical or radiologic features by several days. Antigen testing may be falsely positive in patients receiving certain β -lactam/ β -lactamase inhibitor antibiotic combinations, such as tazocillin/sulbactam and amoxicillin/clavulanic acid; in these cases, a second test is required for confirmation. Antigen testing and molecular testing on bronchoalveolar lavage fluid and cerebrospinal fluid are useful if performed before antifungal therapy has been given for more than a few days. The sensitivity of antigen detection is reduced by antifungal prophylaxis.

Definitive confirmation of the diagnosis requires (1) a positive culture of a sample taken directly from an

ordinarily sterile site (e.g., a brain abscess) or (2) positive results of both histologic testing and culture of a sample taken from an affected organ (e.g., sinuses or skin). Most diagnoses of invasive aspergillosis are inferred from fewer data, including the presence of the *halo sign* on a high-resolution thoracic CT scan, in which a localized ground-glass appearance representing hemorrhagic infarction surrounds a nodule. While a halo sign may be produced by other fungi, *Aspergillus* spp. are by far the most common cause. Halo signs are present for ~7 days early in the course of infection in neutropenic patients and are a good prognostic feature. Thick CT sections can give the false appearance of a halo sign, as can other technical factors. Other common radiologic features of invasive pulmonary aspergillosis include pleural-based infarction or cavitation.

For chronic invasive aspergillosis, *Aspergillus* antibody testing is invaluable although relatively imprecise. Titers fall with successful therapy. Cultures are infrequently positive. Some patients with chronic pulmonary aspergillosis also have elevated titers of total serum IgE and *Aspergillus*-specific IgE.

ABPA and SAFS are diagnosed serologically or with skin-prick tests. Allergic *Aspergillus* sinusitis is usually diagnosed histologically, although precipitating antibodies in blood may also be useful.

Rx Treatment: **ASPERGILLOSIS**

Antifungal drugs active against *Aspergillus* include voriconazole, itraconazole, posaconazole, caspofungin, micafungin, and amphotericin B. Initial IV administration is preferred for acute invasive aspergillosis and oral administration for all other disease that requires antifungal therapy. Current recommendations are shown in **Table 108-2**. Voriconazole is the preferred agent for invasive aspergillosis; caspofungin, posaconazole, and lipid-associated amphotericin B are second-line agents. Amphotericin B is not active against *A. terreus* or *A. nidulans*. An infectious disease consultation is advised for patients with invasive disease, given the complexity of management. It is not clear whether combination therapy for acute invasive aspergillosis is beneficial, but it is widely used for very ill patients and for those with a poor prognosis. Commonly used combinations include an azole with either caspofungin or micafungin. The interactions of voriconazole and itraconazole with many drugs must be considered before these agents are prescribed. In addition, the effects of both drugs vary substantially from one patient to another, and many authorities recommend monitoring to ensure that drug concentrations are adequate but not excessive. The duration of therapy for invasive aspergillosis varies from ~3 months to several years, depending on the patient's immune status and response to therapy. Relapse occurs if the response is suboptimal and immune reconstitution is not complete.

Itraconazole is the preferred oral agent for chronic and allergic forms of aspergillosis. Voriconazole and posaconazole can be substituted when failure, emergence of resistance, or adverse events occur. An itraconazole dose of 200 mg twice daily is recommended, with monitoring of drug concentrations in the blood. Chronic cavitary pulmonary aspergillosis probably requires life-long therapy, whereas the duration of treatment for other forms of chronic and allergic aspergillosis requires case-by-case evaluation.

Resistance to one or more azoles, although uncommon, may develop during long-term treatment, and a positive culture during antifungal therapy is an indication for susceptibility testing. Glucocorticoids should be used with caution in chronic cavitary pulmonary aspergillosis.

Surgical treatment is important in several forms of aspergillosis, including maxillary fungal ball and single aspergillomas, in which surgery is curative; invasive aspergillosis involving bone, heart valve, sinuses, proximal areas of the lung, and areas impinging on the great vessels; brain abscess; keratitis; and endophthalmitis. In allergic fungal sinusitis, removal of abnormal mucus and polyps, with local and occasionally systemic glucocorticoid treatment, usually leads to resolution. Persistent or recurrent signs and symptoms may require more extensive surgery (ethmoidectomy) and possibly local antifungal therapy. Surgery is problematic in chronic pulmonary aspergillosis, usually resulting in serious complications. Bronchial artery embolization is preferred for problematic hemoptysis.

PROPHYLAXIS

In situations in which moderate or high risk is predicted (e.g., after induction therapy for acute myeloid leukemia), the need for antifungal prophylaxis for superficial and systemic candidiasis and for invasive aspergillosis is generally accepted. Fluconazole is commonly used in these situations but has no activity against *Aspergillus* spp. Itraconazole capsules are ineffective, and itraconazole solution offers only modest efficacy. Posaconazole solution is probably more effective. Some data support the use of IV low-dose micafungin. No prophylactic regimen is completely successful.

OUTCOME

Invasive aspergillosis is curable if immune reconstitution occurs, whereas allergic and chronic forms are not. The mortality rate for invasive aspergillosis is ~50% if the infection is diagnosed and treated but is 100% if the diagnosis is missed. Cerebral aspergillosis, *Aspergillus* endocarditis, and bilateral extensive invasive pulmonary aspergillosis have very poor outcomes, as does invasive infection in patients with late-stage AIDS, patients with relapsed uncontrolled leukemia, and recipients of allogeneic hematopoietic stem cell transplants.

TABLE 108-2

TREATMENT OF ASPERGILLOSIS

| INDICATION | PRIMARY TREATMENT | EVIDENCE LEVEL ^a | PRECAUTIONS | SECONDARY TREATMENT | COMMENTS |
|--------------------------------|-------------------------------------|-----------------------------|--|--|--|
| Invasive ^a | Voriconazole | AI | Drug interactions (especially with rifampin), renal failure (IV only) | Amphotericin B, caspofungin, posaconazole, micafungin | As primary therapy, voriconazole carries 20% more responses than amphotericin B. If azole prophylaxis fails, it is unclear whether a class change is required for therapy. |
| Prophylaxis | Itraconazole solution, posaconazole | AI | Diarrhea and vomiting with itraconazole, vincristine interaction | Micafungin, aerosolized amphotericin B | Some centers monitor plasma levels of itraconazole. |
| ABPA | Itraconazole | AI | Some glucocorticoid interactions, including with inhaled formulations | Voriconazole | Long-term therapy is helpful in most patients. Others can discontinue treatment. No evidence indicates whether or not therapy modifies progression to bronchiectasis/fibrosis. |
| Single aspergilloma | Surgery | BII | Multicavity disease: poor outcome of surgery; medical therapy preferable | Itraconazole, voriconazole, intracavity amphotericin B | Single large cavities with an aspergilloma are best resected. |
| Chronic pulmonary ^b | Itraconazole | BII | Poor absorption of capsules with proton pump inhibitors or H ₂ blockers | Voriconazole, IV amphotericin B | Resistance may emerge during treatment, especially if plasma drug levels are subtherapeutic. |

Note: The oral dose is usually 200 mg bid for voriconazole and itraconazole and 400 mg bid for posaconazole. The IV dose of voriconazole is 6 mg/kg twice at 12-h intervals (loading doses) followed by 4 mg/kg q12h. Plasma monitoring is helpful in optimizing the dosage. Caspofungin is given as a single loading dose of 70 mg, followed by 50 mg/d; some authorities use 70 mg/d for patients weighing >80 kg, and lower doses are required with hepatic dysfunction. Micafungin is given as 50 mg/d for prophylaxis and as at least 150 mg/d for treatment; this drug is not yet approved by the U.S. Food and Drug Administration (FDA) for this indication. Amphotericin B deoxycholate is given at a daily dose of 1 mg/kg if tolerated. Several strategies are available for minimizing renal dysfunction. Lipid-associated amphotericin B is given at 3 mg/kg (AmBisome) or 5 mg/kg (Abelcet). Different regimens are available for aerosolized amphotericin B, but none is FDA approved. Other considerations that may alter dose selection or route include age; concomitant medications; renal, hepatic, or intestinal dysfunction; and drug tolerability.

^aEvidence levels are those used in treatment guidelines (Stevens DA et al: Practice guidelines for diseases caused by *Aspergillus*. Clin Infect Dis 30:696, 2000).

^bAn infectious disease consultation is appropriate for these patients.

CHAPTER 109

MUCORMYCOSIS

Alan M. Sugar

Mucormycosis (also called *zygomycosis*) is a serious, relatively uncommon invasive fungal infection and one of the most aggressive and lethal invasive mycoses. Physicians caring for patients with diabetes mellitus, immunocompromise (including that following organ transplantation), or iron overload syndromes (particularly those associated with hemodialysis) should be acutely aware of the enhanced susceptibility of these individuals to infection with the Mucorales. Timely diagnosis is critical to survival and minimization of morbidity. Institution of aggressive surgical and medical therapy is critical in maximizing the likelihood of a good outcome. Delay in considering the diagnosis and instituting appropriate therapeutic measures results in increasingly severe disfigurement at best and in death at worst.

ETIOLOGY

Fungi from the order Mucorales are the etiologic agents of mucormycosis. Despite the name of this infection, *Mucor* is not the most common genus recovered from patients. Rather, *Rhizopus* and *Rhizomucor* are the genera usually cultured from tissue samples. Other, less common fungi, including *Absidia*, *Cunninghamella*, *Apophysomyces*, and *Saksenaea*, are increasingly

being isolated and, for the most part, cause similar clinical syndromes. Thus, there is no specific clinical feature that permits identification of the precise fungus involved. Submission of appropriate biopsy material to the microbiology laboratory is mandatory to ensure a pathogen's identification.

PATHOGENESIS

Mucorales are found commonly in the environment, and spores of these usually nonpathogenic fungi are likely to be inhaled daily. In the normal human lung, spores are inhibited from germinating into hyphae by alveolar macrophages. However, in diabetic patients, especially those with elevated blood sugar levels and acidemia, the spores germinate, hyphae develop (Fig. 109-1), and the fungi begin an inexorable march throughout the lung tissue, invading blood vessels and surrounding tissues. As blood vessels become involved, thrombosis occurs, tissue necrosis results, and the fungi continue to grow in this devitalized tissue. The use of deferoxamine to treat iron overload is a risk factor for mucormycosis; the siderophore supplies the fungi with iron that enhances their growth.

FIGURE 109-1

A. Hematoxylin and eosin-stained section of lung tissue showing the broad, infrequently septate, thin-walled hyphae of *Absidia corymbifera*. **B.** Grocott's methenamine silver-stained section of lung tissue showing typical zygomycete hyphae of

A. corymbifera. (Courtesy of David Ellis, PhD, Mycology Unit, Women's and Children's Hospital, Adelaide, Australia; with permission.)

Spores settle in the upper airways, lower airways, or gastrointestinal tract and can spread beyond the initial site of infection, causing disseminated mucormycosis. Increasingly, patients are presenting with extensive cutaneous involvement after direct implantation of spores into the skin as a result of trauma (e.g., that sustained in a motor vehicle accident). The pathology in all these sites is the same, with blood vessel invasion and tissue necrosis as hallmarks and specific organ dysfunction depending on the location of the infection.

CLINICAL MANIFESTATIONS

The manifestations of mucormycosis depend on the site of infection. Patients with *rhinocerebral mucormycosis* may present with symptoms typical of sinusitis. However, progression of symptoms over several days indicates a more serious process than the more common bacterial or viral sinusitis. As the infection spreads, hypesthesia or numbness of the face overlying the infection may develop. Concomitant symptoms include headache, bloody nasal discharge, and changes in mental status. The black eschar of the palate is widely described as a hallmark of rhinocerebral mucormycosis, but the astute clinician will recognize earlier manifestations of this end-stage lesion reflecting invasion of the palate. These subtler lesions, which may consist of discolored, often hyperemic areas on the palate, will, if untreated, progress rapidly to the commonly recognized black eschar, which indicates angioinvasion and tissue necrosis. Involvement of the orbit (**Fig. 109-2**) compromises proper ocular-muscle function and normal movement of the eye within the skull, resulting in double vision. If the blood supply to the eye is affected by invasion of the retinal artery, blindness develops, often quite rapidly. Proptosis and ptosis are late findings reflecting a mass lesion within the orbit and cranial nerve involvement,

respectively. Progression of the infection into the brain results in the formation of brain abscesses and phlegmon; symptoms and signs depend on the location of these lesions. Cavernous sinus thrombosis is an ominous sign. CT and MRI reveal sinus opacification and destruction of contiguous bone, and brain involvement can be readily appreciated.

Pulmonary mucormycosis presents as severe, progressive, tissue-destructive pneumonia. Neutropenia is a common predisposing factor. A high fever and a critical clinical condition are typical. Cavitation of involved lung develops rapidly, and hematogenous spread beyond the lungs to the brain and other organs may occur.

Gastrointestinal mucormycosis occurs primarily in those patients with protein-calorie malnutrition and usually presents as a perforated viscus. Premortem diagnosis is rare, and most patients with this form of mucormycosis do not survive.

Cutaneous mucormycosis is more common than disease at other sites and develops after traumatic injuries in which wounds are contaminated with dirt. Areas of tissue necrosis enlarge rapidly, involving all layers of the skin and underlying structures.

DIAGNOSIS

Laboratory Features

There are no pathognomonic hematologic changes. The abnormalities that are found reflect underlying predisposing conditions (e.g., diabetic ketoacidosis) and general indications of infection, such as elevated white blood cell counts and acute-phase reactant levels. Blood cultures are virtually always negative.

Microscopic examination and culture of biopsy samples from the involved area are critical in making an accurate diagnosis. As much tissue as possible should be submitted to the microbiology and histopathology laboratories.

A

FIGURE 109-2

B

Swabs are insufficient. These fungi grow rapidly and are usually visible on culture plates within a day or two. Their identification is based on traditional morphologic features. Fixed tissue samples are treated with special stains for fungi; for example, Gomori methenamine silver stains the fungi black against a green background, and periodic acid–Schiff stains the hyphae red. Mucorales appear as broad (diameter, 6–50 μm), usually nonseptate hyphae with branches at right angles; the organisms are often described as ribbon-like. Hyphae cut and viewed on end can deceptively appear yeast-like. The microscopic appearance of the Mucorales is sufficiently different from that of *Aspergillus*, *Fusarium*, and other pathogenic molds (which characteristically appear as narrow, septate hyphae with narrow-angle branching) that a pathologist can readily make a preliminary diagnosis of mucormycosis. Identification of the specific organism requires culture. In the laboratory, each species of Mucorales exhibits characteristic morphologic features that permit specific identification. Molecular methods of speciation are still used only as research tools.

Differential Diagnosis

Other fungal infections, including aspergillosis, fusariosis, and scedosporiosis, must be ruled out by culture and histopathologic analysis. Microscopic examination easily distinguishes the etiologic agents of these infections from the Mucorales. Aggressive pyogenic bacterial infections—e.g., those caused by *Pseudomonas*, *Aeromonas*, or *Vibrio* species; *Staphylococcus aureus*; and a variety of anaerobes—occasionally produce similar clinical presentations but can be ruled out by Gram's staining, culture, and microscopic analysis of tissue samples.

Treatment: MUCORMYCOSIS

Three factors are key to a successful outcome of therapy for mucormycosis: (1) reversal of the underlying predisposition; (2) aggressive surgical debridement; and (3) aggressive antifungal therapy, with early initiation and high drug doses. Failure to undertake all three of these interventions simultaneously has a significant and negative impact on outcome.

Reversal of underlying disease is relatively easy in patients with diabetic ketoacidosis but is more difficult in patients who require continued immunosuppression for control of an underlying disease or after organ transplantation. In all cases, minimization of immunosuppressive medications enhances overall control of the fungal infection.

Aggressive surgical debridement requires the removal of all dead tissue and of tissue that appears to be so severely compromised that its continued viability is in question. Extensive reconstructive surgery may be required once the infection has been cured.

Traditionally, high-dose conventional amphotericin B has been used for the treatment of mucormycosis, but doses have been limited to <1.5 mg/kg per day because of the nearly universal development of nephrotoxicity. Use of lipid formulations at doses of 15–20 mg/kg per day (AmBisome) or 15 mg/kg per day (Abelcet) maximizes the amount of amphotericin B delivered to the tissues as well as the speed of its delivery. At these doses, nephrotoxicity occurs in <50% of patients.

Posaconazole, an experimental triazole antifungal agent, has been shown to be active against mucormycosis in mouse models of infection and in patients who cannot tolerate or do not respond to other antifungal drugs. The precise clinical role for posaconazole in the treatment of mucormycosis is not clear, but this drug may prove to be a valuable alternative to amphotericin B in selected cases. Given the relative rarity of mucormycosis, it is not likely that a randomized study will rigorously compare the roles of the various antifungal agents.

The optimal duration of therapy for mucormycosis is not known precisely. If possible, antifungal administration should be continued for at least 3 months after (1) all clinical abnormalities resolve or stabilize, leaving no clinical evidence of infection at the involved site(s); and (2) scans, x-rays, and laboratory studies yield normal or stable results. Careful follow-up should continue for at least 1 year to confirm that there is no evidence of recurrent infection. With this approach, recurrences should be rare.

CHAPTER 110

MISCELLANEOUS MYCOSES AND ALGAL INFECTIONS

Stanley W. Chapman ■ Donna C. Sullivan

MYCOSES

The clinical spectrum of fungal disease varies from superficial infections of the skin, hair, and nails to life-threatening systemic infections. Superficial infections involve the outermost layers of skin and hair and are associated with little or no inflammation. Cutaneous infections involve deeper layers of the skin, hair follicles, and nails and are accompanied by inflammation. Subcutaneous infections involve the dermis and subcutaneous tissues. Systemic disease involves deep tissue invasion of one or more internal organs and usually follows inhalation of the fungus. In immunocompromised patients, disseminated disease may result from superficial, cutaneous, or subcutaneous fungal infections.

SUPERFICIAL INFECTIONS

Malasseziasis

Tinea (pityriasis) versicolor, caused by lipophilic yeasts of the genus *Malassezia*, is the most common superficial skin infection. The clinical presentation usually consists of scaly hypo- or hyperpigmented macular lesions on the chest, back, neck, and arms.

■ Etiologic Agents

Malassezia species are components of the human cutaneous flora that are dimorphic, existing in both yeast and mycelial phases. Each phase was originally classified as a separate genus: *Pityrosporum* for the yeast form and *Malassezia* for the mycelial form. The two genera were reclassified in 1986 as a single genus, *Malassezia*. Initially, only one species, *M. furfur*, was recognized, but seven distinct species have since been identified: *M. furfur*, *M. sympodialis*, *M. obtusa*, *M. globosa*, *M. restricta*, *M. slooffiae*, and *M. pachydermatis*.

■ Epidemiology

Malassezia species can be isolated from sebaceous-rich areas of the skin, most frequently from the chest and the midline of the back. The prevalence of tinea versicolor in susceptible age groups (primarily adolescents and young adults) is low in temperate climates but may reach 40–60% in tropical climates.

■ Pathogenesis

The pathogenesis of tinea versicolor is unclear but may involve the conversion of colonizing yeasts into the mycelial form, which then invades the stratum corneum.

■ Clinical Manifestations

The lesions of tinea versicolor are usually asymptomatic. Most patients seek medical advice for cosmetic reasons. Lesions typically appear as patches of pink or coppery-brown skin but may appear paler than the surrounding skin, especially in dark-skinned individuals. Although some patients report mild pruritus, the lesions do not usually elicit an immune response. Other cutaneous manifestations associated with *Malassezia* species include seborrheic dermatitis, folliculitis, atopic dermatitis, and dandruff.

■ Diagnosis

Tinea versicolor is diagnosed on clinical grounds by the characteristic distribution and appearance of skin lesions. Lesions may fluoresce yellow-green under long-wave UVA (Wood's light). Treatment of skin scrapings with potassium hydroxide (KOH) reveals yeasts and hyphal elements with a “spaghetti and meatballs” appearance.

Rx Treatment: MALASSEZIASIS

Malassezia species are susceptible to a variety of topical antifungal agents, including 2.5% selenium sulfide shampoo (a 10- to 15-min application followed by rinsing); topical azoles such as clotrimazole, miconazole, econazole, and ketoconazole; terbinafine gel; and ciclopirox cream/solution. The typical treatment duration is 2 weeks. In patients with extensive or persistent lesions, short-course or pulse therapy with oral ketoconazole (a single 400-mg dose), fluconazole (a single 400-mg dose or 150 mg every week for 4 weeks), or itraconazole (200 mg every other day for 7 days) has proved effective.

■ Complications

M. furfur is lipophilic and causes catheter-related fungemia in premature neonates and immunocompromised adults receiving IV lipids by central venous catheter. Infection of the lungs is pronounced and frequently results

in respiratory failure. *M. pachydermatis*, although not lipophilic, is an increasingly important pathogen in neonatal intensive care units. When its presence is suspected, the microbiology laboratory should be notified because its isolation requires special culture conditions. Catheter-related *Malassezia* infections should be managed with prompt catheter removal and systemic antifungal therapy with amphotericin B or an azole (Table 110-1). Because transmission of both *M. furfur* and *M. pachydermatis* on the hands of health care workers has been documented, a strict hand-washing protocol should be enforced when outbreaks are identified.

Prognosis

In general, the prognosis in tinea versicolor is excellent, but the disease recurs in up to 80% of patients within 2 years after cessation of treatment. Early diagnosis and treatment in patients with disseminated infection improve outcome.

Other Superficial Mycoses

Tinea nigra is a rare infection of the palms caused by the dematiaceous fungus *Hortaea* (formerly *Exophiala) werneckii*. Two types of piedra characterized by nodules of fungal elements on the hair shaft have been reported: black piedra caused by *Piedraia hortae* and white piedra caused by *Trichosporon* species (which may also be associated with other superficial infections as well as with invasive trichosporonosis). *T. beigeli* has historically been the most significant pathogen in the genus *Trichosporon*. Recently proposed revisions in classification and nomenclature are based on analysis of 26S rRNA sequences and use of nonmolecular techniques to differentiate 17 species—only 6 of which cause human disease—and 5 varieties of *Trichosporon*. Under this system, *T. beigeli* will be designated *T. cutaneum*. The other five human pathogens included in this revised classification are *T. asteroides*, *T. ovoides*, *T. inkin*, *T. asahii*, and *T. mucoides*. In addition, four serotypes of *Trichosporon* (serotypes I, II, III, and I-III) have been recognized, of which only serotypes I (*T. cutaneum* and *T. mucoides*) and II (*T. asahii*, *T. asteroides*, *T. inkin*, and *T. ovoides*) are pathogenic. Given that this revised nomenclature has not been universally adopted, the previous classification system may remain in use for some time and may be a source of confusion.

T. ovoides is usually associated with white piedra of the scalp, whereas *T. inkin* is primarily associated with white piedra of the groin. *T. ovoides* has also been implicated in summer-type hypersensitivity pneumonitis. The treatment of white piedra requires shaving off all the hair in the affected areas and applying a topical azole for 1–4 months.

CUTANEOUS INFECTIONS

The cutaneous mycoses are caused by *dermatophytes*, which infect keratinized tissues, including skin, hair follicles, and nails. These dermatophytic fungi invade the epidermis and elicit an inflammatory reaction, including redness and pruritus. Dermatophytic infections are designated according

to the anatomic location of the lesions—e.g., *tinea corporis* (the trunk, shoulders, or limbs), *tinea cruris* (the warm moist areas of the groin, perianal, and perineal areas), *tinea faciei* (the nonhairy areas of the face), *tinea pedis* (the feet), *tinea unguium* (the nails), and *tinea capitis* (the scalp).

Etiologic Agents

Three genera of dermatophytes—*Microsporum*, *Trichophyton*, and *Epidermophyton*—are associated with human infections. Members of these genera can be divided into three groups according to their natural reservoir and potential for infection: anthropophilic, zoophilic, and geophilic organisms.

Epidemiology

Tinea is common worldwide. It is estimated that more than 8 million office visits to primary care physicians are made annually for tinea-related symptoms.

Pathogenesis

Dermatophytic fungi release proteolytic enzymes and keratinases into the skin. These exocellular enzymes release nutrients and facilitate dissemination through the stratum corneum. A specific host immune response is directed against the organisms.

Clinical Manifestations

Any dermatophyte can cause tinea corporis, which is commonly called “ringworm” because of the typical appearance of lesions: annular scaly patches with raised, erythematous vesicular borders and central clearing. Tinea faciei, like tinea corporis, can be caused by any dermatophyte. *T. rubrum* and *E. floccosum* are common causes of tinea cruris; similar lesions can be caused by *Candida* infection.

Tinea pedis, the most common clinical dermatophytic infection, usually presents with interdigital cracking, scaling, and maceration. Hyperkeratosis and peeling of the soles of the feet are common, with a scaly red “moccasin-like” appearance in chronic cases. The most common cause of tinea pedis is *T. rubrum*. Clinical lesions similar to those of tinea pedis can be caused by nondermatophytic fungi, yeasts, and bacteria.

Tinea unguium is caused by *T. rubrum*, *T. mentagrophytes*, and *E. floccosum*. The term *onychomycosis* encompasses nail infections due to either dermatophytes or nondermatophytic fungi. Dermatophytes cause 80–90% of cases of onychomycosis. The prevalence of these infections is ~2% among young adults and increases to 20% among individuals 40–60 years of age. Onychomycosis occurs in diabetic patients at the same rate as in the general population but poses a greater risk of bacterial superinfection in diabetes.

Tinea capitis is a common dermatophytic disease of children but is relatively rare among adults. The clinical presentation may vary from a diffuse scaly scalp to scattered areas of scale with or without alopecia. Hair may break off at the scalp (“black-dot ringworm”). Pruritus is not a constant symptom. Inflammatory responses may be minimal or severe, with the formation of a kerion

TABLE 110-1

SYSTEMIC THERAPY FOR MISCELLANEOUS INVASIVE MYCOSES AND THE ALGAL INFECTION PROTOTHECOSIS

| TYPE OF INFECTION | FIRST-LINE THERAPY | ALTERNATIVE THERAPY |
|---|---|---|
| Malasseziasis | | |
| Central venous catheter-related infections | Removal of central venous catheter AmB ^a | In vitro susceptibility studies indicate that azoles may offer a therapeutic alternative. |
| Trichosporonosis | AmB in combination with voriconazole ^b (300 mg bid) | GM-CSF or IFN- γ may be a useful therapeutic adjunct. |
| Sporotrichosis | | |
| Cutaneous/ lymphocutaneous | Itraconazole ^c (100–200 mg/d for 3–6 months) | Terbinafine, 500–1000 mg/d |
| Non-life-threatening pulmonary, osteoarticular, or disseminated disease | Itraconazole (200 mg bid for 12 months) | AmB (lipid formulation) or fluconazole (800 mg/d for 12 months) in patients who cannot tolerate AmB or itraconazole |
| Life-threatening pulmonary or disseminated disease | AmB | Selected patients may be switched to oral itraconazole (200 mg bid for 12 months) |
| Eumycetoma | Surgery in combination with: Ketoconazole (200–400 mg/d) or Voriconazole (600 mg/d) or Terbinafine (500 mg/d) | Posaconazole is currently being evaluated. |
| Dematiaceous fungal infections | Surgical excision or cryosurgery combined with: | ... |
| Chromoblastomycosis | Itraconazole (200–600 mg/d), alone or with 5-fluorocytosine (50–100 mg/kg qd in 3 or 4 divided doses) | |
| Phaeohyphomycosis | | |
| Cutaneous or subcutaneous disease | Itraconazole (200 mg once or twice daily before surgery and to prevent relapse) | |
| Systemic/CNS | AmB in combination with itraconazole (200 mg bid) or voriconazole (200 mg bid) | |
| Paracoccidioidomycosis | | |
| Mild to moderate disease | Itraconazole (200–400 mg/d) | ... |
| Severe disease | AmB | Selected patients may be switched to itraconazole after an initial course of AmB. |
| Penicilliosis | | |
| Mild to moderate disease | Itraconazole (200 mg bid for 2 months) | ... |
| Severe disease | AmB | Selected patients may be switched to itraconazole (200 mg bid) after an initial course of AmB. The duration of primary treatment is 2 months. |
| Suppressive therapy for patients with HIV infection or AIDS | Itraconazole (200 mg/d) | |
| Fusariosis and pseudallescheriasis/scedosporiosis | IV voriconazole (6 mg/kg q12h for first 24 h, then 4 mg/kg q12h until neutropenia resolves and clinical response is documented) | Selected patients may be switched to oral voriconazole (200 mg bid) after a clinical response and reversal of neutropenia. |
| Protothecosis | Itraconazole (200 mg/d for 2 months or until lesions resolve) | Disseminated infections should be treated with IV AmB. |

^aUnless otherwise noted, AmB dosages are 0.6–1.0 mg/kg per day of the deoxycholate formulation or 3–5 mg/kg per day of a lipid formulation.

^bAn initial loading dose of voriconazole is recommended on day 1 for both IV therapy (6 mg/kg q12h) and oral therapy (400 mg q12h).

^cAn initial loading dose of itraconazole is recommended for both IV therapy (200 mg bid for 2 days) and oral therapy (200 mg bid for 2 days).

Note: AmB, amphotericin B; CNS, central nervous system; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN- γ , interferon γ .

1034 characterized by alopecia, a tender or painful boggy scalp, purulent drainage, and localized lymphadenopathy. *T. tonsurans* is the most common dermatophyte associated with tinea capitis.

■ Diagnosis

Some skin lesions have distinctive characteristics that allow a presumptive diagnosis, and topical therapy is often initiated solely on the basis of the lesions' appearance. However, the ease of obtaining specimens for microscopic examination and culture should encourage definitive diagnosis. Scrapings of skin lesions can be examined as a wet preparation, with a drop of 10% KOH used to dissolve cells and debris. Samples for fungal cultures should be obtained from patients whose history, physical examination, and KOH-treated specimens are inconclusive with regard to the diagnosis of dermatophytic infection. It is recommended that a definitive diagnosis be established in patients before systemic antifungal agents are administered.

R_x Treatment: **CUTANEOUS INFECTIONS**

Most tinea infections can be treated with topical agents alone. Many such antifungal agents are widely available as both prescription and over-the-counter products. Topical imidazoles (e.g., clotrimazole, miconazole, econazole, and ketoconazole) are generally well tolerated and efficacious when used twice daily for at least 2 weeks. The allylamines, including terbinafine and naftifine (available in 1% creams or 1% solutions), provide cure rates of ≥75% and require only once-daily application for shorter periods. Tolnaftate powder is best suited for prevention of tinea pedis.

Systemic therapy is indicated for patients who are unresponsive to topical therapy; for those who have infections involving the scalp or bearded areas, who have hyperkeratotic areas on the palms or soles, or who have widespread disease; and for immunocompromised individuals. Once-daily itraconazole (200 mg), terbinafine (250 mg), and griseofulvin (500 mg of the microcrystalline formulation or 375 mg of the ultramicrocrystalline formulation) has proved effective. Treatment should be administered until lesions resolve. For patients with nail disease, itraconazole (200 mg/d) or terbinafine (250 mg/d) is preferred. The duration of therapy is 2–3 months for fingernails and 4–6 months for toenails. Pulse therapy with itraconazole and terbinafine is an option. Relapse of nail disease is common.

■ Complications

Sites of tinea pedis frequently become superinfected with bacteria. Sometimes these infections are serious, especially in diabetic patients, patients who have undergone saphenous-vein harvest for coronary artery bypass grafts, and patients with any significant venous incompetence.

SUBCUTANEOUS INFECTIONS

Fungal infections that primarily involve the dermis and subcutaneous tissue result from implantation of the organism in the skin through trauma. The major subcutaneous mycoses are sporotrichosis, mycetoma, chromoblastomycosis, and phaeohyphomycosis.

Sporotrichosis

Sporotrichosis most commonly presents as chronic cutaneous, lymphocutaneous, and/or subcutaneous disease. This infection may also be extracutaneous, occurring at pulmonary, osteoarticular, or disseminated sites.

■ Etiologic Agent

Sporotrichosis is caused by the thermally dimorphic fungus *Sporothrix schenckii*, which is found in soil, plants, and moss and on animals. *S. schenckii* exists worldwide but is most common in tropical and warmer temperate regions, such as Mexico and Central and South America.

■ Epidemiology

Sporotrichosis is usually an occupational disease of gardeners, farmers, forestry workers, florists, and horticulturists. There have been well-documented epidemics (e.g., among South African gold miners) as well as scattered outbreaks (e.g., among workers handling sphagnum, hay, and wood). Recent reports indicate that infection can be related to zoonotic spread from cats and armadillos.

■ Pathogenesis

Sporotrichosis most often follows inoculation of the organism into the skin.

■ Clinical Manifestations

The majority of infections with *S. schenckii* present either as fixed cutaneous sporotrichosis or as lymphangitic or lymphocutaneous disease. Fixed cutaneous disease (plaque sporotrichosis) is limited to the site of inoculation. The primary lesion enlarges and may ulcerate and become verrucous. In lymphocutaneous disease, which accounts for ~80% of cases, secondary lesions ascend along the lymphatics that drain the area, producing small painless nodules that erupt, drain, and ulcerate. Other organisms (e.g., nontuberculous mycobacteria, *Nocardia*, *Leishmania*, and chromoblastomycotic agents) may cause similar lesions. Osteoarticular sporotrichosis is an uncommon complication but may cause granulomatous tenosynovitis and bursitis, particularly in alcoholic patients. Pulmonary sporotrichosis following inhalation of *S. schenckii* conidia has been reported in alcoholic patients with chronic obstructive pulmonary disease. Disseminated disease, including that involving the central nervous system, is most likely to occur in patients who have AIDS or are otherwise immunocompromised.

■ Diagnosis

A definitive diagnosis is made by culture of *S. schenckii* on any of a variety of media. Histopathologic examination of biopsy material may also contribute to the diagnosis, with detection of the characteristic ovoid or cigar-shaped yeast forms.

R_x Treatment: SPOROTRICHOSIS

Sporotrichosis requires systemic therapy (Table 110-1). Historically, oral therapy with a saturated solution of potassium iodide (SSKI; 5 drops 3 times daily, increasing to 40–50 drops 3 times daily as tolerated) has been successful, but the use of this intervention is often limited by its toxicity. Because it has fewer side effects and is better tolerated, oral itraconazole has replaced SSKI as the treatment of choice for cutaneous and lymphocutaneous sporotrichosis. Terbinafine has also been effective against lymphocutaneous disease, although it has not been approved for this indication by the U.S. Food and Drug Administration. Patients with non-life-threatening pulmonary disease and those with osteoarticular disease should be treated with itraconazole for at least 12 months. Amphotericin B is the preferred agent for patients with life-threatening pulmonary disease or disseminated infection, for patients who cannot tolerate itraconazole, and for patients in whom itraconazole treatment has failed.

Complications

Hematogenous dissemination of *S. schenckii* is most common among immunocompromised patients, including those with HIV infection or AIDS. These patients may develop widespread cutaneous ulcers, granulomas, and systemic disease with pulmonary, meningeal, articular, or generalized infection.

Prognosis

Success rates of 90–100% have been reported for itraconazole treatment of lymphocutaneous sporotrichosis. A clinical response usually occurs within 4–6 weeks of the start of therapy. Patients who relapse usually respond to a second course of itraconazole.

Mycetoma

Mycetoma is a chronic suppurative infection that begins in the subcutaneous tissue and spreads to fascia and bone. Mycetoma due to fungi is called *eumycetoma*, while that caused by actinomycetes is referred to as *actinomycetoma*. Both diseases are characterized by abscesses containing grains composed of large aggregates of filaments (fungal or actinomycete). Traumatic inoculation is responsible for initial infection.

Etiology and Epidemiology

Mycetomas are common in Mexico, Central America, Venezuela, Brazil, Africa, the Middle East, India, Pakistan, and Bangladesh. The most common cause of eumycetoma worldwide is *Madurella mycetomatis*, while the rare cases that occur in the United States are associated with *Pseudallescheria boydii*. Actinomycetoma, the usual form of mycetoma in Mexico and Central America, is associated with *Nocardia brasiliensis*, *Streptomyces somaliensis*, *Actinomyces madurae*, and *Actinomyces pelletieri*.

Clinical Manifestations

Clinically, eumycetoma and actinomycetoma are similar, beginning as small, firm, painless subcutaneous plaques or nodules on the foot or leg and, less frequently, on the arms, torso, and scalp. Patients usually present with draining sinus tracts, subcutaneous abscesses, fibrosis with woody induration, and extension to fascia and bone.

Diagnosis

Diagnosis is based on visualization of grains in pus, sinus exudate, or tissue biopsy. Fungal hyphae must be distinguished from the filamentous forms seen in actinomycetoma. Organisms associated with mycetoma, whether fungi or actinomycetes, can be grown on a variety of culture media.

R_x Treatment: MYCETOMA

The treatment of mycetoma is problematic. A combined medical/surgical approach is the option of choice (Table 110-1). Because actinomycetoma does not respond to antifungal agents, the differentiation between eumycetoma and actinomycetoma is crucial. (For the treatment of actinomycetoma, see Chaps. 63 and 64.) Amphotericin B has not generally been effective for the treatment of eumycetoma. A limited number of patients have responded to long-term azole therapy. Posaconazole, an investigational agent, may have a role in the treatment of eumycetoma in the future.

Dematiaceous Fungal Infections

Of the many names applied to infections caused by brown- or black-pigmented soil fungi, *phaeohyphomycosis* and *chromoblastomycosis* are the most widely accepted. *Phaeohyphomycosis* refers to infections in which the organisms in tissue occur as pigmented yeast-like forms and/or hyphae. *Chromoblastomycosis* is distinguished by the presence of pigmented sclerotic bodies in tissue.

Chromoblastomycosis is characterized by slow-growing verrucous plaques or nodules, usually on the lower extremities. The most common etiologic agents are *Fonsecaea pedrosoi*, *F. compacta*, *Phialophora verrucosa*, *Rhinocladiella aquaspersa*, and *Cladosporium (Cladophialophora) carrionii*. Most cases affect rural workers living in tropical and subtropical regions, and infection is acquired by traumatic inoculation. Small verrucous papules enlarge slowly but remain painless. Lesions seen in late stages may be superficial or raised purplish irregular plaques; less commonly, they may be nodular, tumorous, verrucous, or cicatricial. In advanced cases, secondary lymphedema, bacterial infections, and keratin necrosis can develop. Although histologic examination of scrapings or biopsy material for characteristic sclerotic bodies can lead to the diagnosis of chromoblastomycosis, culture is required for identification of the causative agent. Treatment is difficult, although many therapeutic interventions have been described (Table 110-1). Results are best

when early surgical excision or cryosurgery is used in combination with antifungal therapy. Treatment with itraconazole—either alone or with 5-fluorocytosine—has had some success.

Phaeohyphomycosis presents in four clinical forms: superficial, cutaneous-corneal, subcutaneous, and systemic. *Exophiala jeanselmei*, *Wangiella dermatitidis*, and *Bipolaris* species are the most common etiologic agents. The route of infection is most likely implantation, with the subsequent formation of an inflammatory cyst. A single inflammatory nondraining cyst located on a proximal limb is the most typical presentation. The diagnosis is usually made by histopathologic detection (in biopsy material) of a fibrous capsule with a granulomatous reaction and a necrotic center. Culture is required to identify specific organisms. Surgical excision of the lesion is essential. Itraconazole treatment reduces the size of large lesions before excision and prevents relapse afterward (Table 110-1). Cerebral phaeohyphomycosis is thought to be due to direct extension from adjacent paranasal sinuses or from a penetrating trauma to the head. Most cases present as a brain abscess with focal neurologic deficits and/or generalized seizures. A review of 101 cases revealed that one-half of patients had no apparent immunocompromising condition. Infections in immunocompromised patients are more likely to disseminate; disseminated infections have been reported in patients with HIV infection, solid-organ transplant recipients, patients with malignancies, and one pregnant woman. Rhinocerebral disease requires surgical drainage along with antifungal therapy. A combination of amphotericin B and itraconazole or voriconazole is recommended.

SYSTEMIC MYCOSES

Paracoccidioidomycosis

Often referred to as South American blastomycosis, paracoccidioidomycosis is a systemic disease caused by the dimorphic fungus *Paracoccidioides brasiliensis*. Pulmonary infection follows inhalation of conidia and may disseminate to other organs, producing secondary lesions in the skin, lymph nodes, and adrenal glands. Subclinical infections have been documented in healthy residents of endemic regions. Paracoccidioidomycosis is most common in Venezuela, Colombia, Ecuador, Argentina, and Brazil. Histopathologic examination of clinical specimens may reveal globose yeast cells with multiple buds. Definitive diagnosis relies on culture of the organism. Itraconazole treatment has been effective (Table 110-1). An initial course of amphotericin B may be required in seriously ill patients.

Penicilliosis

Caused by the thermally dimorphic fungus *Penicillium marneffei*, penicilliosis is a disease of immunocompromised individuals living in or traveling to Southeast Asia. The primary portal of entry is the lungs, and hematologic dissemination follows. Clinical manifestations are similar to those of disseminated histoplasmosis and include fever, chills, weight loss, anemia, generalized lymphadenopathy, and hepatomegaly. Diffuse papular lesions similar to those of molluscum contagiosum are common in patients with

HIV infection or AIDS. Small yeast cells may be seen on histopathologic examination of tissue, but definitive diagnosis depends on culture. Amphotericin B is the treatment of choice for severely ill patients (Table 110-1). Patients who have less severe disease or who have responded to an initial course of amphotericin B may be treated with itraconazole. Primary therapy is usually given for 2 months; in patients with HIV infection or AIDS, suppressive therapy with itraconazole may be useful in preventing relapse.

Fusariosis

Fusariosis is an invasive mold infection associated with *Fusarium* species, most commonly *F. solani*. The skin and respiratory tract are the primary portals of entry. Localized skin infections may occur at sites of trauma in immunocompetent hosts. Disease may disseminate from the skin or respiratory tract in immunocompromised patients; 90% of such cases are reported in neutropenic patients with leukemia or recipients of allogeneic bone marrow transplants. The clinical presentation is generally nonspecific, with fever and skin lesions that eventually become necrotic and resemble ecthyma gangrenosum. Clinical, radiographic, and pathologic findings are similar to those in invasive aspergillosis or zygomycosis. Blood cultures are positive in up to 50% of cases, and the presence of a mold in cultured blood from neutropenic patients suggests fusariosis. *Fusarium* species are often resistant to antifungal therapy. High-dose amphotericin B has met with limited success. Therapy with voriconazole (Table 110-1) has been successful in a few patients. Therapy is continued until neutropenia resolves and a clinical response is documented. The prognosis of disseminated infection is related to the reversal of neutropenia and other immunodeficiencies.

Pseudallescheriasis and Scedosporiosis

The emerging pathogens *P. boydii*, *Scedosporium apiospermum* (the asexual form of *P. boydii*), and *S. prolificans* are molds that cause rare sinopulmonary infections in immunocompetent hosts and that may present as fungus balls in the lungs or paranasal sinuses. Severe pneumonia, invasive sinusitis, and hematogenous dissemination (including brain abscess) occur in immunosuppressed hosts, especially bone marrow transplant recipients. The hyphal elements seen in the tissues of patients with *Pseudallescheria* and *Scedosporium* infections resemble those seen in intravascular invasion by *Aspergillus*. The outcome of treatment is poor, and most patients with disseminated disease die. Amphotericin B is not effective in the treatment of pseudallescheriasis or scedosporiosis. A small number of patients have been cured with voriconazole in the same doses listed for fusariosis (Table 110-1). Surgical debridement and drainage of abscesses may also be necessary.

Trichosporonosis

Trichosporon species, predominantly *T. asahii* and to a lesser extent *T. mucoides*, can cause disseminated trichosporonosis in immunocompromised patients, especially those with profound neutropenia. Unpublished studies describe isolation of *Trichosporon* from pubic sites of white piedra,

sputum, skin lesions, and blood. *T. pullulans* (formerly *Monilia pullulans*) is a rare cause of systemic infection. Portals of entry include the skin, gastrointestinal tract, and lungs. The clinical presentation mimics candidiasis. Cultures of blood, skin lesions, or biopsy specimens confirm the diagnosis. *Trichosporon* shares antigens with *Cryptococcus neoformans* and produces positive results in the latex agglutination test. Treatment of *Trichosporon* infections is complicated by resistance to amphotericin B. Mortality rates of >80% have been reported. The azoles, especially voriconazole, have been effective alone or in combination with amphotericin B (Table 110-1). Adjunctive therapy with granulocyte-macrophage colony-stimulating factor or interferon γ may be beneficial. The prognosis, however, is related to the resolution of neutropenia.

ALGAL INFECTIONS

Prototheca, an achlorophyllic alga common in nature, has been associated with rare human infections in Europe, Asia, Oceania, and the United States (particularly the southeastern states). This organism has been isolated from slime flux of trees, industrial ponds, tap water, sewage systems, swimming pools, and soil. Infections with *P. wickerhamii* and *P. zopfii* occur primarily in immunocompromised patients. Protothecosis may present as a cutaneous disease with erythematous nodules, plaques, or superficial ulcers on exposed skin; as olecranon bursitis; or as a systemic infection. Histologic examination of biopsy

material may reveal multinucleated giant cells and extra- and intracellular, basophilic to amphiphilic organisms containing endospores. *Prototheca* can be cultured on Sabouraud's agar. The most frequently used therapeutic agent is amphotericin B, which has proved effective even in patients with disseminated protothecosis. Azole antifungal agents such as itraconazole, ketoconazole, and fluconazole have also been used successfully. Surgical excision may play a role in the treatment of localized cutaneous lesions.

CHAPTER 111

PNEUMOCYSTIS INFECTION

A. George Smulian ■ Peter D. Walzer

DEFINITION AND DESCRIPTION

Pneumocystis is an opportunistic fungal pulmonary pathogen that is an important cause of pneumonia in the immunocompromised host. Although organisms within the *Pneumocystis* genus are morphologically very similar, they are genetically diverse and host-specific. *P. jirovecii* infects humans, whereas *P. carinii*—the original species described in 1909—infects rats. For clarity, only the genus designation *Pneumocystis* will be used in this chapter.

Developmental stages of the organism include the trophic form, the cyst, and the precyst (an intermediate stage). The life cycle of *Pneumocystis* probably involves sexual and asexual reproduction, although definitive proof awaits the development of a reliable culture system.

Pneumocystis contains several different antigen groups, the most prominent of which is the 95- to 140-kDa major surface glycoprotein (MSG). MSG plays a central role in the interaction of *Pneumocystis* with its host.

EPIDEMIOLOGY

Serologic surveys have demonstrated that *Pneumocystis* has a worldwide distribution and that most healthy children have been exposed to the organism by 3–4 years of age. Airborne transmission of *Pneumocystis* has been documented in animal studies; person-to-person transmission has been suggested by hospital outbreaks of *Pneumocystis* pneumonia (PcP) and by molecular epidemiologic

PATHOGENESIS AND PATHOLOGY

The host factors that predispose to the development of PcP include defects in cellular and humoral immunity. The risk of PcP among HIV-infected patients rises markedly when circulating CD4+ T-cell counts fall below 200/ μ L. Other persons at risk for PcP are patients receiving immunosuppressive agents (particularly glucocorticoids) for cancer and organ transplantation; those receiving biologic agents such as infliximab and etanercept for rheumatoid arthritis and inflammatory bowel disease; children with primary immunodeficiency diseases; and premature malnourished infants.

The principal host effector cells against *Pneumocystis* are alveolar macrophages, which ingest and kill the organism, releasing a variety of inflammatory mediators. Proliferating organisms remain extracellular within the alveolus, attaching tightly to type I cells. Alveolar damage results in increased alveolar-capillary permeability and surfactant abnormalities, including a fall in phospholipids and an increase in surfactant proteins A and D. The host inflammatory response to lung injury leads to increases in levels of interleukin 8 and in neutrophil counts in bronchoalveolar lavage (BAL) fluid. These changes correlate with disease severity.

On lung sections stained with hematoxylin and eosin, the alveoli are filled with a typical foamy, vacuolated exudate. Severe disease may include interstitial edema, fibrosis, and hyaline membrane formation. The host inflammatory changes usually consist of hypertrophy of alveolar type II cells, a typical reparative response, and a mild mononuclear cell interstitial infiltrate. Malnourished infants display an intense plasma cell infiltrate that gave the disease its early name: interstitial plasma cell pneumonia.

CLINICAL FEATURES

Patients with PcP develop dyspnea, fever, and nonproductive cough. HIV-infected patients are usually ill for several weeks and may have relatively subtle manifestations. Symptoms in non-HIV-infected patients are of shorter duration and often begin after the glucocorticoid dose has been tapered. A high index of suspicion and a thorough history are key factors in early detection.

Physical findings include tachypnea, tachycardia, and cyanosis, but lung auscultation reveals few abnormalities. Reduced arterial oxygen pressure (Pa_{O_2}), increased alveolar-arterial oxygen gradient ($PA_{O_2} - Pa_{O_2}$), and respiratory alkalosis are evident. Diffusion capacity is reduced, and heightened uptake with nonspecific nuclear imaging techniques (gallium scan) may be noted. Elevated serum concentrations of lactate dehydrogenase, reflecting lung parenchymal damage, have been reported; however, the increase is not specific for PcP.

The classic findings on chest radiography consist of bilateral diffuse infiltrates beginning in the perihilar regions (Fig. 111-1A), but various atypical manifestations (nodular densities, cavitory lesions) have also been reported. Pneumothorax occurs, and its management is often difficult. Early in the course of PcP, the chest radiograph may be normal, although high-resolution CT of the lung may reveal ground-glass opacities at this stage (Fig. 111-1B).

While *Pneumocystis* usually remains confined to the lungs, cases of disseminated infection have occurred in both HIV-infected and non-HIV-infected patients. Common sites of involvement include the lymph nodes, spleen, liver, and bone marrow.

DIAGNOSIS

Because of the nonspecific nature of the clinical picture, the diagnosis must be based on specific identification of the organism. A definitive diagnosis is made by histopathologic staining. Traditional cell wall stains such as methenamine silver selectively stain the wall of

A

FIGURE 111-1

showing ground-glass opacification in an HIV-infected patient with PcP. (Courtesy of Dr. Christopher Meyer, with permission.)

Pneumocystis cysts, while reagents such as Wright-Giemsa stain the nuclei of all developmental stages. Immunofluorescence with monoclonal antibodies is more sensitive and specific than histologic staining. DNA amplification by PCR may become part of routine diagnostics but may not distinguish colonization from infection.

The successful diagnosis of PcP depends on the collection of proper specimens. In general, the yield from different diagnostic procedures is higher in HIV-infected patients than in non-HIV-infected patients because of the higher organism burden in the former group. Sputum induction and oral washes have gained popularity as simple, noninvasive techniques; however, these procedures require trained and dedicated personnel. Fiberoptic bronchoscopy with BAL, which provides information about the organism burden, the host inflammatory response, and the presence of other opportunistic infections, continues to be the mainstay of *Pneumocystis* diagnosis. Transbronchial biopsy and open lung biopsy, the most invasive procedures, are used only when a diagnosis cannot be made by BAL.

COURSE AND PROGNOSIS

In the typical case of untreated PcP, progressive respiratory embarrassment leads to death. Therapy is most effective when instituted early, before there is extensive alveolar damage. If examination of induced sputum is nondiagnostic and BAL cannot be performed in a timely manner, empirical therapy for PcP is reasonable. However, this practice does not eliminate the need for a specific etiologic diagnosis. With improved management of HIV and its complications, mortality from PcP is 15–20% at 1 month and 50–55% at 1 year. Rates of early death remain high among patients who require mechanical ventilation (60%) and among non-HIV-infected patients (40%).

Rx Treatment: **PNEUMOCYSTIS INFECTION**

Trimethoprim-sulfamethoxazole (TMP-SMX), which acts by inhibiting folic acid synthesis, is considered the drug of choice for all forms of PcP (Table 111-1). Therapy is continued for 14 days in non-HIV-infected patients and for 21 days in persons infected with HIV. Since HIV-infected patients respond more slowly than non-HIV-infected patients, it is prudent to wait at least 7 days after the initiation of treatment before concluding that therapy has failed. TMP-SMX is well tolerated by non-HIV-infected patients, whereas more than half of HIV-infected patients experience serious adverse reactions.

Several alternative regimens are available for the treatment of mild to moderate cases of PcP (a Pa_{O_2} of >70 mmHg or a $PA_{O_2} - Pa_{O_2}$ of <35 mmHg on breathing room air). TMP plus dapsone and clindamycin plus primaquine are about as effective as TMP-SMX. Dapsone and primaquine should not be administered to patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Atovaquone is less effective than TMP-SMX but is better tolerated. Since *Pneumocystis* lacks ergosterol, it is

TABLE 111-1

TREATMENT OF PNEUMOCYSTOSIS

| DRUG(S), DOSE, ROUTE | ADVERSE EFFECTS |
|---|--|
| First Choice^a | |
| TMP-SMX (5 mg/kg TMP, 25 mg/kg SMX ^b) q6–8h PO or IV | Fever, rash, cytopenias, hepatitis, hyperkalemia, GI disturbances |
| Other Agents^a | |
| TMP, 5 mg/kg q6–8h, plus dapsone, 100 mg qd PO | Hemolysis (G6PD deficiency), methemoglobinemia, fever, rash, GI disturbances |
| Atovaquone, 750 mg bid PO | Rash, fever, GI and hepatic disturbances |
| Clindamycin, 300–450 mg q6h PO or 600 mg q6–8h IV, plus primaquine, 15–30 mg qd PO | Hemolysis (G6PD deficiency), methemoglobinemia, rash, colitis, neutropenia |
| Pentamidine, 3–4 mg/kg qd IV | Hypotension, azotemia, cardiac arrhythmias, pancreatitis, dysglycemias, hypocalcemia, neutropenia, hepatitis |
| Trimetrexate, 45 mg/m ² qd IV, plus leucovorin, ^c 20 mg/kg q6h PO or IV | Cytopenias, peripheral neuropathy, hepatic disturbances |
| Adjunctive Agent | |
| Prednisone, 40 mg bid × 5 d, 40 mg qd × 5 d, 20 mg qd × 11 d; PO or IV | Immunosuppression, peptic ulcer, hyperglycemia, mood changes, hypertension |

^aTherapy is administered for 14 days to non-HIV-infected patients and for 21 days to HIV-infected patients.

^bEquivalent of 2 double-strength (DS) tablets. (One DS tablet contains 160 mg of TMP and 800 mg of SMX.)

^cLeucovorin prevents bone marrow toxicity from trimetrexate.

Note: GI, gastrointestinal; G6PD, glucose-6-phosphate dehydrogenase; TMP-SMX, trimethoprim-sulfamethoxazole.

not susceptible to antifungal agents that inhibit ergosterol synthesis.

Alternative regimens that are recommended for the treatment of moderate to severe PcP (a Pa_{O_2} of ≤ 70 mmHg or a $PA_{O_2} - Pa_{O_2}$ of ≥ 35 mmHg) are parenteral pentamidine, parenteral clindamycin plus primaquine, or trimetrexate plus leucovorin. Parenteral clindamycin plus primaquine may be more efficacious than pentamidine.

Molecular evidence of resistance to sulfonamides and to atovaquone has emerged among human *Pneumocystis* isolates. Although prior sulfonamide exposure is a risk factor, this resistance has also occurred in HIV-infected patients who have never received sulfonamides. The outcome of therapy appears to be linked more

strongly to traditional measures—e.g., high Acute Physiology, Age, and Chronic Health Evaluation III (APACHE III) scores, need for positive-pressure ventilation, delayed intubation, and development of pneumothorax—than to the presence of molecular markers of sulfonamide resistance. HIV-infected patients frequently experience deterioration of respiratory function shortly after receiving anti-*Pneumocystis* drugs. The adjunctive administration of tapering doses of glucocorticoids to HIV-infected patients with moderate to severe PcP can prevent this problem and improve the rate of survival (Table 111-1). For maximal benefit, this adjunctive therapy should be started early in the course of the illness. The use of steroids as adjunctive therapy in HIV-infected patients with mild PcP or in non-HIV-infected patients remains to be evaluated.

PREVENTION

Prophylaxis is indicated for HIV-infected patients with CD4+ T-cell counts of <200/μL or a history of oropharyngeal candidiasis and for both HIV-infected and non-HIV-infected patients who have recovered from PcP. Prophylaxis may be discontinued in HIV-infected patients once CD4+ T-cell counts have risen to >200/μL and remained at that level for ≥3 months. Primary prophylaxis guidelines for immunocompromised hosts not infected with HIV are less clear.

TMP-SMX is the drug of choice for primary and secondary prophylaxis (Table 111-2).

This agent also provides protection against toxoplasmosis and some bacterial infections. Alternative regimens are available for individuals intolerant of TMP-SMX (Table 111-2). Although there are no specific recommendations for preventing the spread of *Pneumocystis* in health care facilities, it seems prudent to prevent direct contact between patients with PcP and other susceptible hosts.

SECTION VIII

PROTOZOAL AND HELMINTHIC INFECTIONS

CHAPTER 112

LABORATORY DIAGNOSIS OF PARASITIC INFECTIONS

Sharon L. Reed ■ Charles E. Davis

The cornerstone for the diagnosis of parasitic infections is a thorough history of the patient's illness. Epidemiologic aspects of the illness are especially important because the risks of acquiring many parasites are closely related to occupation, recreation, or travel to areas of high endemicity. Without a basic knowledge of the epidemiology and life cycles of the major parasites, it is difficult to approach the diagnosis of parasitic infections systematically. Accordingly, the medical classification of important human parasites in this chapter emphasizes their geographic distribution, their transmission, and the anatomic location and stages of their life cycle in humans. The text and tables are intended to serve as a guide to the correct diagnostic procedures for the major parasitic infections and to direct the reader to other chapters that contain more comprehensive information about each infection. **Tables 112-1 to 112-3** summarize the geographic distributions, anatomic locations, and methods employed for the diagnosis of flatworm, roundworm, and protozoal infections, respectively.

In addition to selecting the correct diagnostic procedures, physicians must counsel their patients to ensure that specimens are collected properly and arrive at the laboratory promptly. For example, the diagnosis of bancroftian filariasis is unlikely to be confirmed by the laboratory unless blood is drawn near midnight, when the nocturnal microfilariae are active. Laboratory personnel and surgical pathologists should be notified in advance when a parasitic infection is suspected. Continuing interaction with the laboratory staff and the surgical pathologists increases the likelihood that parasites in body fluids or biopsy specimens will be examined carefully by the most capable individuals.

INTESTINAL PARASITES

Most helminths and protozoa exit the body in the fecal stream. The patient should be instructed to collect feces in a clean waxed or cardboard container and to record the time of collection on the container. Contamination with

water (which could contain free-living protozoa) or with urine (which can damage trophozoites) should be avoided. Fecal samples should be collected before ingestion of barium or other contrast agents for radiologic procedures and before treatment with antidiarrheal agents and antacids, because these substances change the consistency of the feces and interfere with microscopic detection of parasites. Because of the cyclic shedding of most parasites in the feces, a minimum of three samples collected on alternate days should be examined. Examination of a single sample can be up to 50% less sensitive. When delays in transport to the laboratory are unavoidable, fecal samples should be kept in polyvinyl alcohol or another fixative to preserve protozoal trophozoites. New collection kits with instructions for the patient to transfer portions of the sample directly into fixative and bacterial carrier medium may enhance the recovery of trophozoites. Refrigeration will also preserve trophozoites for a few hours and protozoal cysts and helminthic ova for several days.

Analysis of fecal samples entails both macroscopic and microscopic examination. Watery or loose stools are more likely to contain protozoal trophozoites, but protozoal cysts and all stages of helminths may be found in formed feces. If adult worms or tapeworm segments are observed, they should be transported promptly to the laboratory or washed and preserved in fixative for later examination. The only tapeworm with motile segments is *Taenia saginata*, the beef tapeworm, which patients sometimes bring to the physician. Motility is an important distinguishing characteristic, because the ova of *T. saginata* are morphologically indistinguishable from those of *Taenia solium*, the cause of cysticercosis.

Microscopic examination of feces is not complete until direct wet mounts have been evaluated and concentration techniques as well as permanent stains have been applied. Before accepting a report of negativity for ova and parasites as final, the physician should insist that the laboratory undertake each of these procedures. Some intestinal parasites are more readily detected in material other than feces. For example, examination of duodenal

TABLE 112-1

FLATWORM INFECTIONS

| Parasite | Geographic Distribution | Life-cycle Hosts | | Diagnosis | | | |
|--|--|-------------------------------|---------------------------|----------------|--------------------------|-----------------|--|

^a Stains and concentration techniques are discussed in the text.
^b Commercial string test is satisfactory; *Isospora* and *Cryptosporidium* are acid-fast.

contents is sometimes necessary to detect *Giardia lamblia*, *Cryptosporidium*, and *Strongyloides* larvae. Use of the “cellophane-tape” technique to detect pinworm ova on the perianal skin sometimes also reveals ova of *T. saginata* deposited perianally when the motile segments disintegrate (Table 112-4).

Two routine solutions are used to make wet mounts for the identification of the various life stages of helminths and protozoa: (1) physiologic saline for trophozoites, cysts, ova, and larvae; and (2) dilute iodine solution for protozoal cysts and ova. Iodine solution must never be used to examine specimens for trophozoites because it kills the parasites and thus eliminates their characteristic motility.

The two most common concentration procedures for detecting small numbers of cysts and ova are formalin-ether sedimentation and zinc sulfate flotation. The formalin-ether technique is preferable, because all parasites sediment but not all float. Slides permanently stained for trophozoites should be prepared before concentration. Additional slides stained for cysts and ova may be made from the concentrate.

In many instances, especially in the differentiation of *Entamoeba histolytica* from other amebas, identification of parasites from wet mounts or concentrates must be considered tentative. Permanently stained smears allow study of the cellular detail necessary for definitive identification. The iron-hematoxylin stain is excellent for critical work,

but trichrome staining, which can be completed in 1 h, is a satisfactory alternative that also reveals parasites in specimens preserved in polyvinyl alcohol fixative. Modified acid-fast staining and fluorescent auramine microscopy are useful adjuncts for detection and identification of several intestinal protozoa, including *Cryptosporidium* and *Cyclospora* (Table 112-3).

BLOOD AND TISSUE PARASITES

Invasion of tissue by protozoa and helminths renders the choice of diagnostic techniques more difficult. For example, physicians must understand that aspiration of an amebic liver abscess rarely reveals *E. histolytica* because the trophozoites are located primarily in the abscess wall. They must remember that the urine sediment offers the best opportunity to detect *Schistosoma haematobium* in the young Ethiopian immigrant or the American traveler who returns from Africa with hematuria. Tables 112-1 to 112-3, which offer a quick guide to the geographic distribution and anatomic locations of the major tissue parasites, should help the physician to select the appropriate body fluid or biopsy site for microscopic examination. Tables 112-5 and 112-6 provide additional information about the identification of parasites in samples from specific anatomic locations. The laboratory procedures for

TABLE 112-5

IDENTIFICATION OF PARASITES IN BLOOD AND OTHER BODY FLUIDS

| BODY FLUID, PARASITE | ENRICHMENT/STAIN | CULTURE TECHNIQUE |
|---------------------------------------|---|--|
| Blood | | |
| <i>Plasmodium</i> spp. | Thick and thin smears/Giemsa or Wright's | Not useful for diagnosis |
| <i>Leishmania</i> spp. | Buffy coat/Giemsa | Media available from CDC |
| African trypanosomes ^a | Buffy coat, anion column/wet mount and Giemsa | Mouse or rat inoculation ^b |
| <i>Trypanosoma cruzi</i> ^c | As for African species | As above and xenodiagnosis |
| <i>Toxoplasma gondii</i> | Buffy coat/Giemsa | Fibroblast cell lines |
| Microfilariae ^d | Nuclepore filtration/wet mount and Giemsa | None |
| Urine | | |
| <i>Schistosoma haematobium</i> | Centrifugation/wet mount | None |
| Microfilariae (in chyluria) | As for blood | None |
| Spinal Fluid | | |
| African trypanosomes | Centrifugation, anion column/wet mount and Giemsa | As for blood |
| <i>Naegleria fowleri</i> | Centrifugation/wet mount and Giemsa or trichrome | Nonnutrient agar overlaid with <i>Escherichia coli</i> |

^a *Trypanosoma rhodesiense* and *T. gambiense*.

^b Inject mice intraperitoneally with 0.2 mL of whole heparinized blood (0.5 mL for rats). After 5 days, tail blood should be checked daily for trypanosomes as described above. Call the CDC (770-488-7775) for information on diagnosis and treatment.

^c Detectable in blood by conventional techniques only during acute disease. Xenodiagnosis is successful in ~50% of patients with chronic Chagas' disease.

^d Day (1000–1400 h) and night (2200–0200 h) blood should be drawn to maximize the chance of detecting *Wuchereria* (nocturnal except for Pacific strains), *Brugia* (nocturnal), and *Loa loa* (diurnal).

detection of parasites in other body fluids are similar to those used in the examination of feces. The physician should insist on wet mounts, concentration techniques, and permanent stains for all body fluids. The trichrome or iron-hematoxylin stain is satisfactory for all tissue

helminths in body fluids other than blood, but microfilarial worms and blood protozoa are more easily visualized when stained with Giemsa or Wright's stain.

The most common parasites detected in Giemsa-stained blood smears are the plasmodia, microfilariae,

TABLE 112-6

MINOR PROCEDURES FOR DIAGNOSIS OF PARASITIC INFECTIONS

| PARASITE(S) AND STAGE | PROCEDURE |
|--|--|
| <i>Onchocerca volvulus</i> and <i>Mansonella streptocerca</i> microfilariae | <i>Skin snips</i> : Lift skin with a needle and excise ~1 mg to a depth of 0.5 mm from several sites. Weigh each sample, place it in 0.5 mL of saline for 4 h, and examine wet mounts and Giemsa stains of the saline either directly or after filtration. Count microfilariae. ^a |
| <i>Loa loa</i> adults and <i>O. volvulus</i> adults and microfilariae | <i>Biopsies of subcutaneous nodules</i> : Stain routine histopathologic sections and impression smears with Giemsa. |
| <i>Trichinella spiralis</i> larvae (and perhaps <i>Taenia solium</i> cysticerci) | <i>Muscle biopsies</i> : Excise ~1.0 g of deltoid or gastrocnemius muscle and squash between two glass slides for direct microscopic examination. |
| <i>Schistosoma</i> ova of all species, but especially <i>S. mansoni</i> | <i>Rectal snips</i> : From four areas of mucosa, take 2-mg snips, tease onto a glass slide, and flatten with a second slide before examining directly at 10×. Preparations may be fixed in alcohol or stained. |
| <i>Trypanosoma gambiense</i> and <i>T. rhodesiense</i> trypomastigotes | <i>Aspirate of chancre or lymph node</i> : ^b Aspirate center with 18-gauge needle, place a drop on a slide, and examine for motile forms. An otherwise insufficient volume of material may be stained with Giemsa. |
| <i>Acanthamoeba</i> spp. trophozoites or cysts | <i>Corneal scrapings</i> : Obtain sample from ophthalmologist for immediate Giemsa staining and culture on nutrient agar overlaid with <i>Escherichia coli</i> . |
| Cutaneous and mucocutaneous <i>Leishmania</i> spp. | <i>Swabs, aspirates, or punch biopsies of skin lesions</i> : Obtain specimen from margin of lesion for Giemsa staining of impression smears, and section and culture on special media from CDC. |

^a Counts of >100/mg are associated with significant risk of complications.

^b Lymph node aspiration is contraindicated in some infections and should be used judiciously.

and African trypanosomes (Table 112-5). Most patients with Chagas' disease present in the chronic phase, when *Trypanosoma cruzi* is no longer microscopically detectable in blood smears. Wet mounts are sometimes more sensitive than stained smears for the detection of microfilariae and African trypanosomes because these active parasites cause noticeable movement of the erythrocytes in the microscopic field. Nuclepore filtration of blood facilitates the detection of microfilariae. The intracellular amastigote forms of *Leishmania* spp. and *T. cruzi* can sometimes be visualized in stained smears of peripheral blood, but aspirates of the bone marrow, liver, and spleen are the best sources for microscopic detection and culture of *Leishmania* in kala-azar and of *T. cruzi* in chronic Chagas' disease. The diagnosis of malaria and the critical distinction among the various *Plasmodium* species are made by microscopic examination of stained thick and thin blood films (Chap. 116).

Although most tissue parasites stain with the traditional hematoxylin and eosin, surgical biopsy specimens should also be stained with appropriate special stains. The surgical pathologist who is accustomed to applying silver stains for *Pneumocystis* to induced sputum and transbronchial biopsies may need to be reminded to examine wet mounts and iron-hematoxylin-stained preparations of pulmonary specimens for helminthic ova and *E. histolytica*. The clinician should also be able to advise the surgeon and pathologist about optimal techniques for the identification of parasites in specimens obtained by certain specialized minor procedures (Table 112-6). For example, the excision of skin snips for the diagnosis of onchocerciasis, the collection of rectal snips for the diagnosis of schistosomiasis, and punch biopsy of skin lesions for the identification and culture of cutaneous and mucocutaneous species of *Leishmania* are simple procedures, but the diagnosis can be missed if the specimens are improperly obtained or processed.

NONSPECIFIC TESTS

Eosinophilia (>500/ μ L) is a common accompaniment of infections with most of the tissue helminths; absolute numbers of eosinophils may be high in trichinellosis and the migratory phases of filariasis (Table 112-7). Intestinal helminths provoke eosinophilia only during pulmonary migration of the larval stages. Eosinophilia is not a manifestation of protozoal infections, with the possible exceptions of those due to *Iso spor a* and *Dientamoeba fragilis*.

Like the hypochromic, microcytic anemia of heavy hookworm infections, other nonspecific laboratory abnormalities may suggest parasitic infection in patients with appropriate geographic and/or environmental exposures. Biochemical evidence of cirrhosis or an abnormal urine sediment in an African immigrant certainly raises the possibility of schistosomiasis, and anemia and thrombocytopenia in a febrile traveler or immigrant are among the hallmarks of malaria. CT and MRI also contribute to the diagnosis of infections with many tissue parasites and have become invaluable adjuncts in the diagnosis of neurocysticercosis and cerebral toxoplasmosis.

TABLE 112-7
PARASITES FREQUENTLY ASSOCIATED WITH EOSINOPHILIA^a

| PARASITE | COMMENT |
|---|--|
| Tapeworms (Cestodes) | |
| <i>Echinococcus granulosus</i> | When hydatid cyst leaks |
| <i>Taenia solium</i> | During muscle encystation and in CSF with neurocysticercosis |
| Flukes (Trematodes) | |
| <i>Paragonimus</i> spp. | Uniformly high in acute stage |
| <i>Fasciola hepatica</i> | May be high in acute stage |
| <i>Clonorchis</i> (<i>Opisthorchis</i>) <i>sinensis</i> | Variable |
| <i>Schistosoma mansoni</i> | 50% of infected travelers |
| <i>S. haematobium</i> | 25% of infected travelers |
| <i>S. japonicum</i> | Up to 6000/ μ L in acute infection |
| Roundworms | |
| <i>Ascaris lumbricoides</i> | During larval migration |
| Hookworm species | During larval migration |
| <i>Strongyloides stercoralis</i> | Profound during migration and early years of infection |
| <i>Trichinella spiralis</i> | Up to 7000/ μ L |
| Filarial species ^b | Varies but can reach 5000–8000/ μ L |
| <i>Toxocara</i> spp. | >3000/ μ L |
| <i>Ancylostoma braziliense</i> | With extensive cutaneous eruption |
| <i>Gnathostoma spinigerum</i> | In visceral larva migrans and eosinophilic meningitis |
| <i>Angiostrongylus cantonensis</i> | In eosinophilic meningitis |
| <i>A. costaricensis</i> | During larval migration in mesenteric vessels |

^a Virtually every helminth has been associated with eosinophilia. This table includes both common and uncommon parasites that frequently elicit eosinophilia during infection.

^b *Wuchereria bancrofti*, *Brugia* spp., *Loa loa*, and *Onchocerca volvulus*.

ANTIBODY AND ANTIGEN DETECTION

Useful antibody assays for many of the important tissue parasites are available; most of those listed in Table 112-8 can be obtained from the Centers for Disease Control and Prevention (CDC) in Atlanta. The results of serologic tests not listed in the tables should be interpreted with caution.

The value of antibody assays is limited by several factors. For example, the preparation of thick and thin blood smears remains the procedure of choice for the diagnosis of malaria in individual patients because diagnostic titers to plasmodia develop slowly and do not differentiate

TABLE 112-8

SEROLOGIC AND MOLECULAR TESTS FOR PARASITIC INFECTIONS^a

| PARASITE, INFECTION | ANTIBODY | ANTIGEN OR DNA/RNA |
|-----------------------|-----------------------------|--|

| Balmuthiasis | | DFA |

^a Unless otherwise noted, all tests are available at the CDC.

^b Research or commercial laboratories only.

^c Available at the NIH (301-496-5398) and commercially.

^d Of limited use for management of acute disease.

^e Determination of infection within the last 3 months may require additional tests by a research laboratory.

Note: EIA, enzyme immunoassay; WB, western blot; IIF, indirect immunofluorescence; DFA, direct fluorescent antibody; PCR, polymerase chain reaction; RAPID, rapid immunographic assay. Most antigen and antibody parasite detection kits are available commercially. Most PCRs listed are now available at the CDC and in commercial or research laboratories. Contact the CDC.

species—a critical step in patient management. Filarial antigens cross-react with those from other nematodes; as in assays for antibody to most parasites, the presence of antibody in the filarial assay fails to distinguish between past and current infection. Despite these specific limitations, the restricted geographic distribution of many tropical parasites increases the diagnostic usefulness of both the presence and the absence of antibody in travelers from industrialized countries. In contrast, a large proportion of

the world's population has been exposed to *Toxoplasma gondii*, and the presence of IgG antibody to *T. gondii* does not constitute proof of active disease.

Fewer antibody assays are available for the diagnosis of infection with intestinal parasites. *E. histolytica* is the major exception. Sensitive, specific serologic tests are invaluable in the diagnosis of amebiasis. Commercial kits for the detection of antigen by enzyme-linked immunosorbent assay or of whole organisms by fluorescent antibody assay are now available for several protozoan parasites (Table 112-8).

MOLECULAR TECHNIQUES

DNA hybridization with probes that are repeated many times in the genome of a specific parasite and amplification of a specific DNA fragment by the polymerase chain reaction (PCR) have now been established as useful techniques for the diagnosis of several protozoan infections (Table 112-8). Although PCR is very sensitive, it is an adjunct to conventional techniques for parasite detection and should be requested only when microscopic and immunodiagnostic procedures fail to establish the probable diagnosis. For example, only multiple negative blood smears or the failure to identify the infecting species justifies PCR for the diagnosis or proper management of malaria. In addition to PCR of anticoagulated blood, the CDC and several commercial laboratories now perform PCRs for detection of certain specific parasites in stool samples, biopsy specimens, and bronchoalveolar lavage fluid (Table 112-8). Although PCRs are now used primarily for the detection of protozoans, active research efforts are likely to establish their feasibility for the detection of several helminths.

CHAPTER 113

AGENTS USED TO TREAT PARASITIC INFECTIONS

Thomas A. Moore

Parasitic infections afflict more than half of the world's population and impose a substantial health burden, particularly in underdeveloped nations, where they are most prevalent. The remarkable success of global campaigns aimed at controlling or eliminating ancient scourges such as dracunculiasis and onchocerciasis has been offset by the spread of other diseases such as trypanosomiasis due to crumbling infrastructures in settings of HIV infection, civil war, and unstable government. The reach of some parasitic diseases, including malaria, has expanded over the past few decades as a result of factors such as deforestation, population shifts, global warming, and other climatic events. Despite major efforts at vaccine development and vector control, chemotherapy remains the single most effective means of controlling parasitic infections. However, efforts to combat the spread of some diseases are hindered by the development and spread of drug resistance, the limited introduction of new antiparasitic agents, and the proliferation of counterfeit medications. Significant advances toward the reduction of the burden of parasitic disease have nevertheless been

made, and the significant increase in funding of global health initiatives offers promise for the future.

This chapter deals exclusively with the agents used to treat infections due to parasites. Specific treatment recommendations for the parasitic diseases of humans are listed in subsequent chapters. The pharmacology of the antiparasitic agents is discussed in great detail in Chap. 114.

Table 113-1 presents a brief overview of each agent (including some drugs that are covered in other chapters), along with its major toxicities, spectrum of activity, and safety for use during pregnancy and lactation. Many of the agents are approved by the U.S. Food and Drug Administration but are considered investigational for the treatment of certain infections; these drugs are marked accordingly in the table. In addition, drugs available only through the Centers for Disease Control and Prevention (CDC) Drug Service (telephone: 404-639-3670 or 404-639-2888; www.cdc.gov/ncidod/dpd/professional/drug_service.htm) or only through their manufacturers (whose contact information may be available from the CDC) are specified by footnotes in the table.

TABLE 113-1

OVERVIEW OF AGENTS USED FOR THE TREATMENT OF PARASITIC INFECTIONS

| DRUGS BY CLASS | PARASITIC INFECTION(S) | ADVERSE EFFECTS | MAJOR DRUG-DRUG INTERACTIONS | PREGNANCY CLASS ^a | BREAST MILK |
|---|--|---|--|---|-----------------------|
| 4-Aminoquinolines Amodiaquine Chloroquine | Malaria ^b Malaria ^b | Agranulocytosis, hepatotoxicity <i>Occasional</i> : pruritus, nausea, vomiting, headache, hair depigmentation, exfoliative dermatitis, reversible corneal opacity. <i>Rare</i> : irreversible retinal injury, nail discoloration, blood dyscrasias | No information Antacids and kaolin: reduced absorption of chloroquine Ampicillin: bioavailability reduced by chloroquine Cimetidine: increased serum levels of chloroquine Cyclosporine: serum levels increased by chloroquine | Not assigned Not assigned ^c | No information Yes |
| 8-Aminoquinolines Primaquine | Malaria ^b | <i>Frequent</i> : hemolysis in patients with G6PD deficiency. <i>Occasional</i> : methemoglobinemia, GI disturbances. <i>Rare</i> : CNS symptoms | Quinacrine: potentiated toxicity of primaquine | Contraindicated | No information |

CHAPTER 114

PHARMACOLOGY OF AGENTS USED TO TREAT PARASITIC INFECTIONS

Thomas A. Moore

This chapter deals exclusively with the pharmacologic properties of the agents used to treat infections due to parasites. Specific treatment recommendations for the parasitic diseases of humans are listed in the chapters on those diseases. Information on these agents' major toxicities, spectrum of activity, and safety for use during pregnancy and lactation is presented in Chap. 113. Many of the agents discussed herein are approved by the U.S. Food and Drug Administration (FDA) but are considered investigational for the treatment of certain infections (see Table 113-1). Drugs marked in the text with an asterisk (*) are available only through the Centers for Disease Control and Prevention (CDC) Drug Service (telephone: 404-639-3670 or 404-639-2888; www.cdc.gov/ncidod/dpd/professional/drug_service.htm). Drugs marked with a dagger (†) are available only through their manufacturers; contact information for these manufacturers may be available from the CDC.

ALBENDAZOLE

Like all benzimidazoles, albendazole acts by selectively binding to free β -tubulin in nematodes, inhibiting the polymerization of tubulin and the microtubule-dependent uptake of glucose. Irreversible damage occurs in gastrointestinal (GI) cells of the nematodes, resulting in starvation, death, and expulsion by the host. While highly injurious to nematodes, this fundamental disruption of cellular metabolism also offers treatment for a wide range of parasitic diseases.

Albendazole is poorly absorbed from the GI tract. Administration with a fatty meal increases its absorption by two- to sixfold. Poor absorption may be advantageous for the treatment of intestinal helminths, but successful treatment of tissue helminth infections (e.g., hydatid disease and neurocysticercosis) requires that a sufficient amount of active drug reach the site of infection. The metabolite albendazole sulfoxide is responsible for the drug's therapeutic effect outside the gut lumen. Albendazole sulfoxide crosses the blood-brain barrier, reaching a level significantly higher than that achieved in plasma. The high concentrations of albendazole sulfoxide attained in cerebrospinal fluid (CSF) probably explain the efficacy of albendazole in the treatment of neurocysticercosis.

Albendazole is extensively metabolized in the liver, but there are few data regarding the drug's use in patients

with hepatic disease. Single-dose albendazole therapy in humans is largely without side effects (overall frequency, $\leq 1\%$). More prolonged courses (e.g., as administered for cystic and alveolar echinococcal disease) have been associated with liver function abnormalities and bone marrow toxicity. Thus, when prolonged use is anticipated, the drug should be administered in treatment cycles of 28 days interrupted by 14 days off therapy. Prolonged therapy with full-dose albendazole (800 mg/d) should be approached cautiously in patients also receiving drugs with known effects on the cytochrome P450 system.

AMODIAQUINE

Amodiaquine has been widely used in the treatment of malaria for >40 years. Like chloroquine (the other major 4-aminoquinoline), amodiaquine is now of limited use because of the spread of resistance. Amodiaquine interferes with hemozoin formation through complexation with heme. Although rapidly absorbed, amodiaquine behaves as a prodrug after oral administration, with the principal plasma metabolite monodesethylamodiaquine as the predominant antimalarial agent. Amodiaquine and its metabolites are all excreted in urine, but there are no recommendations concerning dosage adjustment in patients with impaired renal function. Severe adverse events can occur, albeit rarely (1 case in 2000 treatment courses), with amodiaquine administration. Agranulocytosis and hepatotoxicity can develop with repeated use; therefore, this drug should not be used for prophylaxis.

AMPHOTERICIN B

See Table 113-1 and Chap. 102.

ANTIMONIALS*

Despite associated adverse reactions and the need for prolonged parenteral treatment, the pentavalent antimonial compounds (designated Sb^v) have remained the first-line therapy for all forms of leishmaniasis throughout the world, primarily because they are affordable, are effective, and have survived the test of time. Although they have been used for almost 100 years, their mechanism of action against *Leishmania* spp. has only recently

come to light. Pentavalent antimonials are active only after bio-reduction to the trivalent Sb(III) form. This form inhibits trypanothione reductase, a critical enzyme involved in the oxidative stress management of *Leishmania* spp. The fact that *Leishmania* spp. use trypanothione rather than glutathione (which is used by mammalian cells) may explain the parasite-specific activity of antimonials. The drugs are taken up by the reticuloendothelial system, and their activity against *Leishmania* spp. may be enhanced by this localization. Sodium stibogluconate is the only pentavalent antimonial available in the United States; meglumine antimonate is principally used in francophone countries.

Resistance is a major problem in some areas. Although low-level unresponsiveness to Sb^v was identified in India in the 1970s, incremental increases in both the recommended daily dosage (to 20 mg/kg) and the duration of treatment (to 28 days) satisfactorily compensated for the growing resistance until around 1990. There has since been a steady erosion in the capacity of Sb^v to induce long-term cure in patients with kala-azar who live in eastern India. Foremost among the many factors that have probably contributed to this failure is the provision of suboptimal treatment for years, which led to the development of drug resistance among parasites. Co-infection with HIV impairs the treatment response.

Sodium stibogluconate is available in aqueous solution and is administered parenterally. Antimony appears to have two elimination phases. When administered IV, the mean half-life of the first phase is <2 h; the mean half-life of the terminal elimination phase is nearly 36 h. This slower phase may be due to conversion of pentavalent antimony to a trivalent form that is the likely cause of the side effects often seen with prolonged therapy.

ARTEMISININ DERIVATIVES

Artesunate, artemether, arteether, and the parent compound artemisinin are sesquiterpene lactones derived from the wormwood plant *Artemisia annua*. These agents are at least 10-fold more potent in vivo than other antimalarial drugs and presently show no cross-resistance with known antimalarial drugs; thus, they have become first-line agents for the treatment of severe falciparum malaria in some areas where multidrug resistance is a major problem. However, to limit the development of resistance, the World Health Organization (WHO) has recommended that artemisinin and its derivatives be used only in areas where there is proven multidrug resistance. Artemether appears to be effective for the treatment of schistosomiasis and is being evaluated for community-based treatment programs.

The artemisinin compounds are rapidly effective against the asexual blood forms of *Plasmodium* spp. but are not active against intrahepatic forms. Artemisinin and its derivatives are highly lipid soluble and readily cross both host and parasite cell membranes. One factor that explains the drugs' highly selective toxicity against malaria is that parasitized erythrocytes concentrate artemisinin and its

derivatives to concentrations 100-fold higher than those in uninfected erythrocytes. The antimalarial effect of these agents results primarily from dihydroartemisinin, a compound to which artemether and artesunate are both converted. In the presence of heme or molecular iron, the endoperoxide moiety of dihydroartemisinin decomposes, generating free radicals and other metabolites that damage parasite proteins. Long treatment courses are required. When these agents are used alone, recrudescence may occur. The compounds are available for oral, rectal, IV, or IM administration, depending on the derivative. Artemisinin and its derivatives are cleared rapidly from the circulation. Their short half-lives limit their value for prophylaxis and monotherapy. A combined formulation of artemether and lumefantrine has been developed for the treatment of acute uncomplicated falciparum malaria in areas where *Plasmodium falciparum* is resistant to chloroquine and antifolates.

ATOVAQUONE

Atovaquone is a hydroxynaphthoquinone that exerts broad-spectrum antiprotozoal activity via selective inhibition of parasite mitochondrial electron transport. This agent exhibits potent activity against toxoplasmosis and babesiosis when used with pyrimethamine and azithromycin, respectively. Atovaquone possesses a novel mode of action against *Plasmodium* spp., inhibiting the electron transport system at the level of the cytochrome bc₁ complex. The drug is active against both the erythrocytic and the exoerythrocytic stages of *Plasmodium* spp.; however, because it does not eradicate hypnozoites from the liver, patients with *Plasmodium vivax* or *Plasmodium ovale* infections must be given radical prophylaxis.

Malarone is a fixed-dose combination of atovaquone and proguanil used for malaria prophylaxis as well as for the treatment of acute, uncomplicated *P. falciparum* malaria. Malarone has been shown to be effective in regions with multidrug-resistant *P. falciparum*. Resistance to atovaquone has yet to be reported.

The bioavailability of atovaquone varies considerably. Absorption after a single oral dose is slow, increases two- to threefold with a fatty meal, and is dose-limited above 750 mg. The elimination half-life is increased in patients with moderate hepatic impairment. Because of the potential for drug accumulation, the use of atovaquone is contraindicated in persons with severe renal impairment (creatinine clearance rate <30 mL/min). No dosage adjustments are needed in patients with mild to moderate renal impairment. It is unknown if atovaquone is dialyzable.

AZITHROMYCIN

See Table 113-1 and Chap. 33.

AZOLES

See Table 113-1 and Chap. 102.

BENZNIDAZOLE

This oral nitroimidazole derivative is used to treat Chagas' disease, with cure rates of 80–90% recorded in acute infections. Benznidazole is believed to exert its trypanocidal effects by generating oxygen radicals to which the parasites are more sensitive than mammalian cells because of a relative deficiency in antioxidant enzymes. Benznidazole also appears to alter the balance between pro- and anti-inflammatory mediators by downregulating the synthesis of nitrite, interleukin (IL) 6, and IL-10 in macrophages. Benznidazole is highly lipophilic and readily absorbed. The drug is extensively metabolized; only 5% of the dose is excreted unchanged in the urine.

BITHIONOL

Bithionol is a chlorinated bisphenol with activity against trematodes. *Fasciola hepatica* uses fumarate reduction coupled to rhodoquinone for anaerobic energy metabolism. Bithionol competitively inhibits electron transfer to fumarate by rhodoquinone; the result is impaired anaerobic energy metabolism and trematode death. Bithionol is parasite specific for two reasons: (1) Fumarate reductase catalyzes the reverse of the reaction of mammalian succinic dehydrogenase in the Krebs cycle. (2) The rhodoquinone respiratory chain link is unique to the parasite. In the mammalian respiratory chain, the quinone electron carrier is ubiquinone. Bithionol is readily absorbed from the GI tract. It is no longer produced, but limited supplies are available from the CDC.

CHLOROQUINE

This 4-aminoquinoline has marked, rapid schizontocidal and gametocidal activity against blood forms of *P. ovale* and *Plasmodium malariae* and against susceptible strains of *P. vivax* and *P. falciparum*. It is not active against intrahepatic forms (*P. vivax* and *P. ovale*). Parasitized erythrocytes accumulate chloroquine in significantly greater concentrations than do normal erythrocytes. Chloroquine, a weak base, concentrates in the food vacuoles of intraerythrocytic parasites because of a relative pH gradient between the extracellular space and the acidic food vacuole. Once it enters the acidic food vacuole, chloroquine is rapidly converted to a membrane-impermeable protonated form and is trapped. Continued accumulation of chloroquine in the parasite's acidic food vacuoles results in drug levels that are 600-fold higher at this site than in plasma. The high accumulation of chloroquine results in an increase in pH within the food vacuole to a level above that required for the acid proteases' optimal activity, inhibiting parasite heme polymerase; as a result, the parasite is effectively killed with its own metabolic waste. Compared with susceptible strains, chloroquine-resistant plasmodia transport chloroquine out of intraparasitic compartments more rapidly and maintain lower chloroquine concentrations in their acid vesicles. Hydroxychloroquine, a congener of chloroquine, is equivalent to

chloroquine in its antimalarial efficacy but is preferred to chloroquine for the treatment of autoimmune disorders because it produces less ocular toxicity when used in high doses.

Chloroquine is well absorbed. However, because it exhibits extensive tissue binding, a loading dose is required to yield effective plasma concentrations. A therapeutic drug level in plasma is reached 2–3 h after oral administration (the preferred route). Chloroquine can be administered IV, but excessively rapid parenteral administration can result in seizures and death from cardiovascular collapse. The mean half-life of chloroquine is 4 days, but the rate of excretion decreases as plasma levels decline, making once-weekly administration possible for prophylaxis in areas with sensitive strains. About half of the parent drug is excreted in urine, but the dose should not be reduced for persons with acute malaria and renal insufficiency.

CIPROFLOXACIN

See Table 113-1 and Chap. 33.

CLINDAMYCIN

See Table 113-1 and Chap. 33.

DAPSONE

See Table 113-1 and Chap. 69.

DEHYDROEMETINE

Emetine is an alkaloid derived from ipecac; dehydroemetine is synthetically derived from emetine and is considered less toxic. Both agents are active against *Entamoeba histolytica* and appear to work by blocking peptide elongation and thus inhibiting protein synthesis. Emetine is rapidly absorbed after parenteral administration, rapidly distributed throughout the body, and slowly excreted in the urine in unchanged form. Both agents are contraindicated in patients with renal disease.

DIETHYLCARBAMAZINE*

A derivative of the antihelminthic agent piperazine with a long history of successful use, diethylcarbamazine (DEC) remains the treatment of choice for lymphatic filariasis and loiasis and has also been used for visceral larva migrans. While piperazine itself has no antifilarial activity, the piperazine ring of DEC is essential for the drug's activity. Although DEC was shown to be an effective agent for treatment of lymphatic filariasis in 1947, its mechanism of action remains to be fully defined. Proposed mechanisms include immobilization due to inhibition of parasite cholinergic muscle receptors, disruption of microtubule formation, and alteration of helminthic surface membranes resulting in enhanced killing by the host's immune system. In addition, DEC

enhances adherence properties of eosinophils. The development of resistance under drug pressure (i.e., a progressive decrease in efficacy when the drug is used widely in human populations) has not been observed, although DEC's effect is variable when administered to persons with filariasis. Monthly administration provides effective prophylaxis against both bancroftian filariasis and loiasis.

DEC is well absorbed after oral administration, with peak plasma concentrations reached within 1–2 h. No parenteral form is available. The drug is eliminated largely by renal excretion, with <5% found in feces. If more than one dose is to be administered to an individual with renal dysfunction, the dose should be reduced commensurate with the reduction in creatinine clearance rate. Alkalinization of the urine prevents renal excretion and increases the half-life of DEC. Use in patients with onchocerciasis can precipitate a Mazzotti reaction, with pruritus, fever, and arthralgias. Like other piperazines, DEC is active against *Ascaris* spp. Patients co-infected with this nematode may expel live but paralyzed worms after treatment.

DILOXANIDE FUROATE

Diloxanide furoate, a substituted acetanilide, is a luminal active agent used to eradicate the cysts of *E. histolytica*. After ingestion, diloxanide furoate is hydrolyzed by enzymes in the lumen or mucosa of the intestine, releasing furoic acid and the ester diloxanide; the latter acts directly as an amebicide.

Diloxanide furoate is given alone to asymptomatic cyst passers. For patients with active amebic infections, diloxanide is generally administered in combination with a 5-nitroimidazole such as metronidazole or tinidazole. Diloxanide furoate is rapidly absorbed after oral administration. When coadministered with a 5-nitroimidazole, only diloxanide appears in the systemic circulation; levels peak within 1 h and disappear within 6 h. About 90% of an oral dose is excreted in the urine within 48 h, chiefly as the glucuronide metabolite. Diloxanide furoate is contraindicated in pregnant and breast-feeding women and in children <2 years of age.

EFLORNITHINE[†]

Eflornithine (difluoromethylornithine, or DFMO) is a fluorinated analogue of the amino acid ornithine. Although originally designed as an antineoplastic agent, eflornithine has proven effective against some trypanosomatids. At one point, the production of this effective agent ceased despite the increasing incidence of human African trypanosomiasis; however, production resumed after eflornithine was discovered to be an effective cosmetic depilatory agent.

Eflornithine has specific activity against all stages of infection with *Trypanosoma brucei gambiense*; however, it is inactive against *T. b. rhodesiense*. The drug acts as an irreversible suicide inhibitor of ornithine decarboxylase, the first enzyme in the biosynthesis of the polyamines putrescine and spermidine. Polyamines are essential for the synthesis of trypanothione, an enzyme required for the maintenance of intracellular thiols in the correct

redox state and in the removal of reactive oxygen metabolites. However, polyamines are also essential for cell division in eukaryotes, and ornithine decarboxylase is similar in trypanosomes and mammals. The selective antiparasitic activity of eflornithine is partly explained by the structure of the trypanosomal enzyme, which lacks a 36-amino-acid C-terminal sequence found on mammalian ornithine decarboxylase. This difference results in a lower turnover of ornithine decarboxylase and a more rapid decrease of polyamines in trypanosomes than in the mammalian host. The diminished effectiveness of eflornithine against *T. b. rhodesiense* appears to be due to the parasite's ability to replace the inhibited enzyme more rapidly than *T. b. gambiense*.

Eflornithine is less toxic but more costly than conventional therapy. Eflornithine HCl can be administered IV or PO; however, its bioavailability after oral administration is only 54%. Eflornithine readily crosses the blood-brain barrier; CSF levels are highest in persons with the most severe central nervous system (CNS) involvement. The kidney excretes >80% of the drug dose; therefore, the dosage should be reduced in patients with renal failure.

FUMAGILLIN

Fumagillin is a water-insoluble antibiotic that is derived from the fungus *Aspergillus fumigatus* and is active against microsporidia. This drug is effective when used topically to treat ocular infections due to *Encephalitozoon* spp. When given systemically, fumagillin was effective but caused thrombocytopenia in all recipients in the second week of treatment; this side effect was readily reversed when administration of the drug was stopped. The mechanisms by which fumagillin inhibits microsporidial replication are poorly understood, although the drug may inhibit methionine aminopeptidase 2 by irreversibly blocking the active site.

FURAZOLIDONE

This nitrofur derivative is an effective alternative agent for the treatment of giardiasis and also exhibits activity against *Isospora belli*. Since it is the only agent active against *Giardia* that is available in liquid form, it is often used to treat young children. Furazolidone undergoes reductive activation in *Giardia lamblia* trophozoites—an event that, unlike the reductive activation of metronidazole, involves an NADH oxidase. The killing effect correlates with the toxicity of reduced products, which damage important cellular components, including DNA. Although furazolidone had been thought to be largely unabsorbed when administered orally, the occurrence of systemic adverse reactions indicates that this is not the case. More than 65% of the drug dose can be recovered from the urine as colored metabolites. Omeprazole reduces the oral bioavailability of furazolidone.

Furazolidone is a monoamine oxidase (MAO) inhibitor; thus caution should be used in its concomitant administration with other drugs (especially indirectly acting sympathomimetic amines) and in the consumption of

food and drink containing tyramine during treatment. However, hypertensive crises have not been reported in patients receiving furazolidone, and it has been suggested that—since furazolidone inhibits MAO gradually over several days—the risks are small if treatment is limited to a 5-day course. Because hemolytic anemia can occur in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency and glutathione instability, furazolidone treatment is contraindicated in mothers who are breast-feeding and in neonates.

HALOFANTRINE

This 9-phenanthrenemethanol is one of three classes of arylaminoalcohols first identified as potential antimalarial agents by the World War II Malaria Chemotherapy Program. Its activity is believed to be similar to that of chloroquine, although it is an oral alternative for the treatment of malaria due to chloroquine-resistant *P. falciparum*. Although the mechanism of action is poorly understood, halofantrine is thought to share mechanism(s) with the 4-aminoquinolines, forming a complex with ferriprotoporphyrin IX and interfering with the degradation of hemoglobin.

Halofantrine exhibits erratic bioavailability, but its absorption is significantly enhanced when it is taken with a fatty meal. The elimination half-life of halofantrine is 1–2 days; it is excreted mainly in feces. Halofantrine is metabolized into *N*-debutyl-halofantrine by the cytochrome P450 enzyme CYP3A4. Grapefruit juice should be avoided during treatment because it increases both halofantrine's bioavailability and halofantrine-induced QT interval prolongation by inhibiting CYP3A4 at the enterocyte level.

IDOQUINOL

Iodoquinol (diiodohydroxyquin), a hydroxyquinoline, is an effective luminal agent for the treatment of amebiasis, balantidiasis, and infection with *Dientamoeba fragilis*. Its mechanism of action is unknown. It is poorly absorbed. Because the drug contains 64% organically bound iodine, it should be used with caution in patients with thyroid disease. Iodine dermatitis occurs occasionally during iodoquinol treatment. Protein-bound serum iodine levels may be increased during treatment and can interfere with certain tests of thyroid function. These effects may persist for as long as 6 months after discontinuation of therapy. Iodoquinol is contraindicated in patients with liver disease. Most serious are the reactions related to prolonged high-dose therapy (optic neuritis, peripheral neuropathy), which should not occur if the recommended dosage regimens are followed.

IVERMECTIN

Ivermectin (22,23-dihydroavermectin) is a derivative of the macrocyclic lactone avermectin produced by the soil-dwelling actinomycete *Streptomyces avermitilis*. Ivermectin is active at low doses against a wide range

of helminths and ectoparasites. It is the drug of choice for the treatment of onchocerciasis, strongyloidiasis, cutaneous larva migrans, and scabies. Ivermectin is highly active against microfilariae of the lymphatic filariases but has no macrofilaricidal activity. When ivermectin is used in combination with other agents such as DEC or albendazole for treatment of lymphatic filariasis, synergistic activity is seen. While active against the intestinal helminths *Ascaris lumbricoides* and *Enterobius vermicularis*, ivermectin is only variably effective in trichuriasis and is ineffective against hookworms. Widespread use of ivermectin for treatment of intestinal nematode infections in sheep and goats has led to the emergence of drug resistance in veterinary practice; this development may portend problems in human medical use.

Recent data suggest that ivermectin acts by opening the neuromuscular membrane-associated, glutamate-dependent chloride channels. The influx of chloride ions results in hyperpolarization and muscle paralysis—particularly of the nematode pharynx, with consequent blockage of the oral ingestion of nutrients. Because these chloride channels are present only in invertebrates, the paralysis is seen only in the parasite.

Ivermectin is available only as an oral formulation. The drug is highly protein bound; it is almost completely excreted in feces. The effect of food on bioavailability is unknown. Ivermectin is distributed widely throughout the body; animal studies indicate that it accumulates at the highest concentration in adipose tissue and liver, with little accumulation in the brain. Few data exist to guide therapy in hosts with conditions that may influence drug pharmacokinetics.

Ivermectin is generally administered as a single dose of 150–200 µg/kg. In the absence of parasitic infection, the adverse effects of ivermectin in therapeutic doses are minimal. Adverse effects in patients with filarial infections include fever, myalgia, malaise, lightheadedness, and (occasionally) postural hypotension. The severity of such side effects is related to the intensity of parasite infection, with more symptoms in individuals with a heavy parasite burden. In onchocerciasis, skin edema, pruritus, and mild eye irritation may also occur. The adverse effects are generally self-limiting and only occasionally require symptom-based treatment with antipyretics or antihistamines. More severe complications of ivermectin therapy for onchocerciasis include encephalopathy in patients heavily infected with *Loa loa*. This reaction has led to the suspension of ivermectin distribution for this indication in regions where the two filarial infections are coendemic.

LEVAMISOLE

Levamisole is the levo-isomer of tetramisole and is used to treat ascariasis and hookworm infection. Levamisole appears to act by binding to a distinctive ion channel that forms a nicotinic acetylcholine receptor on nematode muscle. This event causes sustained depolarization of the muscle membrane and results in paralysis of the worm. Levamisole is rapidly absorbed from the GI tract and is extensively metabolized in the liver; the metabolites are

excreted in the urine. The use of this drug is contraindicated in patients with preexisting blood disorders (e.g., agranulocytosis) or Sjögren's syndrome. When used for the treatment of helminthic infections, levamisole is well tolerated, with side effects usually limited to GI disturbances.

LUMEFANTRINE

Lumefantrine (benflumetol), a fluorene (benzindene) derivative synthesized in the 1970s by the Chinese Academy of Military Medical Sciences (Beijing), has marked blood schizontocidal activity against a wide range of plasmodia. This agent conforms structurally and in mode of action to the arylaminoalcohol group of antimalarial drugs, including quinine, mefloquine, and halofantrine. Lumefantrine exerts its antimalarial effect as a consequence of its interaction with heme, a degradation product of hemoglobin metabolism. Although its antimalarial activity is slower than that of the artemisinin-based drugs, the recrudescence rate with the recommended lumefantrine regimen is lower. The pharmacokinetic properties of lumefantrine are reminiscent of those of halofantrine, with variable oral bioavailability, considerable augmentation of oral bioavailability by concomitant fat intake, and a terminal elimination half-life of ~4–5 days in patients with malaria.

Artemether and lumefantrine have synergistic activity, and clinical studies in China on several hundred patients show the combination to be safe and well tolerated. The combined formulation of artemether and lumefantrine has been developed for the treatment of falciparum malaria in areas where *P. falciparum* is resistant to chloroquine and antifolates.

MEBENDAZOLE

This benzimidazole is a broad-spectrum antiparasitic agent widely used to treat intestinal helminthiasis. Its mechanism of action is similar to that of albendazole; however, it is a more potent inhibitor of parasite malic dehydrogenase and exhibits a more specific and selective effect against intestinal nematodes than the other benzimidazoles.

Mebendazole is available only in oral form but is poorly absorbed from the GI tract; only 5–10% of a standard dose is measurable in plasma. The proportion absorbed from the GI tract is extensively metabolized in the liver. Metabolites appear in the urine and bile; impaired liver or biliary function results in higher plasma mebendazole levels in treated patients. No dose reduction is warranted in patients with renal function impairment. Because mebendazole is poorly absorbed, its incidence of side effects is low. Transient abdominal pain and diarrhea sometimes occur, usually in persons with massive parasite burdens.

MEFLOQUINE

Mefloquine is the preferred drug for prophylaxis of chloroquine-resistant malaria; high doses can be used for treatment. Despite the development of drug-resistant

strains of *P. falciparum* in parts of Africa and Southeast Asia, mefloquine is an effective drug throughout most of the world. Cross-resistance of mefloquine with halofantrine and with quinine has been documented in limited areas. Like quinine and chloroquine, this quinoline is active only against the asexual erythrocytic stages of malarial parasites. Unlike quinine, however, mefloquine has a relatively poor affinity for DNA and, as a result, does not inhibit the synthesis of parasitic nucleic acids and proteins. Although both mefloquine and chloroquine inhibit hemozoin formation and heme degradation, mefloquine differs in that it forms a complex with heme that may be toxic to the parasite.

Mefloquine HCl is poorly water soluble and intensely irritating when given parenterally; thus it is available only in tablet form. Its absorption is adversely affected by vomiting and diarrhea but is significantly enhanced when the drug is administered with or after food. About 98% of the drug binds to protein. Mefloquine is excreted mainly in the bile and feces; therefore, no dose adjustment is needed in persons with renal insufficiency. The drug and its main metabolite are not appreciably removed by hemodialysis. No special chemoprophylactic dosage adjustments are indicated for the achievement of plasma concentrations in dialysis patients that are similar to those in healthy persons. Pharmacokinetic differences have been detected among various ethnic populations. In practice, however, these distinctions are of minor importance compared with host immune status and parasite sensitivity. In patients with impaired liver function, the elimination of mefloquine may be prolonged, leading to higher plasma levels.

Mefloquine should be used with caution by individuals participating in activities requiring alertness and fine-motor coordination. If the drug is to be administered for a prolonged period, periodic evaluations are recommended, including liver function tests and ophthalmic examinations. Sleep abnormalities (insomnia, abnormal dreams) have occasionally been reported. Psychosis and seizures occur rarely; mefloquine should not be prescribed to patients with neuropsychiatric conditions, including depression, generalized anxiety disorder, psychosis, schizophrenia, and seizure disorder. If acute anxiety, depression, restlessness, or confusion develops during prophylaxis, these psychiatric symptoms may be considered prodromal to a more serious event, and the drug should be discontinued.

Concomitant use of quinine, quinidine, or drugs producing β -adrenergic blockade may cause significant electrocardiographic abnormalities or cardiac arrest. Halofantrine must not be given simultaneously with or <3 weeks after mefloquine because a potentially fatal prolongation of the QTc interval on electrocardiography may occur. No data exist on mefloquine use after halofantrine use. Administration of mefloquine with quinine or chloroquine may increase the risk of convulsions. Mefloquine may lower plasma levels of anticonvulsants. Caution should be exercised with regard to concomitant antiretroviral therapy, since mefloquine has been shown to exert variable effects on ritonavir pharmacokinetics that are not explained by hepatic CYP3A4

activity or ritonavir protein binding. Vaccinations with attenuated live bacteria should be completed at least 3 days before the first dose of mefloquine.

Women of childbearing age who are traveling to areas where malaria is endemic should be warned against becoming pregnant and encouraged to practice contraception during malaria prophylaxis with mefloquine and for up to 3 months thereafter. However, in the case of unplanned pregnancy, use of mefloquine is not considered an indication for pregnancy termination.

MELARSOPROL*

Melarsoprol has been used since 1949 for the treatment of human African trypanosomiasis (HAT). This trivalent arsenical compound is indicated for the treatment of HAT with neurologic involvement and for the treatment of early HAT that is resistant to suramin or pentamidine. The changing view on the mode of action of arsenicals is well documented. Melarsoprol, like other drugs containing heavy metals, interacts with thiol groups of several different proteins; however, its antiparasitic effects appear to be more specific. Trypanothione reductase is a key enzyme involved in the oxidative stress management of both *Trypanosoma* and *Leishmania* spp., helping to maintain an intracellular reducing environment by reduction of disulfide trypanothione to its dithiol derivative dihydrotrypanothione. Melarsoprol sequesters dihydrotrypanothione, depriving the parasite of its main sulfhydryl antioxidant, and inhibits trypanothione reductase, depriving the parasite of the essential enzyme system that is responsible for keeping trypanothione reduced. These effects are synergistic. The selectivity of arsenical action against trypanosomes is due at least in part to the greater melarsoprol affinity of reduced trypanothione than of other monothiols (e.g., cysteine) on which the mammalian host depends for maintenance of high thiol levels. Melarsoprol enters the parasite via an adenosine transporter; drug-resistant strains lack this transport system.

Melarsoprol is always administered IV. A small but therapeutically significant amount of the drug enters the CSF. The compound is excreted rapidly, with ~80% of the arsenic found in feces.

Melarsoprol is highly toxic. The most serious adverse reaction is reactive encephalopathy, which affects 6% of treated individuals and usually develops within 4 days of the start of therapy, with an average case-fatality rate of 50%. Glucocorticoids are administered with melarsoprol to prevent this development. Because melarsoprol is intensely irritating, care must be taken to avoid infiltration of the drug.

METRIFONATE

Metrifonate has selective activity against *Schistosoma haematobium*. This organophosphorus compound is a prodrug that is converted nonenzymatically to dichlorvos (2,2-dichlorovinyl dimethylphosphate, DDVP), a highly active chemical that irreversibly inhibits the acetylcholinesterase enzyme. Schistosomal cholinesterase

is more susceptible to dichlorvos than is the corresponding human enzyme. The exact mechanism of action of metrifonate is uncertain, but the drug is believed to inhibit tegumental acetylcholine receptors that mediate glucose transport.

Metrifonate is administered in a series of three doses at 2-week intervals. After a single oral dose, metrifonate produces a 95% decrease in plasma cholinesterase activity within 6 h, with a fairly rapid return to normal. However, 2.5 months are required for erythrocyte cholinesterase levels to return to normal. Treated persons should not be exposed to neuromuscular blocking agents or organophosphate insecticides for at least 48 h after treatment.

METRONIDAZOLE AND OTHER NITROIMIDAZOLES

See Table 113-1 and Chap. 33.

MILTEFOSINE

In the early 1990s, miltefosine (hexadecylphosphocholine), originally developed as an antineoplastic agent, was discovered to have significant antiproliferative activity against *Leishmania* spp., *Trypanosoma cruzi*, and *T. brucei* parasites in vitro and in experimental animal models. In 1995, Tropical Disease Research, a program sponsored by the WHO and other international groups, entered into an agreement with the company now known as ASTA Medica/Zentaris to develop miltefosine for the treatment of visceral leishmaniasis in India. Miltefosine is the first oral drug that has proved to be highly effective and comparable to amphotericin B against visceral leishmaniasis in India, where antimonial-resistant cases are prevalent. Miltefosine is also effective in previously untreated visceral infections. Cure rates in cutaneous leishmaniasis are comparable to those obtained with antimony.

The activity of miltefosine is attributed to interaction with cell signal transduction pathways and inhibition of phospholipid and sterol biosynthesis. Resistance to miltefosine has not been observed clinically. The drug is readily absorbed from the GI tract, is widely distributed, and accumulates in several tissues. The efficacy of a 28-day treatment course in Indian visceral leishmaniasis is equivalent to that of amphotericin B therapy; however, it appears that a shortened course of 21 days may be equally efficacious.

General recommendations for the use of miltefosine are limited by the exclusion of specific groups from the published clinical trials: persons <12 or >65 years of age, persons with the most advanced disease, breast-feeding women, HIV-infected patients, and individuals with significant renal or hepatic insufficiency.

NICLOSAMIDE

Niclosamide is active against a wide variety of adult tapeworms but not against tissue cestodes. It is also a molluscicide and is used in snail-control programs.

The drug uncouples oxidative phosphorylation in parasite mitochondria, thereby blocking the uptake of glucose by the intestinal tapeworm and resulting in the parasite's death. Niclosamide rapidly causes spastic paralysis of intestinal cestodes in vitro. Its use is limited by its side effects, the necessarily long duration of therapy, the recommended use of purgatives, and—most important—limited availability (i.e., on a named-patient basis from the manufacturer).

Niclosamide is poorly absorbed. Tablets are given on an empty stomach in the morning after a liquid meal the night before, and this dose is followed by another 1 h later. For treatment of hymenolepiasis, the drug is administered for 7 days. A second course is often prescribed. The scolex and proximal segments of the tapeworms are killed on contact with niclosamide and may be digested in the gut. However, disintegration of the adult tapeworm results in the release of viable ova, which theoretically can result in autoinfection. Although fears of the development of cysticercosis in patients with *Taenia solium* infections have proved unfounded, it is still recommended that a brisk purgative be given 2 h after the first dose.

NIFURTIMOX*

This nitrofurantoin compound is a cheap and effective oral agent for the treatment of acute Chagas' disease. Trypanosomes lack catalase and have very low levels of peroxidase; as a result, they are very vulnerable to by-products of oxygen reduction. When nifurtimox is reduced in the trypanosome, a nitro anion radical is formed and undergoes autooxidation, resulting in the generation of the superoxide anion O_2^- , hydrogen peroxide (H_2O_2), hydroperoxyl radical (HO_2), and other highly reactive and cytotoxic molecules. Despite the abundance of catalases, peroxidases, and superoxide dismutases that neutralize these destructive radicals in mammalian cells, nifurtimox has a poor therapeutic index. Prolonged use is required, but the course may have to be interrupted because of drug toxicity, which develops in 40–70% of recipients. Nifurtimox is well absorbed and undergoes rapid and extensive biotransformation; <0.5% of the original drug is excreted in urine.

NITAZOXANIDE

Nitazoxanide is a 5-nitrothiazole compound used for the treatment of cryptosporidiosis and giardiasis; it is active against other intestinal protozoa as well. The drug is approved for use in children 1–11 years of age.

The antiprotozoal activity of nitazoxanide is believed to be due to interference with the pyruvate-ferredoxin oxidoreductase (PFOR) enzyme-dependent electron transfer reaction that is essential to anaerobic energy metabolism. Studies have shown that the PFOR enzyme from *G. lamblia* directly reduces nitazoxanide by transfer of electrons in the absence of ferredoxin. The DNA-derived PFOR protein sequence of *Cryptosporidium parvum* appears to be similar to that of *G. lamblia*. Interference with the PFOR

enzyme-dependent electron transfer reaction may not be the only pathway by which nitazoxanide exerts antiprotozoal activity.

After oral administration, nitazoxanide is rapidly hydrolyzed to an active metabolite, tizoxanide (desacetyl-nitazoxanide). Tizoxanide then undergoes conjugation, primarily by glucuronidation. It is recommended that nitazoxanide be taken with food; however, no studies have been conducted to determine whether the pharmacokinetics of tizoxanide and tizoxanide glucuronide differ in fasted versus fed subjects. Tizoxanide is excreted in urine, bile, and feces, and tizoxanide glucuronide is excreted in urine and bile. The pharmacokinetics of nitazoxanide in patients with impaired hepatic and/or renal function have not been studied. Tizoxanide is highly bound to plasma protein (>99.9%). Therefore, caution should be used when administering this agent concurrently with other highly plasma protein-bound drugs with narrow therapeutic indices, as competition for binding sites may occur.

OXAMNIQUINE

This tetrahydroquinoline derivative is an effective alternative agent for the treatment of *Schistosoma mansoni*, although susceptibility to this drug exhibits regional variation. Oxamniquine exhibits anticholinergic properties, but its primary mode of action seems to rely on ATP-dependent enzymatic drug activation generating an intermediate that alkylates essential macromolecules, including DNA. In treated adult schistosomes, oxamniquine produces marked tegumental alterations that are similar to those seen with praziquantel but that develop less rapidly, becoming evident 4–8 days after treatment.

Oxamniquine is administered orally as a single dose and is well absorbed. Food retards absorption and reduces bioavailability. About 70% of an administered dose is excreted in urine as a mixture of pharmacologically inactive metabolites. Patients should be warned that their urine might have an intense orange-red color. Side effects are uncommon and usually mild, although hallucinations and seizures have been reported.

PAROMOMYCIN (AMINOSIDINE)

First isolated in 1956, this aminoglycoside is an effective oral agent for the treatment of infections due to intestinal protozoa. Parenteral paromomycin appears to be effective against visceral leishmaniasis in India.

Paromomycin inhibits protozoan protein synthesis by binding to the 30S ribosomal RNA in the aminoacyl-tRNA site, causing misreading of mRNA codons. Paromomycin is less active against *G. lamblia* than standard agents; however, like other aminoglycosides, paromomycin is poorly absorbed from the intestinal lumen, and the high levels of drug in the gut compensate for this relatively weak activity. If absorbed or administered systemically, paromomycin can cause ototoxicity and nephrotoxicity. However, systemic absorption is very limited, and toxicity

should not be a concern in persons with normal kidneys. Topical formulations are not generally available.

PENTAMIDINE ISETHIONATE

This diamidine is an effective alternative agent for some forms of leishmaniasis and trypanosomiasis. It is available for parenteral and aerosolized administration. While its mechanism of action remains undefined, it is known to exert a wide range of effects, including interaction with trypanosomal kinetoplast DNA; interference with polyamine synthesis by a decrease in the activity of ornithine decarboxylase; and inhibition of RNA polymerase, ribosomal function, and the synthesis of nucleic acids and proteins.

Pentamidine isethionate is well absorbed, is highly tissue bound, and is excreted slowly over several weeks, with an elimination half-life of 12 days. No steady-state plasma concentration is attained in persons given daily injections; the result is extensive accumulation of pentamidine in tissues, primarily the liver, kidney, adrenal, and spleen. Pentamidine does not penetrate well into the CNS. Pulmonary concentrations of pentamidine are increased when the drug is delivered in aerosolized form.

PIPERAZINE

The antihelmintic activity of piperazine is confined to ascariasis and enterobiasis. Piperazine acts as an agonist at extrasynaptic γ -aminobutyric acid (GABA) receptors, causing an influx of chloride ions in the nematode somatic musculature. The ultimate effect is flaccid paralysis of the muscle fibers, leading to the expulsion of live but mostly paralyzed worms. Patients should be warned, as this occurrence can be unsettling.

PRAZIQUANTEL

This heterocyclic pyrazinoisoquinoline derivative is highly active against a broad spectrum of trematodes and cestodes. It is the mainstay of treatment for schistosomiasis and is a critical part of community-based control programs.

All of the effects of praziquantel can be attributed either directly or indirectly to an alteration of intracellular calcium concentrations. Although the exact mechanism of action remains unclear, the major mechanism is disruption of the parasite tegument, causing tetanic contractions with loss of adherence to host tissues and, ultimately, disintegration or expulsion. Praziquantel induces changes in the antigenicity of the parasite by causing the exposure of concealed antigens. Praziquantel also produces alterations in schistosomal glucose metabolism, including decreases in glucose uptake, lactate release, glycogen content, and ATP levels.

Praziquantel exerts its parasitic effects directly and does not need to be metabolized to be effective. It is well absorbed but undergoes extensive first-pass hepatic clearance. Levels of the drug are increased when it is taken

with food, particularly carbohydrates, or with cimetidine. Serum levels are reduced by glucocorticoids, chloroquine, carbamazepine, and phenytoin. Praziquantel is completely metabolized in humans, with 80% of the dose recovered as metabolites in urine within 4 days. It is not known to what extent praziquantel crosses the placenta.

Patients with schistosomiasis who have heavy parasite burdens may develop abdominal discomfort, nausea, headache, dizziness, and drowsiness. Symptoms begin 30 min after ingestion, may require spasmolytics for relief, and usually disappear spontaneously after a few hours.

PRIMAQUINE PHOSPHATE

Primaquine, an 8-aminoquinoline, has a broad spectrum of activity against all stages of plasmodial development in humans but has been used most effectively for eradication of the hepatic stage of these parasites. Despite its toxicity, it remains the drug of choice for radical cure of *P. vivax* infections. Primaquine must be metabolized by the host to be effective. It is, in fact, rapidly metabolized; only a small fraction of the dose of the parent drug is excreted unchanged. Although the parasitocidal activity of the three oxidative metabolites remains unclear, they are believed to affect both pyrimidine synthesis and the mitochondrial electron transport chain. The metabolites appear to have significantly less antimalarial activity than primaquine; however, their hemolytic activity is greater than that of the parent drug.

Primaquine causes marked hypotension after parenteral administration and therefore is given only by the oral route. It is rapidly and almost completely absorbed from the GI tract.

Patients should be tested for G6PD deficiency before they receive primaquine. The drug may induce the oxidation of hemoglobin into methemoglobin, irrespective of the G6PD status of the patient. Primaquine is otherwise well tolerated.

PROGUANIL (CHLOROGUANIDE)

Proguanil inhibits plasmodial dihydrofolate reductase and is used with atovaquone for oral treatment of uncomplicated malaria or with chloroquine for malaria prophylaxis in parts of Africa without widespread chloroquine-resistant *P. falciparum*.

Proguanil exerts its effect primarily by means of the metabolite cycloguanil, whose inhibition of dihydrofolate reductase in the parasite disrupts deoxythymidylate synthesis, thus interfering with a key pathway involved in the biosynthesis of pyrimidines required for nucleic acid replication. There are no clinical data indicating that folate supplementation diminishes drug efficacy; women of childbearing age for whom atovaquone/proguanil is prescribed should continue taking folate supplements to prevent neural-tube birth defects.

Proguanil is extensively absorbed regardless of food intake. The drug is 75% protein-bound. The main routes of elimination are hepatic biotransformation and renal excretion; 40–60% of the proguanil dose is excreted by

PYRANTEL PAMOATE

Pyrantel is a tetrahydropyrimidine formulated as pamoate. This safe, well-tolerated, inexpensive drug is used to treat a variety of intestinal nematode infections but is ineffective in trichuriasis. Pyrantel pamoate is usually effective in a single dose. Like levamisole, the drug has as its target the nicotinic acetylcholine receptor on the surface of nematode somatic muscle. Pyrantel depolarizes the neuromuscular junction of the nematode, resulting in its irreversible paralysis and allowing the natural expulsion of the worm.

Pyrantel pamoate is poorly absorbed from the intestine; >85% of the dose is passed unaltered in feces. The absorbed portion is metabolized and excreted in urine. Piperazine, which produces hyperpolarization of muscle cells in intestinal helminths, is antagonistic to pyrantel pamoate and should not be used concomitantly.

Pyrantel pamoate has minimal toxicity at the oral doses used to treat intestinal helminthic infection. It is not recommended for pregnant women or for children <12 months old.

PYRIMETHAMINE

When combined with short-acting sulfonamides, this diaminopyrimidine is effective in malaria, toxoplasmosis, and isosporiasis. Unlike mammalian cells, the parasites that cause these infections cannot utilize preformed pyrimidines obtained through salvage pathways but rather rely completely on de novo pyrimidine synthesis, for which folate derivatives are essential cofactors. The efficacy of pyrimethamine is increasingly limited by the development of resistant strains of *P. falciparum* and *P. vivax*. Single amino acid substitutions to parasite dihydrofolate reductase confer resistance to pyrimethamine by decreasing the enzyme's binding affinity for the drug.

Pyrimethamine is well absorbed; the drug is 87% bound to human plasma proteins. In healthy volunteers, drug concentrations remain at therapeutic levels for up to 2 weeks; drug levels are lower in patients with malaria.

At the usual dosage, pyrimethamine alone causes little toxicity except for occasional skin rashes and, more rarely, blood dyscrasias. Bone marrow suppression sometimes occurs at the higher doses used for toxoplasmosis; at these doses, the drug should be administered with folinic acid.

QUINACRINE*

First introduced as an antimalarial agent in 1930, quinacrine is the only drug approved by the FDA for the treatment of giardiasis. Its production was discontinued in 1992. Although not commercially available, quinacrine can be obtained from alternative sources through the CDC Drug Service. The antiprotozoal mechanism of quinacrine has not been fully elucidated. The drug inhibits NADH oxidase—the same enzyme that activates

furazolidone. The differing relative quinacrine uptake rate between human cells and *G. lamblia* may explain the selective toxicity of the drug. Resistance correlates with decreased drug uptake.

Quinacrine is rapidly absorbed from the intestinal tract and is widely distributed in body tissues. Alcohol is best avoided due to a disulfiram-like effect.

QUININE AND QUINIDINE

When combined with another agent, the cinchona alkaloid quinine is effective for the oral treatment of both uncomplicated, chloroquine-resistant malaria and babesiosis. Quinine acts rapidly against the asexual blood stages of all forms of human malaria. For severe malaria, only quinidine (the dextroisomer of quinine) is available in the United States. Quinine concentrates in the acidic food vacuoles of *Plasmodium* spp. The drug inhibits the nonenzymatic polymerization of the highly reactive, toxic heme molecule into the nontoxic polymer pigment hemozoin.

Quinine is readily absorbed when given orally. In patients with malaria, the elimination half-life of quinine increases according to the severity of the infection. However, toxicity is avoided by an increase in the concentration of plasma glycoproteins. The cinchona alkaloids are extensively metabolized, particularly by CYP3A4; only 20% of the dose is excreted unchanged in urine. The drug's metabolites are also excreted in urine and may be responsible for toxicity in patients with renal failure. Renal excretion of quinine is decreased when cimetidine is taken and increased when the urine is acidic. The drug readily crosses the placenta.

Quinidine is both more potent as an antimalarial and more toxic than quinine. Its use requires cardiac monitoring. Dose reduction is necessary in persons with severe renal impairment.

SPIRAMYCIN†

This macrolide is used to treat acute toxoplasmosis in pregnancy and congenital toxoplasmosis. While the mechanism of action is similar to that of other macrolides, the efficacy of spiramycin in toxoplasmosis appears to stem from its rapid and extensive intracellular penetration, which results in macrophage drug concentrations 10–20 times greater than serum concentrations.

Spiramycin is rapidly and widely distributed throughout the body and reaches concentrations in the placenta up to five times those in serum. This agent is excreted mainly in bile. Indeed, in humans, the urinary excretion of active compounds represents only 20% of the administered dose.

Serious reactions to spiramycin are rare. Of the available macrolides, spiramycin appears to have the lowest risk of drug interactions. Complications of treatment are rare but, in neonates, can include life-threatening ventricular arrhythmias that disappear with drug discontinuation.

SULFONAMIDES

See Table 113-1 and Chap. 33.

SURAMIN*

This derivative of urea is the drug of choice for the early stage of African trypanosomiasis. The drug is polyanionic and acts by forming stable complexes with proteins, thus inhibiting multiple enzymes essential to parasite energy metabolism. Suramin appears to inhibit all trypanosome glycolytic enzymes more effectively than it inhibits the corresponding host enzymes.

Suramin is parenterally administered. It binds to plasma proteins and persists at low levels for several weeks after infusion. Its metabolism is negligible. This drug does not penetrate the CNS.

TAFENOQUINE

Tafenoquine is an 8-aminoquinoline with causal prophylactic activity. Its prolonged half-life (2–3 weeks) allows longer dosing intervals when the drug is used for prophylaxis. Tafenoquine has been well tolerated in clinical trials. When tafenoquine is taken with food, its absorption is increased by 50% and the most commonly reported adverse event—mild GI upset—is diminished. Like primaquine, tafenoquine is a potent oxidizing agent, causing hemolysis in patients with G6PD deficiency as well as methemoglobinemia.

TETRACYCLINES

See Table 113-1 and Chap. 33.

THIABENDAZOLE

Discovered in 1961, thiabendazole remains one of the most potent of the numerous benzimidazole derivatives. However, its use has declined significantly because of a higher frequency of adverse effects than is seen with other, equally effective agents.

Thiabendazole is active against most intestinal nematodes that infect humans. Although the exact mechanism of its antihelmintic activity has not been fully elucidated, it is likely to be similar to that of other benzimidazole drugs; namely, inhibition of polymerization of parasite β -tubulin. The drug also inhibits the helminth-specific enzyme fumarate reductase. In animals, thiabendazole has anti-inflammatory, antipyretic, and analgesic effects, which may explain its usefulness in dracunculiasis and trichinosis. Thiabendazole also suppresses egg and/or larval production by some nematodes and may inhibit the subsequent development of eggs or larvae passed in feces. Despite the emergence and global spread of thiabendazole-resistant trichostrongyliasis among sheep, there have been no reports of drug resistance in humans.

Thiabendazole is available in tablet form and as an oral suspension. The drug is rapidly absorbed from the GI tract but can also be absorbed through the skin. Thiabendazole should be taken after meals. This agent is extensively metabolized in the liver before ultimately being excreted; most of the dose is excreted within the

first 24 h. The usual dose of thiabendazole is determined by the patient's weight, but some treatment regimens are parasite specific. No particular adjustments are recommended in patients with renal or hepatic failure; only cautious use is advised.

Coadministration of thiabendazole in patients taking theophylline can result in an increase in theophylline levels by >50%. Therefore, serum levels of theophylline should be monitored closely in this situation.

TINIDAZOLE

This nitroimidazole is effective for the treatment of amebiasis, giardiasis, and trichomoniasis. Like metronidazole, tinidazole must undergo reductive activation by the parasite's metabolic system before it can act on protozoal targets. Tinidazole inhibits the synthesis of new DNA in the parasite and causes degradation of existing DNA. The reduced free-radical derivatives alkylate DNA, with consequent cytotoxic damage to the parasite. This damage appears to be produced by short-lived reduction intermediates, resulting in helix destabilization and strand breakage of DNA. The mechanism of action and side effects of tinidazole are similar to those of metronidazole, but adverse events appear to be less frequent and severe with tinidazole. In addition, the significantly longer half-life of tinidazole (>12h) offers potential cure with a single dose.

TRICLABENDAZOLE

While most benzimidazoles have broad-spectrum antihelmintic activity, they exhibit minimal or no activity against *F. hepatica*. In contrast, the antihelmintic activity of triclabendazole is highly specific for *Fasciola* spp. and *Paragonimus* spp., with little activity against nematodes, cestodes, and other trematodes. Triclabendazole is effective against all stages of *Fasciola* spp. The active sulfoxide metabolite of triclabendazole binds to fluke tubulin by assuming a unique nonplanar configuration and disrupts microtubule-based processes. Resistance to triclabendazole in veterinary use has been reported in Australia and Europe; however, no resistance has been documented in humans.

Triclabendazole is rapidly absorbed after oral ingestion; administration with food enhances its absorption and shortens the elimination half-life of the active metabolite. Both the sulfoxide and the sulfone metabolites are highly protein bound (>99%). Treatment with triclabendazole is typically given in one or two doses. No clinical data are available regarding dose adjustment in renal or hepatic insufficiency; however, given the short course of therapy and extensive hepatic metabolism of triclabendazole, dose adjustment is unlikely to be necessary. No information exists on drug interactions.

PART 2

PROTOZOAL INFECTIONS

CHAPTER 115

AMEBIASIS AND INFECTION WITH FREE-LIVING AMEBAS

Sharon L. Reed

AMEBIASIS

DEFINITION

Amebiasis is an infection with the intestinal protozoan *Entamoeba histolytica*. About 90% of infections are asymptomatic, and the remaining 10% produce a spectrum of clinical syndromes ranging from dysentery to abscesses of the liver or other organs.

LIFE CYCLE AND TRANSMISSION

E. histolytica is acquired by ingestion of viable cysts from fecally contaminated water, food, or hands. Food-borne exposure is most prevalent and is particularly likely when food handlers are shedding cysts or food is being grown with feces-contaminated soil, fertilizer, or water. Besides the drinking of contaminated water, less common means of transmission include oral and anal sexual practices and—in rare instances—direct rectal inoculation through colonic irrigation devices. Motile trophozoites are released from cysts in the small intestine and, in most patients, remain as harmless commensals in the large bowel. After encystation, infectious cysts are shed in the stool and can survive for several weeks in a moist environment. In some patients, the trophozoites invade either the bowel mucosa, causing symptomatic colitis, or the bloodstream, causing distant abscesses of the liver, lungs, or brain. The trophozoites may not encyst in patients with

active dysentery, and motile hematophagous trophozoites are frequently present in fresh stools. Trophozoites are rapidly killed by exposure to air or stomach acid, however, and therefore cannot transmit infection.

EPIDEMIOLOGY

About 10% of the world's population is infected with *Entamoeba*, the majority with noninvasive *Entamoeba dispar*. Amebiasis results from infection with *E. histolytica* and is the third most common cause of death from parasitic disease (after schistosomiasis and malaria). The wide spectrum of clinical disease caused by *Entamoeba* is due in part to the differences between these two infecting species. Cysts of *E. histolytica* and *E. dispar* are morphologically identical, but *E. histolytica* has unique isoenzymes, surface antigens, DNA markers, and virulence properties (Table 115-1). Most asymptomatic carriers, including homosexual men and patients with AIDS, harbor *E. dispar* and have self-limited infections. These observations indicate that *E. dispar* is incapable of causing invasive disease, since *Cryptosporidium* and *Isospora belli*, which also cause only self-limited illnesses in immunocompetent people, cause devastating diarrhea in patients with AIDS. However, host factors play a role as well. In one study, 10% of asymptomatic patients who were colonized with *E. histolytica* went on to develop amebic colitis, while the rest remained asymptomatic and cleared the infection within 1 year.

TABLE 115-1***E. HISTOLYTICA* AND *E. DISPAR*, COMPARED AND CONTRASTED****Similarities**

1. Both species are spread through ingestion of infectious cysts.
2. Cysts of the two species are morphologically identical.
3. Both species colonize the large intestine.

Differences

1. Only *E. histolytica* causes invasive disease.
2. Only *E. histolytica* infections elicit a positive amebic serology.
3. The two species have distinct rRNA sequences.
4. The two species have distinct surface antigens and isoenzyme markers.
5. Gal/GalNAc lectin can be used to differentiate the two species in stool ELISA.

Note: ELISA, enzyme-linked immunosorbent assay; Gal/GalNAc, galactose *N*-acetylgalactosamine. See text.

Areas of highest incidence (due to inadequate sanitation and crowding) include most developing countries in the tropics, particularly Mexico, India, and nations of Central and South America, tropical Asia, and Africa. In a 4-year follow-up study of preschool children in a highly endemic area of Bangladesh, 80% of children had at least one episode of infection with *E. histolytica* and 53% had more than one episode. Naturally acquired immunity did develop but was usually short-lived and correlated with the presence in the stool of secretory IgA antibody to the major adherence lectin galactose *N*-acetylgalactosamine (Gal/GalNAc). The main groups at risk for amebiasis in developed countries are returned travelers, recent immigrants, homosexual men, and inmates of institutions.

PATHOGENESIS AND PATHOLOGY

Both trophozoites (Fig. 115-1) and cysts (Fig. 115-2) are found in the intestinal lumen, but only trophozoites of *E. histolytica* invade tissue. The trophozoite is 20–60 μ m in

**FIGURE 115-1**

Trophozoite of *E. histolytica* demonstrating a single nucleus with a central, dot-like nucleolus (trichrome stain).

**FIGURE 115-2**

Cyst of *E. histolytica* showing three of the four nuclei (trichrome stain).

diameter and contains vacuoles and a nucleus with a characteristic central nucleolus. In animals, depletion of intestinal mucus, diffuse inflammation, and disruption of the epithelial barrier occur before trophozoites actually come into contact with the colonic mucosa. Trophozoites attach to colonic mucus and epithelial cells by Gal/GalNAc. The earliest intestinal lesions are microulcerations of the mucosa of the cecum, sigmoid colon, or rectum that release erythrocytes, inflammatory cells, and epithelial cells. Proctoscopy reveals small ulcers with heaped-up margins and normal intervening mucosa. Submucosal extension of ulcerations under viable-appearing surface mucosa causes the classic “flask-shaped” ulcer containing trophozoites at the margins of dead and viable tissues. Although neutrophilic infiltrates may accompany the early lesions in animals, human intestinal infection is marked by a paucity of inflammatory cells, probably in part because of the killing of neutrophils by trophozoites (Fig. 115-3).

**FIGURE 115-3**

Pathology of amebic ulcer with colonic invasion. Arrow points to trophozoites (hematoxylin and eosin, 400 \times).

Treated ulcers characteristically heal with little or no scarring. Occasionally, however, full-thickness necrosis and perforation occur.

Rarely, intestinal infection results in the formation of a mass lesion, or *ameboma*, in the bowel lumen. The overlying mucosa is usually thin and ulcerated, while other layers of the wall are thickened, edematous, and hemorrhagic; this condition results in exuberant formation of granulation tissue with little fibrous-tissue response.

A number of virulence factors have been linked to the ability of *E. histolytica* to invade through the interglandular epithelium. One consists of the extracellular cysteine proteinases that degrade collagen, elastin, IgA, IgG, and the anaphylatoxins C3a and C5a. Other enzymes may disrupt glycoprotein bonds between mucosal epithelial cells in the gut. Amebas can lyse neutrophils, monocytes, lymphocytes, and cells of colonic and hepatic lines. The cytolytic effect of amebas appears to require direct contact with target cells and may be linked to the release of phospholipase A and pore-forming peptides. *E. histolytica* trophozoites also cause apoptosis of human cells.

Liver abscesses are always preceded by intestinal colonization, which may be asymptomatic. Blood vessels may be compromised early by wall lysis and thrombus formation. Trophozoites invade veins to reach the liver through the portal venous system. *E. histolytica* is resistant to complement-mediated lysis—a property critical to survival in the bloodstream. In contrast, *E. dispar* is rapidly lysed by complement and is thus restricted to the bowel lumen. Inoculation of amebas into the portal system of hamsters results in an acute cellular infiltrate consisting predominantly of neutrophils. Later, the neutrophils are lysed by contact with amebas, and the release of neutrophil toxins may contribute to necrosis of hepatocytes. The liver parenchyma is replaced by necrotic material that is surrounded by a thin rim of congested liver tissue. The necrotic contents of a liver abscess are classically described as “anchovy paste,” although the fluid is variable in color and is composed of bacteriologically sterile granular debris with few or no cells. Amebas, if seen, tend to be found near the capsule of the abscess.

A study in Bangladeshi schoolchildren revealed that an intestinal IgA response to Gal/GalNAc reduced the risk of new *E. histolytica* infection by 64%. Serum IgG antibody is not protective; titers correlate with the duration of illness rather than with the severity of disease. Indeed, Bangladeshi children with a serum IgG response were more likely than those without such a response to develop new *E. histolytica* infection. Studies of animals suggest that cell-mediated immunity may be important for protection, although patients with AIDS appear not to be predisposed to more severe disease.

CLINICAL SYNDROMES

Intestinal Amebiasis

The most common type of amebic infection is asymptomatic cyst passage. Even in highly endemic areas, most patients harbor *E. dispar*.

Symptomatic amebic colitis develops 2–6 weeks after the ingestion of infectious cysts. A gradual onset of

lower abdominal pain and mild diarrhea is followed by malaise, weight loss, and diffuse lower abdominal or back pain. Cecal involvement may mimic acute appendicitis. Patients with full-blown dysentery may pass 10–12 stools per day. The stools contain little fecal material and consist mainly of blood and mucus. In contrast to those with bacterial diarrhea, fewer than 40% of patients with amebic dysentery are febrile. Virtually all patients have heme-positive stools.

More fulminant intestinal infection, with severe abdominal pain, high fever, and profuse diarrhea, is rare and occurs predominantly in children. Patients may develop toxic megacolon, in which there is severe bowel dilation with intramural air. Patients receiving glucocorticoids are at risk for severe amebiasis. Uncommonly, patients develop a chronic form of amebic colitis, which can be confused with inflammatory bowel disease. The association between severe amebiasis complications and glucocorticoid therapy emphasizes the importance of excluding amebiasis when inflammatory bowel disease is suspected. An occasional patient presents with only an asymptomatic or tender abdominal mass caused by an ameboma, which is easily confused with cancer on barium studies. A positive serologic test or biopsy can prevent unnecessary surgery in this setting. The syndrome of postamebic colitis—persistent diarrhea following documented cure of amebic colitis—is controversial; no evidence of recurrent amebic infection can be found, and re-treatment usually has no effect.

Amebic Liver Abscess

Extraintestinal infection by *E. histolytica* most often involves the liver. Of travelers who develop an amebic liver abscess after leaving an endemic area, 95% do so within 5 months. Young patients with an amebic liver abscess are more likely than older patients to present in the acute phase with prominent symptoms of <10 days' duration. Most patients are febrile and have right-upper-quadrant pain, which may be dull or pleuritic in nature and may radiate to the shoulder. Point tenderness over the liver and right-sided pleural effusion is common. Jaundice is rare. Although the initial site of infection is the colon, fewer than one-third of patients with an amebic abscess have active diarrhea. Older patients from endemic areas are more likely to have a subacute course lasting 6 months, with weight loss and hepatomegaly. About one-third of patients with chronic presentations are febrile. Thus, the clinical diagnosis of an amebic liver abscess may be difficult to establish because the symptoms and signs are often nonspecific. Since 10–15% of patients present only with fever, amebic liver abscess must be considered in the differential diagnosis of fever of unknown origin (Chap. 9).

Complications of Amebic Liver Abscess

Pleuropulmonary involvement, which is reported in 20–30% of patients, is the most frequent complication of amebic liver abscess. Manifestations include sterile effusions, contiguous spread from the liver, and rupture into the pleural space. Sterile effusions and contiguous spread

usually resolve with medical therapy, but frank rupture into the pleural space requires drainage. A hepatobronchial fistula may cause cough productive of large amounts of necrotic material that may contain amebas. This dramatic complication carries a good prognosis. Abscesses that rupture into the peritoneum may present as an indolent leak or an acute abdomen and require both percutaneous catheter drainage and medical therapy. Rupture into the pericardium, usually from abscesses of the left lobe of the liver, carries the gravest prognosis; it can occur during medical therapy and requires surgical drainage.

Other Extraintestinal Sites

The genitourinary tract may become involved by direct extension of amebiasis from the colon or by hematogenous spread of the infection. Painful genital ulcers, characterized by a punched-out appearance and profuse discharge, may develop secondary to extension from either the intestine or the liver. Both these conditions respond well to medical therapy. Cerebral involvement has been reported in fewer than 0.1% of patients in large clinical series. Symptoms and prognosis depend on the size and location of the lesion.

DIAGNOSTIC TESTS

Laboratory Diagnosis

Stool examinations, serologic tests, and noninvasive imaging of the liver are the most important procedures in the diagnosis of amebiasis. Fecal findings suggestive of amebic colitis include a positive test for heme, a paucity of neutrophils, and amebic cysts or trophozoites. The definitive diagnosis of amebic colitis is made by the demonstration of hematophagous trophozoites of *E. histolytica* (Fig. 115-1). Because trophozoites are killed rapidly by water, drying, or barium, it is important to examine at least three fresh stool specimens. Examination of a combination of wet mounts, iodine-stained concentrates, and trichrome-stained preparations of fresh stool and concentrates for cysts (Fig. 115-2) or trophozoites (Fig. 115-1) confirms the diagnosis in 75–95% of cases. Cultures of amebas are more sensitive but are not routinely available. If stool examinations are negative, sigmoidoscopy with biopsy of the edge of ulcers may increase the yield, but this procedure is dangerous during fulminant colitis because of the risk of perforation. Trophozoites in a biopsy specimen from a colonic mass confirm the diagnosis of ameboma, but trophozoites are rare in liver aspirates because they are found in the abscess capsule and not in the readily aspirated necrotic center. Accurate diagnosis requires experience, since the trophozoites may be confused with neutrophils and the cysts must be differentiated morphologically from *Entamoeba hartmanni*, *Entamoeba coli*, and *Endolimax nana*, which do not cause clinical disease and do not warrant therapy. Unfortunately, the cysts of *E. histolytica* cannot be distinguished microscopically from those of *E. dispar*. Therefore, the microscopic diagnosis of *E. histolytica* can be made only by the detection of *Entamoeba* trophozoites that have ingested erythrocytes.

In terms of sensitivity, stool diagnostic tests based on the detection of the Gal/GalNAc lectin of *E. histolytica* compare favorably with the polymerase chain reaction and with isolation in culture followed by isoenzyme analysis.

Serology is an important addition to the methods used for parasitologic diagnosis of invasive amebiasis. Enzyme-linked immunosorbent assays (ELISAs) and agar gel diffusion assays are positive in more than 90% of patients with colitis, amebomas, or liver abscess. Positive results in conjunction with the appropriate clinical syndrome suggest active disease because serologic findings usually revert to negative within 6–12 months. Even in highly endemic areas such as South Africa, fewer than 10% of asymptomatic individuals have a positive amebic serology. The interpretation of the indirect hemagglutination test is more difficult because titers may remain positive for as long as 10 years.

Up to 10% of patients with acute amebic liver abscess may have negative serologic findings; in suspected cases with an initially negative result, testing should be repeated in a week. In contrast to carriers of *E. dispar*, most asymptomatic carriers of *E. histolytica* develop antibodies. Thus, serologic tests are helpful in assessing the risk of invasive amebiasis in asymptomatic, cyst-passing individuals in nonendemic areas. Serologic tests also should be performed in patients with ulcerative colitis before the institution of glucocorticoid therapy to prevent the development of severe colitis or toxic megacolon owing to unsuspected amebiasis.

Routine hematology and chemistry tests usually are not very helpful in the diagnosis of invasive amebiasis. About three-fourths of patients with an amebic liver abscess have leukocytosis ($>10,000$ cells/ μ L); this condition is particularly likely if symptoms are acute or complications have developed. Invasive amebiasis does not elicit eosinophilia. Anemia, if present, is usually multifactorial. Even with large liver abscesses, liver enzyme levels are normal or minimally elevated. The alkaline phosphatase level is most often elevated and may remain so for months. Aminotransferase elevations suggest acute disease or a complication.

Radiographic Studies

Radiographic barium studies are potentially dangerous in acute amebic colitis. Amebomas are usually identified first by a barium enema, but biopsy is necessary for differentiation from carcinoma.

Radiographic techniques such as ultrasonography, CT, and MRI are all useful for detection of the round or oval hypoechoic cyst. More than 80% of patients who have had symptoms for >10 days have a single abscess of the right lobe of the liver (Fig. 115-4). Approximately 50% of patients who have had symptoms for <10 days have multiple abscesses. Findings associated with complications include large abscesses (>10 cm) in the superior part of the right lobe, which may rupture into the pleural space; multiple lesions, which must be differentiated from pyogenic abscesses; and lesions of the left lobe, which may rupture into the

FIGURE 115-4
Abdominal CT scan of a large amebic abscess of the right lobe of the liver. (Courtesy of the Department of Radiology, UCSD Medical Center, San Diego; with permission.)

pericardium. Because abscesses resolve slowly and may increase in size in patients who are responding clinically to therapy, frequent follow-up ultrasonography may prove confusing. Complete resolution of a liver abscess within 6 months can be anticipated in two-thirds of patients, but 10% may have persistent abnormalities for a year.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of intestinal amebiasis includes bacterial diarrheas (Chap. 25) caused by *Campylobacter* (Chap. 56); enteroinvasive *Escherichia coli* (Chap. 51); and species of *Shigella* (Chap. 55), *Salmonella* (Chap. 54), and *Vibrio* (Chap. 57). Although the typical patient with amebic colitis has less prominent fever than in these other conditions as well as heme-positive stools with few neutrophils, correct diagnosis requires bacterial cultures, microscopic examination of stools, and amebic serologic testing. As has already been mentioned, amebiasis must be ruled out in any patient thought to have inflammatory bowel disease.

Because of the variety of presenting signs and symptoms, amebic liver abscess can easily be confused with pulmonary or gallbladder disease or with any febrile illness with few localizing signs, such as malaria (Chap. 116) or typhoid fever (Chap. 54). The diagnosis should be considered in members of high-risk groups who have recently traveled outside the United States (Chap. 4) and in inmates of institutions. Once radiographic studies have identified an abscess in the liver, the most important differential diagnosis is between amebic and pyogenic abscess. Patients with pyogenic abscess typically are older and have a history of underlying bowel disease or recent surgery. Amebic serology is helpful, but aspiration of the abscess, with Gram's staining and culture of the material, may be required for differentiation of the two diseases.

R_x Treatment:
AMEBIASIS

INTESTINAL DISEASE (Table 115-2) The drugs used to treat amebiasis can be classified according to their primary site of action. Luminal amebicides are poorly absorbed and reach high concentrations in the bowel, but their activity is limited to cysts and trophozoites close to the mucosa. Only two luminal drugs are available in the United States: iodoquinol and paromomycin. Indications for the use of luminal agents include eradication of cysts in patients with colitis or a liver abscess and treatment of asymptomatic carriers. The majority of asymptomatic individuals who pass cysts are colonized with *E. dispar*, which does not warrant specific therapy. However, it is prudent to treat asymptomatic individuals who pass cysts unless *E. dispar* colonization can be definitively demonstrated by specific antigen-detection tests.

Tissue amebicides reach high concentrations in the blood and tissue after oral or parenteral administration. The development of nitroimidazole compounds, especially metronidazole, was a major advance in the treatment of invasive amebiasis. Patients with amebic colitis should be treated with intravenous or oral metronidazole. Side effects include nausea, vomiting, abdominal discomfort, and a disulfiram-like reaction. Another longer-acting imidazole compound, tinidazole, is also effective and was recently approved in the United States. All patients should also receive a full course of therapy with a luminal agent, since metronidazole does not eradicate cysts. Resistance to metronidazole has been selected in the laboratory but has not been found in clinical isolates. Relapses are not uncommon and probably represent reinfection or failure to eradicate amebas from the bowel because of an inadequate dosage or duration of therapy.

TABLE 115-2
DRUG THERAPY FOR AMEBIASIS

| INDICATION | THERAPY |
|-----------------------|--|
| Asymptomatic carriage | Luminal agent: iodoquinol (650-mg tablets), 650 mg tid for 20 days; or paromomycin (250-mg tablets), 500 mg tid for 10 days |
| Acute colitis | Metronidazole (250- or 500-mg tablets), 750 mg PO or IV tid for 5–10 days, plus Luminal agent as above |
| Amebic liver abscess | Metronidazole, 750 mg PO or IV for 5–10 days, or Tinidazole, 2 g PO once, or Ornidazole, ^a 2 g PO once, plus Luminal agent as above |

^aNot available in the United States.

AMEBIC LIVER ABSCESS Metronidazole is the drug of choice for amebic liver abscess. Longer-acting nitroimidazoles (tinidazole and ornidazole) have been effective as single-dose therapy in developing countries. With early diagnosis and therapy, mortality rates from uncomplicated amebic liver abscess are <1%. The second-line therapeutic agents emetine and chloroquine should be avoided if possible because of the potential cardiovascular and gastrointestinal side effects of the former and the higher relapse rates with the latter. There is no evidence that combined therapy with two drugs is more effective than the single-drug regimen. Studies of South Africans with liver abscesses demonstrated that 72% of patients without intestinal symptoms had bowel infection with *E. histolytica*; thus, all treatment regimens should include a luminal agent to eradicate cysts and prevent further transmission. Amebic liver abscess recurs rarely.

ASPIRATION OF LIVER ABSCESES More than 90% of patients respond dramatically to metronidazole therapy with decreases in both pain and fever within 72 h. Indications for aspiration of liver abscesses are (1) the need to rule out a pyogenic abscess, particularly in patients with multiple lesions; (2) the lack of a clinical response in 3–5 days; (3) the threat of imminent rupture; and (4) the need to prevent rupture of left-lobe abscesses into the pericardium. There is no evidence that aspiration, even of large abscesses (up to 10 cm), accelerates healing. Percutaneous drainage may be successful even if the liver abscess has already ruptured. Surgery should be reserved for instances of bowel perforation and rupture into the pericardium.

PREVENTION

Amebic infection is spread by ingestion of food or water contaminated with cysts. Since an asymptomatic carrier may excrete up to 15 million cysts per day, prevention of infection requires adequate sanitation and eradication of cyst carriage. In high-risk areas, infection can be minimized by the avoidance of unpeeled fruits and vegetables and the use of bottled water. Because cysts are resistant to readily attainable levels of chlorine, disinfection by iodination (tetraglycine hydroperiodide) is recommended. There is no effective prophylaxis.

INFECTION WITH FREE-LIVING AMEBAS

EPIDEMIOLOGY

Free-living amebas of the genera *Acanthamoeba* and *Naegleria* are distributed throughout the world and have been isolated from a wide variety of fresh and brackish water, including that from lakes, taps, hot springs, swimming pools, and heating and air-conditioning units, and even from the nasal passages of healthy children. Encystation may protect the protozoa from desiccation and food deprivation. The persistence of *Legionella pneumophila* in water supplies may be attributable in part to chronic

infection of free-living amebas, particularly *Naegleria*. Free-living amebas of the genus *Balamuthia* have only recently been isolated from soil samples, including a sample from a flowerpot linked to a fatal infection in a child.

NAEGLERIA INFECTIONS

Primary amebic meningoencephalitis caused by *Naegleria fowleri* follows the aspiration of water contaminated with trophozoites or cysts or the inhalation of contaminated dust, leading to invasion of the olfactory neuroepithelium. After an incubation period of 2–15 days, severe headache, high fever, nausea, vomiting, and meningismus develop. Photophobia and palsies of the third, fourth, and sixth cranial nerves are common. Rapid progression to seizures and coma may follow. The prognosis is uniformly poor: most patients die within a week. Only a few survivors, treated with high-dose amphotericin B and rifampin, have been reported. Infection is most common in otherwise-healthy children or young adults, who often report recent swimming in lakes or heated swimming pools.

The diagnosis of *Naegleria* infection should be considered in any patient who has purulent meningitis without evidence of bacteria on Gram's staining, antigen detection assay, and culture. Other laboratory findings resemble those for fulminant bacterial meningitis, with elevated intracranial pressure, high white blood cell counts (up to 20,000/ μ L), and elevated protein concentrations and low glucose levels in cerebrospinal fluid (CSF). Diagnosis depends on the detection of motile trophozoites in wet mounts of fresh spinal fluid. Antibodies to *Naegleria* spp. have been detected in normal adults; serologic testing is not useful in the diagnosis of acute infection.

ACANTHAMOEBA INFECTIONS

Granulomatous Amebic Encephalitis

Infection with *Acanthamoeba* species follows a more indolent course and typically occurs in chronically ill or debilitated patients. Risk factors include lymphoproliferative disorders, chemotherapy, glucocorticoid therapy, lupus erythematosus, and AIDS. Infection usually reaches the central nervous system (CNS) hematogenously from a primary focus in the sinuses, skin, or lungs. In the CNS, the onset is insidious, and the syndrome often mimics a space-occupying lesion. Altered mental status, headache, and stiff neck may be accompanied by focal findings such as cranial nerve palsies, ataxia, and hemiparesis. Cutaneous ulcers or hard nodules containing amebas are frequently detected in AIDS patients with disseminated *Acanthamoeba* infection.

Examination of the CSF for trophozoites may be diagnostically helpful, but lumbar puncture may be contraindicated because of increased intracerebral pressure. CT frequently reveals cortical and subcortical lesions of decreased density consistent with embolic infarcts. In other patients, multiple enhancing lesions with edema may mimic the computed tomographic appearance of toxoplasmosis (Chap. 121). Demonstration of the trophozoites and cysts of *Acanthamoeba* on wet mounts or in biopsy specimens establishes the diagnosis. Culture on nonnutrient agar plates seeded with *E. coli* may also be helpful.

Fluorescein-labeled antiserum is available from the Centers for Disease Control and Prevention (CDC) for the detection of protozoa in biopsy specimens. Granulomatous amebic encephalitis in patients with AIDS may have an accelerated course (with survival for only 3–40 days) because of the difficulty these individuals have in forming granulomas. Various antimicrobial agents have been used to treat *Acanthamoeba* infection, including pentamidine, trimethoprim-sulfamethoxazole, and fluconazole, but the infection is almost uniformly fatal.

Keratitis

The incidence of keratitis caused by *Acanthamoeba* has increased in the past 20 years, in part as a result of improved diagnosis. Earlier infections were associated with trauma to the eye and exposure to contaminated water. At present, most infections are linked to extended-wear contact lenses, and rare cases are associated with laser-assisted in situ keratomileusis (LASIK). Risk factors include the use of homemade saline, the wearing of lenses while swimming, and inadequate disinfection. Since contact lenses presumably cause microscopic trauma, the early corneal findings may be nonspecific. The first symptoms usually include tearing and the painful sensation of a foreign body. Once infection is established, progression is rapid; the characteristic clinical sign is an annular, paracentral corneal ring representing a corneal abscess. Deeper corneal invasion and loss of vision may follow.

The differential diagnosis includes bacterial, mycobacterial, and herpetic infection. The irregular polygonal cysts of *Acanthamoeba* (Fig. 115-5) may be identified in corneal scrapings or biopsy material, and trophozoites can be grown on special media. Cysts are resistant to available drugs, and the results of medical therapy have

FIGURE 115-5

Double-walled cyst of *Acanthamoeba castellanii*, as seen by phase-contrast microscopy. [From DJ Krogstad et al, in A Balows et al (eds): *Manual of Clinical Microbiology*, 5th ed. Washington, DC, American Society for Microbiology, 1991.]

been disappointing. Some reports have suggested partial responses to propamidine isethionate eyedrops. Severe infections usually require keratoplasty.

BALAMUTHIA INFECTIONS

Balamuthia mandrillaris, a free-living amoeba previously referred to as a leptomixid amoeba, is an important etiologic agent of amebic meningoencephalitis in immunocompetent hosts. The course is typically subacute, with focal neurologic signs, fever, seizures, and headaches leading to death within 1 week to several months after onset. Examination of CSF reveals mononuclear or neutrophilic pleocytosis, elevated protein levels, and normal to low glucose concentrations. Multiple hypodense lesions are usually detected with imaging studies. This mixed picture of space-occupying lesions with CSF pleocytosis is suggestive of *Balamuthia*. Detection of an indirect fluorescent antibody response may be helpful in noninvasive diagnosis, but usually a definitive diagnosis is made post-mortem. Fluorescent antibody is available from the CDC. The variety of drugs used to treat the few surviving patients (numbering fewer than five in the United States) include pentamidine, flucytosine, sulfadiazine, and macrolides. The differential diagnosis includes tuberculomas (Chap. 66) and neurocysticercosis (Chap. 127).

CHAPTER 116

MALARIA

Nicholas J. White ■ Joel G. Breman

Humanity has but three great enemies: Fever, famine and war; of these by far the greatest, by far the most terrible, is fever.

William Osler

Malaria is a protozoan disease transmitted by the bite of infected *Anopheles* mosquitoes. It is the most important of the parasitic diseases of humans, with transmission in 107 countries containing 3 billion people and causing 1–3 million deaths each year. Malaria has now been eliminated from the United States, Canada, Europe, and Russia but, despite enormous control efforts, has resurged in many parts of the tropics. Added to this resurgence are the increasing problems of drug resistance of the parasite and insecticide resistance of the vectors. Occasional local transmission after importation of malaria has occurred recently in several southern and eastern areas of the United States and in Europe, indicating the continual danger to nonmalarious countries. Although there are promising new control and research initiatives, malaria remains today, as it has been for centuries, a heavy burden on tropical communities, a threat to nonendemic countries, and a danger to travelers.

ETIOLOGY AND PATHOGENESIS

Four species of the genus *Plasmodium* cause nearly all malarial infections in humans (although rare infections involve species normally affecting other primates). These are *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae* (Table 116-1). Almost all deaths are caused by falciparum malaria. Human infection begins when a female anopheline mosquito inoculates plasmodial *sporozoites* from its salivary gland during a blood meal (Fig. 116-1). These microscopic motile forms of the malarial parasite are carried rapidly via the bloodstream to the liver, where they invade hepatic parenchymal cells and begin a period of asexual reproduction. By this amplification process (known as *intrahepatic* or *preerythrocytic schizogony* or *merogony*), a single sporozoite eventually may produce from 10,000 to >30,000 daughter merozoites. The swollen infected liver cell eventually bursts, discharging motile *merozoites* into the bloodstream. These then invade the red blood cells (RBCs) and multiply six- to twentyfold every 48–72 h. When the parasites reach densities of ~50/μL of blood, the symptomatic stage of the infection

TABLE 116-1

CHARACTERISTICS OF *PLASMODIUM* SPECIES INFECTING HUMANS

| CHARACTERISTIC | FINDING FOR INDICATED SPECIES | | | |
|---|--|--|---|--|
| | <i>P. FALCIPARUM</i> | <i>P. VIVAX</i> | <i>P. OVALE</i> | <i>P. MALARIAE</i> |
| Duration of intrahepatic phase (days) | 5.5 | 8 | 9 | 15 |
| Number of merozoites released per infected hepatocyte | 30,000 | 10,000 | 15,000 | 15,000 |
| Duration of erythrocytic cycle (hours) | 48 | 48 | 50 | 72 |
| Red cell preference | Younger cells (but can invade cells of all ages) | Reticulocytes and cells up to 2 weeks old | Reticulocytes | Older cells |
| Morphology | Usually only ring forms ^a ; banana-shaped gametocytes | Irregularly shaped large rings and trophozoites; enlarged erythrocytes; Schüffner's dots | Infected erythrocytes, enlarged and oval with tufted ends; Schüffner's dots | Band or rectangular forms of trophozoites common |
| Pigment color | Black | Yellow-brown | Dark brown | Brown-black |
| Ability to cause relapses | No | Yes | Yes | No |

^aParasitemias of >2% are suggestive of *P. falciparum* infection.

**FIGURE 116-1**

The malaria transmission cycle from mosquito to human. RBC, red blood cell.

begins. In *P. vivax* and *P. ovale* infections, a proportion of the intrahepatic forms do not divide immediately but remain dormant for a period ranging from 3 weeks to a year or longer before reproduction begins. These dormant forms, or *hypnozoites*, are the cause of the relapses that characterize infection with these two species.

After entry into the bloodstream, merozoites rapidly invade erythrocytes and become *trophozoites*. Attachment is mediated via a specific erythrocyte surface receptor. In the case of *P. vivax*, this receptor is related to the Duffy blood-group antigen Fy^a or Fy^b . Most West Africans and people with origins in that region carry the Duffy-negative $FyFy$ phenotype and are therefore resistant to *P. vivax* malaria. During the early stage of intraerythrocytic development, the small “ring forms” of the four parasitic species appear similar under light microscopy. As the trophozoites enlarge, species-specific characteristics become evident, pigment becomes visible, and the parasite assumes an irregular or ameboid shape. By the end of the 48-h intraerythrocytic life cycle (72 h for *P. malariae*), the parasite has consumed nearly all the hemoglobin and grown to occupy most of the RBC. It is now called a *schizont*. Multiple nuclear divisions have taken place (*schizogony* or *merogony*), and the RBC then ruptures to release 6–30 daughter merozoites, each potentially capable of invading a new RBC and repeating the cycle. The disease in human beings is caused by the direct effects of RBC invasion and destruction by the asexual parasite and the host's reaction. After a series of asexual cycles (*P. falciparum*) or immediately after release from the liver (*P. vivax*, *P. ovale*, *P. malariae*), some of the parasites develop into morphologically distinct, longer-lived sexual forms (*gametocytes*) that can transmit malaria.

After being ingested in the blood meal of a biting female anopheline mosquito, the male and female gametocytes form a zygote in the insect's midgut. This zygote matures into an ookinete, which penetrates and encysts

in the mosquito's gut wall. The resulting oocyst expands by asexual division until it bursts to liberate myriad motile sporozoites, which then migrate in the hemolymph to the salivary gland of the mosquito to await inoculation into another human at the next feeding.

EPIDEMIOLOGY

Malaria occurs throughout most of the tropical regions of the world (Fig. 116-2). *P. falciparum* predominates in Africa, New Guinea, and Haiti; *P. vivax* is more common in Central America. The prevalence of these two species is approximately equal in South America, the Indian subcontinent, eastern Asia, and Oceania. *P. malariae* is found in most endemic areas, especially throughout sub-Saharan Africa, but is much less common. *P. ovale* is relatively unusual outside of Africa and, where it is found, comprises <1% of isolates.

The epidemiology of malaria is complex and may vary considerably even within relatively small geographic areas. Endemicity traditionally has been defined in terms of parasitemia rates or palpable-spleen rates in children 2–9 years of age as hypoendemic (<10%), mesoendemic (11–50%), hyperendemic (51–75%), and holoendemic (>75%); however, it is uncommon to use these indices for planning control programs. In holo- and hyperendemic areas (e.g., certain regions of tropical Africa or coastal New Guinea) where there is intense *P. falciparum* transmission, people may sustain more than one infectious mosquito bite per day and are infected repeatedly throughout their lives. In such settings, rates of morbidity and mortality due to malaria are considerable during childhood. Immunity against disease is hard won in these areas, and the burden of disease in young children is high; by adulthood, however, most malarial infections are asymptomatic. Constant, frequent, year-round infection is termed *stable transmission*.

**FIGURE 116-2**

Malaria-endemic countries in the Americas (**bottom**) and in Africa, the Middle East, Asia, and the South Pacific (**top**), 2007.

CAR, Central African Republic; DROC, Democratic Republic of the Congo; UAE, United Arab Emirates.

In areas where transmission is low, erratic, or focal, full protective immunity is not acquired, and symptomatic disease may occur at all ages. This situation usually exists in hypoendemic areas and is termed *unstable transmission*. Even in stable transmission areas, there is often an increased incidence of symptomatic malaria coinciding with increased mosquito breeding and transmission during the rainy season. Malaria behaves like an epidemic

disease in some areas, particularly those with unstable malaria, such as northern India, Sri Lanka, Southeast Asia, Ethiopia, Eritrea, Rwanda, Burundi, Southern Africa, and Madagascar. An epidemic can develop when there are changes in environmental, economic, or social conditions, such as heavy rains following drought or migrations (usually of refugees or workers) from a nonmalarious region to an area of high transmission; a breakdown in malaria

control and prevention services can intensify epidemic conditions. This situation usually results in considerable mortality among all age groups.

The principal determinants of the epidemiology of malaria are the number (density), the human-biting habits, and the longevity of the anopheline mosquito vectors. Not all of the >400 anophelines can transmit malaria, and those that do vary considerably in their efficiency as malaria vectors. More specifically, the transmission of malaria is directly proportional to the density of the vector, the square of the number of human bites per day per mosquito, and the tenth power of the probability of the mosquito's surviving for 1 day. Mosquito longevity is particularly important, because the portion of the parasite's life cycle that takes place within the mosquito—from gametocyte ingestion to subsequent inoculation (*sporogony*)—lasts 8–30 days, depending on ambient temperature; thus, to transmit malaria, the mosquito must survive for >7 days. In general, at temperatures below 16°–18°C, sporogony is not completed and transmission does not occur, although malaria outbreaks and transmission have recently occurred in the highlands of east Africa—areas (>1500 m) previously free of vectors. The most effective mosquito vectors of malaria are those, such as *Anopheles gambiae* in Africa, which are long-lived, occur in high densities in tropical climates, breed readily, and bite humans in preference to other animals. The entomologic inoculation rate (the number of sporozoite-positive mosquito bites per person per year) is the most common measure of malaria transmission and varies from <1 in some parts of Latin America and Southeast Asia to >300 in parts of tropical Africa.

ERYTHROCYTE CHANGES IN MALARIA

After invading an erythrocyte, the growing malarial parasite progressively consumes and degrades intracellular proteins, principally hemoglobin. The potentially toxic heme is detoxified by polymerization to biologically inert hemozoin (malaria pigment). The parasite also alters the RBC membrane by changing its transport properties, exposing cryptic surface antigens, and inserting new parasite-derived proteins. The RBC becomes more irregular in shape, more antigenic, and less deformable.

In *P. falciparum* infections, membrane protuberances appear on the erythrocyte's surface 12–15 h after the cell's invasion. These “knobs” extrude a high-molecular-weight, antigenically variant, strain-specific erythrocyte membrane adhesive protein (PfEMP1) that mediates attachment to receptors on venular and capillary endothelium—an event termed *cytoadherence*. Several vascular receptors have been identified, of which intercellular adhesion molecule 1 (ICAM-1) is probably the most important in the brain, chondroitin sulfate B in the placenta, and CD36 in most other organs. Thus, the infected erythrocytes stick inside and eventually block capillaries and venules. At the same stage, these *P. falciparum*-infected RBCs may also adhere to uninfected RBCs (to form rosettes) and to other parasitized erythrocytes (agglutination). The processes of cytoadherence, rosetting, and agglutination are central to

the pathogenesis of falciparum malaria. They result in the sequestration of RBCs containing mature forms of the parasite in vital organs (particularly the brain), where they interfere with microcirculatory flow and metabolism. Sequestered parasites continue to develop out of reach of the principal host defense mechanism: splenic processing and filtration. As a consequence, only the younger ring forms of the asexual parasites are seen circulating in the peripheral blood in falciparum malaria, and the level of peripheral parasitemia underestimates the true number of parasites within the body. Severe malaria is also associated with reduced deformability of the uninfected erythrocytes, which compromises their passage through the partially obstructed capillaries and venules and shortens RBC survival.

In the other three (“benign”) malarias, sequestration does not occur, and all stages of the parasite's development are evident on peripheral blood smears. Whereas *P. vivax*, *P. ovale*, and *P. malariae* show a marked predilection for either young RBCs (*P. vivax*, *P. ovale*) or old cells (*P. malariae*) and produce a level of parasitemia that is seldom >2%, *P. falciparum* can invade erythrocytes of all ages and may be associated with very high levels of parasitemia.

HOST RESPONSE

Initially, the host responds to plasmodial infection by activating nonspecific defense mechanisms. Splenic immunologic and filtrative clearance functions are augmented in malaria, and the removal of both parasitized and uninfected erythrocytes is accelerated. The parasitized cells escaping splenic removal are destroyed when the schizont ruptures. The material released induces the activation of macrophages and the release of proinflammatory mononuclear cell–derived cytokines, which cause fever and exert other pathologic effects. Temperatures of ≥40°C damage mature parasites; in untreated infections, the effect of such temperatures is to further synchronize the parasitic cycle, with eventual production of the regular fever spikes and rigors that originally served to characterize the different malarias. These regular fever patterns (tertian, every 2 days; quartan, every 3 days) are seldom seen today in patients who receive prompt and effective antimalarial treatment.

The geographic distributions of sickle cell disease, ovalocytosis, thalassemia, and glucose-6-phosphate dehydrogenase (G6PD) deficiency closely resemble that of malaria before the introduction of control measures. This similarity suggests that these genetic disorders confer protection against death from falciparum malaria. For example, HbA/S heterozygotes (sickle cell trait) have a sixfold reduction in the risk of dying from severe falciparum malaria. This decrease in risk appears to be related to impaired parasite growth at low oxygen tensions. Parasite multiplication in HbA/E heterozygotes is reduced at high parasite densities. In Melanesia, children with α -thalassemia appear to have more frequent malaria (both vivax and falciparum) in the early years of life, and this pattern of infection appears to protect against severe disease. In Melanesian ovalocytosis, rigid erythrocytes

resist merozoite invasion, and the intraerythrocytic milieu is hostile.

Nonspecific host defense mechanisms stop the infection's expansion, and the subsequent specific immune response controls the infection. Eventually, exposure to sufficient strains confers protection from high-level parasitemia and disease but not from infection. As a result of this state of infection without illness (*premunition*), asymptomatic parasitemia is common among adults and older children living in regions with stable and intense transmission (i.e., holo- or hyperendemic areas). Immunity is mainly specific for both the species and the strain of infecting malarial parasite. Both humoral immunity and cellular immunity are necessary for protection, but the mechanisms of each are incompletely understood (Fig. 116-1). Immune individuals have a polyclonal increase in serum levels of IgM, IgG, and IgA, although much of this antibody is unrelated to protection. Antibodies to a variety of parasitic antigens presumably act in concert to limit *in vivo* replication of the parasite. In the case of falciparum malaria, the most important of these antigens is the surface adhesin—the variant protein PfEMP1 mentioned above. Passively transferred IgG from immune adults has been shown to reduce levels of parasitemia in children; although parasitemia in very young infants can occur, passive transfer of maternal antibody contributes to the relative (but not complete) protection of infants from severe malaria in the first months of life. This complex immunity to disease declines when a person lives outside an endemic area for several months or longer.

Several factors retard the development of cellular immunity to malaria. These factors include the absence of major histocompatibility antigens on the surface of infected RBCs, which precludes direct T cell recognition; malaria antigen-specific immune unresponsiveness; and the enormous strain diversity of malarial parasites, along with the ability of the parasites to express variant immunodominant antigens on the erythrocyte surface that change during the period of infection. Parasites may persist in the blood for months (or, in the case of *P. malariae*, for many years) if treatment is not given. The complexity of the immune response in malaria, the sophistication of the parasites' evasion mechanisms, and the lack of a good *in vitro* correlate with clinical immunity have all slowed progress toward an effective vaccine.

CLINICAL FEATURES

Malaria is a very common cause of fever in tropical countries. The first symptoms of malaria are nonspecific; the lack of a sense of well-being, headache, fatigue, abdominal discomfort, and muscle aches followed by fever are all similar to the symptoms of a minor viral illness. In some instances, a prominence of headache, chest pain, abdominal pain, arthralgia, myalgia, or diarrhea may suggest another diagnosis. Although headache may be severe in malaria, there is no neck stiffness or photophobia resembling that in meningitis. While myalgia may be prominent, it is not usually

as severe as in dengue fever, and the muscles are not tender as in leptospirosis or typhus. Nausea, vomiting, and orthostatic hypotension are common. The classic malarial paroxysms, in which fever spikes, chills, and rigors occur at regular intervals, are relatively unusual and suggest infection with *P. vivax* or *P. ovale*. The fever is irregular at first (that of falciparum malaria may never become regular); the temperature of nonimmune individuals and children often rises above 40°C in conjunction with tachycardia and sometimes delirium. Although childhood febrile convulsions may occur with any of the malarias, generalized seizures are specifically associated with falciparum malaria and may herald the development of cerebral disease. Many clinical abnormalities have been described in acute malaria, but most patients with uncomplicated infections have few abnormal physical findings other than fever, malaise, mild anemia, and (in some cases) a palpable spleen. Anemia is common among young children living in areas with stable transmission, particularly where resistance has compromised the efficacy of anti-malarial drugs. In nonimmune individuals with acute malaria, the spleen takes several days to become palpable, but splenic enlargement is found in a high proportion of otherwise healthy individuals in malaria-endemic areas and reflects repeated infections. Slight enlargement of the liver is also common, particularly among young children. Mild jaundice is common among adults; it may develop in patients with otherwise uncomplicated falciparum malaria and usually resolves over 1–3 weeks. Malaria is not associated with a rash like those seen in meningococcal septicemia, typhus, enteric fever, viral exanthems, and drug reactions. Petechial hemorrhages in the skin or mucous membranes—features of viral hemorrhagic fevers and leptospirosis—develop only rarely in severe falciparum malaria.

SEVERE FALCIPARUM MALARIA

Appropriately and promptly treated, uncomplicated falciparum malaria (i.e., the patient can swallow medicines and food) carries a mortality rate of ~0.1%. However, once vital-organ dysfunction occurs or the total proportion of erythrocytes infected increases to >2% (a level corresponding to >10¹² parasites in an adult), mortality risk rises steeply. The major manifestations of severe falciparum malaria are shown in [Table 116-2](#), and features indicating a poor prognosis are listed in [Table 116-3](#).

Cerebral Malaria

Coma is a characteristic and ominous feature of falciparum malaria and, despite treatment, is associated with death rates of ~20% among adults and 15% among children. Any obtundation, delirium, or abnormal behavior should be taken very seriously. The onset may be gradual or sudden following a convulsion.

Cerebral malaria manifests as diffuse symmetric encephalopathy; focal neurologic signs are unusual. Although some passive resistance to head flexion may be detected, signs of meningeal irritation are lacking. The eyes may be divergent and a pout reflex is common, but

MANIFESTATIONS OF SEVERE FALCIPARUM MALARIA

| SIGNS | MANIFESTATIONS |
|---|--|
| Major | |
| Unarousable coma/cerebral malaria | Failure to localize or respond appropriately to noxious stimuli; coma persisting for >30 min after generalized convulsion |
| Acidemia/acidosis | Arterial pH <7.25 or plasma bicarbonate level of <15 mmol/L; venous lactate level of >5 mmol/L; manifests as labored deep breathing, often termed “respiratory distress” |
| Severe normochromic, normocytic anemia | Hematocrit of <15% or hemoglobin level of <50 g/L (<5 g/dL) with parasitemia level of >100,000/μL |
| Renal failure | Urine output (24 h) of <400 mL in adults or <12 mL/kg in children; no improvement with rehydration; serum creatinine level of >265 μmol/L (>3.0 mg/dL) |
| Pulmonary edema/adult respiratory distress syndrome | Noncardiogenic pulmonary edema, often aggravated by overhydration |
| Hypoglycemia | Plasma glucose level of <2.2 mmol/L (<40 mg/dL) |
| Hypotension/shock | Systolic blood pressure of <50 mmHg in children 1–5 years or <80 mmHg in adults; core/skin temperature difference of >10°C; capillary refill >2 s |
| Bleeding/disseminated intravascular coagulation | Significant bleeding and hemorrhage from the gums, nose, and gastrointestinal tract and/or evidence of disseminated intravascular coagulation |
| Convulsions | More than two generalized seizures in 24 h; signs of continued seizure activity sometimes subtle (e.g., tonic-clonic eye movements without limb or face movement) |
| Hemoglobinuria ^a | Macroscopic black, brown, or red urine; not associated with effects of oxidant drugs and red blood cell enzyme defects (such as G6PD deficiency) |
| Other | |
| Impaired consciousness/arousable | Unable to sit or stand without support |
| Extreme weakness | Prostration; inability to sit unaided ^b |
| Hyperparasitemia | Parasitemia level of >5% in nonimmune patients (>20% in any patient) |
| Jaundice | Serum bilirubin level of >50 mmol/L (>3.0 mg/dL) if combined with other evidence of vital-organ dysfunction |

^aHemoglobinuria may occur in uncomplicated malaria.

^bIn a child who is normally able to sit.

Note: G6PD, glucose-6-phosphate dehydrogenase.

other primitive reflexes are usually absent. The corneal reflexes are preserved, except in deep coma. Muscle tone may be either increased or decreased. The tendon reflexes are variable, and the plantar reflexes may be flexor or extensor; the abdominal and cremasteric reflexes are absent. Flexor or extensor posturing may be seen. Approximately 15% of patients have retinal hemorrhages; with pupillary dilatation and indirect ophthalmoscopy, this figure increases to 30–40%. Other funduscopy abnormalities (Fig. 116-3) include discrete spots of retinal opacification (30–60%), papilledema (8% among children, rare among adults), cotton wool spots (<5%), and decolorization of a retinal vessel or segment of vessel (occasional cases). Convulsions, usually generalized and often repeated, occur in up to 50% of children with cerebral malaria. More covert seizure activity is also common, particularly among children, and may manifest as repetitive tonic-clonic eye movements or even hyper-salivation. Whereas adults rarely (i.e., in <3% of cases) suffer neurologic sequelae, ~15% of children surviving cerebral malaria—especially those with hypoglycemia, severe anemia, repeated seizures, and deep coma—have

some residual neurologic deficit when they regain consciousness; hemiplegia, cerebral palsy, cortical blindness, deafness, and impaired cognition and learning (all of varying duration) have been reported. Approximately 10% of children surviving cerebral malaria have a persistent language deficit. The incidence of epilepsy is increased and the life expectancy decreased among these children.

Hypoglycemia

Hypoglycemia, an important and common complication of severe malaria, is associated with a poor prognosis and is particularly problematic in children and pregnant women. Hypoglycemia in malaria results from a failure of hepatic gluconeogenesis and an increase in the consumption of glucose by both host and, to a much lesser extent, the malaria parasites. To compound the situation, quinine and quinidine—drugs used for the treatment of severe chloroquine-resistant malaria—are powerful stimulants of pancreatic insulin secretion. Hyperinsulinemic hypoglycemia is especially troublesome in pregnant women receiving quinine treatment. In severe disease, the clinical

TABLE 116-3**FEATURES INDICATING A POOR PROGNOSIS

diagnosis of hypoglycemia is difficult: the usual physical signs (sweating, gooseflesh, tachycardia) are absent, and the neurologic impairment caused by hypoglycemia cannot be distinguished from that caused by malaria.

Acidosis

Acidosis, an important cause of death from severe malaria, results from accumulation of organic acids. Hyperlactatemia commonly coexists with hypoglycemia. In adults, coexisting renal impairment often compounds the acidosis; in children, ketoacidosis may also contribute. Other still-unidentified organic acids are major contributors to acidosis. Acidotic breathing, sometimes called respiratory distress, is a sign of poor prognosis. It is often followed by circulatory failure refractory to volume expansion or

**FIGURE 116-3**

The eye in cerebral malaria: perimacular whitening and pale-centered retinal hemorrhages. (Courtesy of N. Beare, T. Taylor, S. Harding, S. Lewallen, and M. Molyneux; with permission.)

inotropic drugs and ultimately by respiratory arrest. The plasma concentrations of bicarbonate or lactate are the best biochemical prognosticators in severe malaria. Lactic acidosis is caused by the combination of anaerobic glycolysis in tissues where sequestered parasites interfere with microcirculatory flow, hypovolemia, lactate production by the parasites, and a failure of hepatic and renal lactate clearance. The prognosis of severe acidosis is poor.

Noncardiogenic Pulmonary Edema

Adults with severe falciparum malaria may develop noncardiogenic pulmonary edema even after several days of antimalarial therapy. The pathogenesis of this variant of the adult respiratory distress syndrome is unclear. The mortality rate is $>80\%$. This condition can be aggravated by overly vigorous administration of IV fluid. Noncardiogenic pulmonary edema can also develop in otherwise uncomplicated vivax malaria, where recovery is usual.

Renal Impairment

Renal impairment is common among adults with severe falciparum malaria but rare among children. The pathogenesis of renal failure is unclear but may be related to erythrocyte sequestration interfering with renal microcirculatory flow and metabolism. Clinically and pathologically, this syndrome manifests as acute tubular necrosis, although renal cortical necrosis never develops. Acute renal failure may occur simultaneously with other vital-organ dysfunction (in which case the mortality risk is high) or may progress as other disease manifestations resolve. In survivors, urine flow resumes in a median of 4 days,

1084 and serum creatinine levels return to normal in a mean of 17 days. Early dialysis or hemofiltration considerably enhances the likelihood of a patient's survival, particularly in acute hypercatabolic renal failure.

Hematologic Abnormalities

Anemia results from accelerated RBC removal by the spleen, obligatory RBC destruction at parasite schizogony, and ineffective erythropoiesis. In severe malaria, both infected and uninfected RBCs show reduced deformability, which correlates with prognosis and development of anemia. Splenic clearance of all RBCs is increased. In nonimmune individuals and in areas with unstable transmission, anemia can develop rapidly and transfusion is often required. As a consequence of repeated malarial infections, children in many areas of Africa may develop severe anemia resulting from both shortened RBC survival and marked dyserythropoiesis. Anemia is a common consequence of antimalarial drug resistance, which results in repeated or continued infection.

Slight coagulation abnormalities are common in falciparum malaria, and mild thrombocytopenia is usual. Of patients with severe malaria, <5% have significant bleeding with evidence of disseminated intravascular coagulation. Hematemesis from stress ulceration or acute gastric erosions may also occur.

Liver Dysfunction

Mild hemolytic jaundice is common in malaria. Severe jaundice is associated with *P. falciparum* infections; is more common among adults than among children; and results from hemolysis, hepatocyte injury, and cholestasis. When accompanied by other vital-organ dysfunction (often renal impairment), liver dysfunction carries a poor prognosis. Hepatic dysfunction contributes to hypoglycemia, lactic acidosis, and impaired drug metabolism. Occasional patients with falciparum malaria may develop deep jaundice (with hemolytic, hepatic, and cholestatic components) without evidence of other vital-organ dysfunction.

Other Complications

Septicemia may complicate severe malaria, particularly in children. In endemic areas, *Salmonella* bacteremia has been associated specifically with *P. falciparum* infections. Chest infections and catheter-induced urinary tract infections are common among patients who are unconscious for >3 days. Aspiration pneumonia may follow generalized convulsions. The frequency of complications of severe falciparum malaria is summarized in [Table 116-4](#).

MALARIA IN PREGNANCY

In heavily endemic (hyper- and holoendemic) areas, falciparum malaria in primi- and secundigravid women is associated with low birth weight (average reduction, ~170 g) and consequently increased infant and childhood mortality. In general, infected mothers in areas of stable transmission remain asymptomatic despite intense accumulation of parasitized erythrocytes in the placental

TABLE 116-4

microcirculation. Maternal HIV infection predisposes pregnant women to malaria, predisposes their newborns to congenital malarial infection, and exacerbates the reduction in birth weight associated with malaria.

In areas with unstable transmission of malaria, pregnant women are prone to severe infections and are particularly vulnerable to high-level parasitemia with anemia, hypoglycemia, and acute pulmonary edema. Fetal distress, premature labor, and stillbirth or low birth weight are common results. Fetal death is usual in severe malaria. Congenital malaria occurs in <5% of newborns whose mothers are infected; its frequency and the level of parasitemia are related directly to the parasite density in maternal blood and in the placenta. *P. vivax* malaria in pregnancy is also associated with a reduction in birth weight (average, 110 g), but, in contrast to the situation in falciparum malaria, this effect is more pronounced in multigravid than in primigravid women.

MALARIA IN CHILDREN

Most of the estimated 1–3 million persons who die of falciparum malaria each year are young African children. Convulsions, coma, hypoglycemia, metabolic acidosis, and severe anemia are relatively common among children with severe malaria, whereas deep jaundice, acute renal failure, and acute pulmonary edema are unusual. Severely anemic children may present with labored deep breathing, which in the past has been attributed incorrectly to “anemic congestive cardiac failure” but in fact is usually caused by metabolic acidosis, often compounded by hypovolemia. Evidence is accruing that severe malaria can result in long-term neurocognitive and developmental deficits. In general, children tolerate antimalarial drugs well and respond rapidly to treatment.

TRANSFUSION MALARIA

Malaria can be transmitted by blood transfusion, needle-stick injury, sharing of needles by infected injection drug users, or organ transplantation. The incubation period in these settings is often short because there is no preerythrocytic stage of development. The clinical features and

management of these cases are the same as for naturally acquired infections. Radical chemotherapy with primaquine is unnecessary for transfusion-transmitted *P. vivax* and *P. ovale* infections.

CHRONIC COMPLICATIONS OF MALARIA

TROPICAL SPLENOMEGALY (HYPERREACTIVE MALARIAL SPLENOMEGALY)

Chronic or repeated malarial infections produce hypergammaglobulinemia; normochromic, normocytic anemia; and, in certain situations, splenomegaly. Some residents of malaria-endemic areas in tropical Africa and Asia exhibit an abnormal immunologic response to repeated infections that is characterized by massive splenomegaly, hepatomegaly, marked elevations in serum titers of IgM and malarial antibody, hepatic sinusoidal lymphocytosis, and (in Africa) peripheral B cell lymphocytosis. This syndrome has been associated with the production of cytotoxic IgM antibodies to CD8+ T lymphocytes, antibodies to CD5+ T lymphocytes, and an increase in the ratio of CD4+ T cells to CD8+ T cells. These events may lead to uninhibited B cell production of IgM and the formation of cryoglobulins (IgM aggregates and immune complexes). This immunologic process stimulates reticuloendothelial hyperplasia and clearance activity and eventually produces splenomegaly. Patients with hyperreactive malarial splenomegaly (HMS) present with an abdominal mass or a dragging sensation in the abdomen and occasional sharp abdominal pains suggesting perisplenitis. Anemia and some degree of pancytopenia are usually evident, and in some cases malarial parasites cannot be found in peripheral-blood smears. Vulnerability to respiratory and skin infections is increased; many patients die of overwhelming sepsis. Persons with HMS who are living in endemic areas should receive antimalarial chemoprophylaxis; the results are usually good. In nonendemic areas, antimalarial treatment is advised. In some cases refractory to therapy, clonal lymphoproliferation may develop and then evolve into a malignant lymphoproliferative disorder.

QUARTAN MALARIAL NEPHROPATHY

Chronic or repeated infections with *P. malariae* (and possibly with other malarial species) may cause soluble immune-complex injury to the renal glomeruli, resulting in the nephrotic syndrome. Other unidentified factors must contribute to this process since only a very small proportion of infected patients develop renal disease. The histologic appearance is that of focal or segmental glomerulonephritis with splitting of the capillary basement membrane. Subendothelial dense deposits are seen on electron microscopy, and immunofluorescence reveals deposits of complement and immunoglobulins; in samples of renal tissue from children, *P. malariae* antigens are often visible. A coarse-granular pattern of basement membrane immunofluorescent deposits (predominantly IgG3) with selective proteinuria carries a better prognosis than a

fine-granular, predominantly IgG2 pattern with nonselective proteinuria. Quartan nephropathy usually responds poorly to treatment with either antimalarial agents or glucocorticoids and cytotoxic drugs.

BURKITT'S LYMPHOMA AND EPSTEIN-BARR VIRUS INFECTION

It is possible that malaria-related immunosuppression provokes infection with lymphoma viruses. Burkitt's lymphoma is strongly associated with Epstein-Barr virus. The prevalence of this childhood tumor is high in malarious areas of Africa.

DIAGNOSIS

DEMONSTRATION OF THE PARASITE

The diagnosis of malaria rests on the demonstration of asexual forms of the parasite in stained peripheral-blood smears. After a negative blood smear, repeat smears should be made if there is a high degree of suspicion. Of the Romanowsky stains, Giemsa at pH 7.2 is preferred; Wright's, Field's, or Leishman's stain can also be used. Both thin (Figs. 116-4 and 116-5; see also Figs. 118-1 and 118-2) and thick (Figs. 116-6 to 116-9) blood smears should be examined. The thin blood smear should be rapidly air-dried, fixed in anhydrous methanol, and stained; the RBCs in the tail of the film should then be examined under oil immersion ($\times 1000$ magnification). The level of parasitemia is expressed as the number of parasitized erythrocytes per 1000 RBCs. The thick blood film should be of uneven thickness. The smear should be dried thoroughly and stained without fixing. As many layers of erythrocytes overlie one another and are lysed during the staining procedure, the thick film has the advantage of concentrating the parasites (by 40- to 100-fold compared with a thin blood film) and thus increasing diagnostic sensitivity. Both parasites and white blood cells (WBCs) are counted, and the number of parasites per unit volume is calculated from the total leukocyte count. Alternatively, a WBC count of $8000/\mu\text{L}$ is assumed. This figure is converted to the number of parasitized erythrocytes per microliter. A minimum of 200 WBCs should be counted under oil immersion. Interpretation of blood smear films requires some experience because artifacts are common. Before a thick smear is judged to be negative, 100–200 fields should be examined under oil immersion. In high-transmission areas, the presence of up to 10,000 parasites/ μL of blood may be tolerated without symptoms or signs in partially immune individuals. Thus the detection of malaria parasites is sensitive but only poorly specific in identifying malaria as the cause of illness.

Rapid, simple, sensitive, and specific antibody-based diagnostic stick or card tests that detect *P. falciparum*-specific, histidine-rich protein 2 (PfHRP2) or lactate dehydrogenase antigens in finger-prick blood samples have been introduced (Table 116-5). Some of these tests carry a second antibody, which allows falciparum malaria to be distinguished from the less dangerous malarias. PfHRP2-based tests may remain positive for several

weeks after acute infection. This feature is a disadvantage in high-transmission areas where infections are frequent but is of value in the diagnosis of severe malaria in patients who have taken antimalarial drugs and cleared peripheral parasitemia (but in whom the PfHRP2 test remains strongly positive).

The relationship between parasitemia and prognosis is complex; in general, patients with $>10^5$ parasites/ μL are at increased risk of dying, but nonimmune patients may die with much lower counts, and partially immune persons may tolerate parasitemia levels many times higher with only minor symptoms. In severe malaria, a poor prognosis

FIGURE 116-5

is indicated by a predominance of more mature *P. falciparum* parasites (i.e., >20% of parasites with visible pigment) in the peripheral blood film or by the presence of phagocytosed malarial pigment in >5% of neutrophils. In *P. falciparum* infections, gametocytemia peaks 1 week after the peak of asexual parasites. Because the mature gametocytes of

P. falciparum are not affected by most antimalarial drugs, their persistence does not constitute evidence of drug resistance. Phagocytosed malarial pigment is sometimes seen inside peripheral-blood monocytes or polymorphonuclear leukocytes and may provide a clue to recent infection if malaria parasites are not detectable. After the clearance of the parasites, this intraphagocytic malarial pigment is often evident for several days in the peripheral blood or for longer in bone marrow aspirates or smears of fluid expressed after intradermal puncture. Staining of parasites with the fluorescent dye acridine orange allows more rapid diagnosis of malaria (but not speciation of the infection) in patients with low-level parasitemia.

LABORATORY FINDINGS

Normochromic, normocytic anemia is usual. The leukocyte count is generally normal, although it may be raised in very severe infections. There is slight monocytosis, lymphopenia, and eosinopenia, with reactive lymphocytosis and eosinophilia in the weeks after the acute infection. The erythrocyte sedimentation rate, plasma viscosity, and levels of C-reactive protein and other acute-phase proteins are high. The platelet count is usually reduced to $\sim 10^5/\mu\text{L}$.

TABLE 116-5

METHODS FOR THE DIAGNOSIS OF MALARIA^a

| METHOD | PROCEDURE | ADVANTAGES | DISADVANTAGES |
|---|---|---|---|
| Thick blood film ^b | Blood should be uneven in thickness but sufficiently thin to read watch hands through part of the spot. Stain dried, unfixed blood spot with Giemsa, Field's, or other Romanowsky stain. Count number of asexual parasites per 200 WBCs (or per 500 at low densities). Count gametocytes separately. ^c | Sensitive (0.001% parasitemia); species specific; inexpensive | Requires experience (artifacts may be misinterpreted as low-level parasitemia); underestimates true count |
| Thin blood film ^d | Stain fixed smear with Giemsa, Field's, or other Romanowsky stain. Count number of RBCs containing asexual parasites per 1000 RBCs. In severe malaria, assess stage of parasite development and count neutrophils containing malaria pigment. ^e Count gametocytes separately. ^c | Rapid; species specific; inexpensive; in severe malaria, provides prognostic information ^e | Insensitive (<0.05% parasitemia); uneven distribution of <i>P. vivax</i> , as enlarged infected red cells concentrate at leading edge |
| PfHRP2 dipstick or card test | A drop of blood is placed on the stick or card, which is then immersed in washing solutions. Monoclonal antibody captures the parasite antigen and reads out as a colored band. | Robust and relatively inexpensive; rapid; sensitivity similar to or slightly lower than that of thick films (~0.001% parasitemia) | Detects only <i>Plasmodium falciparum</i> ; remains positive for weeks after infection ^f ; does not quantitate <i>P. falciparum</i> parasitemia |
| <i>Plasmodium</i> LDH dipstick or card test | A drop of blood is placed on the stick or card, which is then immersed in washing solutions. Monoclonal antibodies capture the parasite antigens and read out as colored bands. One band is genus specific (all malarias), and the other is specific for <i>P. falciparum</i> . | Rapid; sensitivity similar to or slightly lower than that of thick films for <i>P. falciparum</i> (~0.001% parasitemia) | Slightly more difficult preparation than PfHRP2 tests; may miss low-level parasitemia with <i>P. vivax</i> , <i>P. ovale</i> , and <i>P. malariae</i> and does not speciate these organisms; does not quantitate <i>P. falciparum</i> parasitemia |
| Microtube concentration methods with acridine orange staining | Blood is collected in a specialized tube containing acridine orange, anticoagulant, and a float. After centrifugation, which concentrates the parasitized cells around the float, fluorescence microscopy is performed. | Sensitivity similar or superior to that of thick films (~0.001% parasitemia); ideal for processing large numbers of samples rapidly | Does not speciate or quantitate; requires fluorescence microscopy |

^aMalaria cannot be diagnosed clinically with accuracy, but treatment should be started on clinical grounds if the laboratory confirmation is likely to be delayed. In areas of the world where malaria is endemic and transmission is high, low-level asymptomatic parasitemia is common in otherwise-healthy people. Thus malaria may not be the cause of a fever, although in this context the presence of >10,000 parasites/μL (~0.2% parasitemia) does indicate that malaria is the cause. Antibody and polymerase chain reaction tests have no role in the diagnosis of malaria.

^bAsexual parasites/200 WBCs × 40 = parasite count/μL (assumes a WBC count of 8000/μL). See Figs. 116-6 to 116-9.

^cGametocytemia may persist for days or weeks after clearance of asexual parasites. Gametocytemia without asexual parasitemia does not indicate active infection.

^dParasitized RBCs (%) × hematocrit × 1256 = parasite count/μL. See Figs. 116-3 and 116-4.

^eThe presence of >100,000 parasites/μL (~2% parasitemia) is associated with an increased risk of severe malaria, but some patients have severe malaria with lower counts. At any level of parasitemia, the finding that >50% of parasites are tiny rings (cytoplasm width less than half of nucleus width) carries a relatively good prognosis. The presence of visible pigment in >20% of parasites or of phagocytosed pigment in >5% of polymorphonuclear leukocytes (indicating massive recent schizogony) carries a worse prognosis.

^fPersistence of PfHRP2 is a disadvantage in high-transmission settings, where many asymptomatic people have positive tests, but can be used to diagnostic advantage in low-transmission settings when a sick patient has received previous unknown treatment (which, in endemic areas, often consists of antimalarial drugs). A positive PfHRP2 test indicates that the illness is falciparum malaria, even if the blood smear is negative.

Note: LDH, lactate dehydrogenase; PfHRP2, *P. falciparum* histidine-rich protein 2; RBCs, red blood cells; WBCs, white blood cells.

Severe infections may be accompanied by prolonged prothrombin and partial thromboplastin times and by more severe thrombocytopenia. Levels of antithrombin III are reduced even in mild infection. In uncomplicated malaria, plasma concentrations of electrolytes, blood urea nitrogen (BUN), and creatinine are usually normal. Findings in severe malaria may include metabolic acidosis, with low plasma concentrations of glucose, sodium, bicarbonate, calcium, phosphate, and albumin together with elevations in lactate, BUN, creatinine, urate, muscle and liver enzymes, and conjugated and unconjugated bilirubin. Hypergammaglobulinemia is usual in immune and semi-immune subjects. Urinalysis generally gives normal results. In adults and children with cerebral malaria, the mean opening pressure at lumbar puncture is ~160 mm of cerebrospinal fluid (CSF); usually the CSF is normal or has a slightly elevated total protein level [<1.0 g/L (<100 mg/dL)] and cell count ($<20/\mu\text{L}$).

Rx Treatment: MALARIA

(Table 116-6) When a patient in or from a malarious area presents with fever, thick and thin blood smears should be prepared and examined immediately to confirm the diagnosis and identify the species of infecting parasite (Figs. 116-4 to 116-9). Repeat blood smears should be performed at least every 12–24 h for 2 days if the first smears are negative and malaria is strongly suspected. Alternatively, a rapid antigen detection card or stick test should be performed. Patients with severe malaria or those unable to take oral drugs should receive parenteral antimalarial therapy. If there is any doubt about the resistance status of the infecting organism, it should be considered resistant. Antimalarial susceptibility testing can be performed but is not generally available and yields results too slowly to influence the choice of treatment. Several drugs are available for oral treatment, and the choice of drug depends on the likely sensitivity of the infecting parasites. Despite recent evidence of chloroquine resistance in *P. vivax* (from parts of Indonesia, Oceania, eastern and southern Asia, and Central and South America), chloroquine remains the treatment of choice for the “benign” human malarias (*P. vivax*, *P. ovale*, *P. malariae*) except in Indonesia and Papua New Guinea, where high levels of resistance are prevalent.

The treatment of falciparum malaria has changed radically in recent years. In endemic areas, the World Health Organization now recommends artemisinin-based combinations as first-line treatment for uncomplicated falciparum malaria everywhere. These rapidly and reliably effective drugs are often unavailable in temperate countries (including the United States), where treatment recommendations are limited by the registered available drugs. Fake or substandard drugs, including antimalarial

agents, are being sold in many low-income countries; thus, careful attention is required at purchase, especially when the patient fails to respond as expected. Characteristics of antimalarial drugs are shown in Table 116-7.

SEVERE MALARIA In large studies conducted in Asia, parenteral artesunate, a water-soluble artemisinin derivative, has been shown to reduce mortality rates in severe falciparum malaria by 35% from rates obtained with quinine. Artesunate has therefore become the drug of choice. Artesunate is given by the IV route but can also be given by IM injection. Artemether and the closely related drug artemotil (arteether) are oil-based formulations given by IM injection; they are erratically absorbed and do not confer the same survival benefit as artesunate. A rectal formulation of artesunate has been developed as a community-based prereferral treatment for patients in the rural tropics who cannot take oral medications. Although the artemisinin compounds are safer than quinine and considerably safer than quinidine, only one formulation is available in the United States. IV artesunate has recently been approved by the FDA for emergency use for severe malaria through the Centers for Disease Control and Prevention (CDC) Drug Service (see end of chapter for contact information). The antiarrhythmic quinidine gluconate is as effective as quinine and, as it is more readily available, has replaced quinine for the treatment of malaria in the United States. The administration of quinidine must be closely monitored if dysrhythmias and hypotension are to be avoided. Total plasma levels >8 $\mu\text{g/mL}$, a QT_c interval >0.6 s, or QRS widening beyond 25% of baseline are indications for slowing infusion rates. If arrhythmia or saline-unresponsive hypotension develops, treatment with this drug should be discontinued. Quinine is safer than quinidine; cardiovascular monitoring is not required except when the recipient has cardiac disease.

Severe falciparum malaria constitutes a medical emergency requiring intensive nursing care and careful management. The patient should be weighed and, if comatose, placed on his or her side or prone. Frequent evaluation of the patient's condition is essential. Ancillary drugs such as high-dose glucocorticoids, urea, heparin, dextran, desferrioxamine, antibody to tumor necrosis factor α , and high-dose phenobarbital (20 mg/kg) have proved either ineffective or harmful in clinical trials and should not be used. In acute renal failure or severe metabolic acidosis, hemofiltration or hemodialysis should be started as early as possible.

Parenteral antimalarial treatment should be started as soon as possible. If artemether, quinine, or quinidine is used, an initial loading dose must be given so that therapeutic concentrations are reached as soon as possible. Both quinine and quinidine will cause dangerous hypotension if injected rapidly; when given IV, they must be administered carefully by rate-controlled infusion only. If this approach is not possible, quinine may be given by deep IM injections into the anterior thigh. The optimal therapeutic range for quinine and quinidine in severe malaria is not known with certainty, but

REGIMENS FOR THE TREATMENT OF MALARIA

| TYPE OF DISEASE OR TREATMENT | REGIMEN(S) |
|---|--|
| Uncomplicated Malaria | |
| Known chloroquine-sensitive strains of <i>Plasmodium vivax</i> , <i>P. malariae</i> , <i>P. ovale</i> , <i>P. falciparum</i> ^a | Chloroquine (10 mg of base/kg stat followed by 5 mg/kg at 12, 24, and 36 h or by 10 mg/kg at 24 h and 5 mg/kg at 48 h) or Amodiaquine (10–12 mg of base/kg qd for 3 days) |
| Radical treatment for <i>P. vivax</i> or <i>P. ovale</i> infection | In addition to chloroquine or amodiaquine as detailed above, primaquine (0.25 mg of base/kg qd; 0.375–0.5 mg of base/kg qd in Southeast Asia and Oceania) should be given for 14 days to prevent relapse. In mild G6PD deficiency, 0.75 mg of base/kg should be given once weekly for 6 weeks. Primaquine should not be given in severe G6PD deficiency. |
| Sensitive <i>P. falciparum</i> malaria ^b | Artesunate (4 mg/kg qd for 3 days) plus sulfadoxine (25 mg/kg)/pyrimethamine (1.25 mg/kg) as a single dose or Artesunate (4 mg/kg qd for 3 days) plus amodiaquine (10 mg of base/kg qd for 3 days) ^c |
| Multidrug-resistant <i>P. falciparum</i> malaria | Either artemether-lumefantrine (1.5/9 mg/kg bid for 3 days with food) or artesunate (4 mg/kg qd for 3 days) plus Mefloquine (25 mg of base/kg—either 8 mg/kg qd for 3 days or 15 mg/kg on day 2 and then 10 mg/kg on day 3) ^c |
| Second-line treatment/treatment of imported malaria | Either artesunate (2 mg/kg qd for 7 days) or quinine (10 mg of salt/kg tid for 7 days) plus 1 of the following 3: 1. Tetracycline ^d (4 mg/kg qid for 7 days) 2. Doxycycline ^d (3 mg/kg qd for 7 days) 3. Clindamycin (10 mg/kg bid for 7 days) or Atovaquone-proguanil (20/8 mg/kg qd for 3 days with food) |
| Severe Falciparum Malaria^e | |
| | Artesunate (2.4 mg/kg stat IV followed by 2.4 mg/kg at 12 and 24 h and then daily if necessary) ^f or Artemether (3.2 mg/kg stat IM followed by 1.6 mg/kg qd) or Quinine dihydrochloride (20 mg of salt/kg ^g infused over 4 h, followed by 10 mg of salt/kg infused over 2–8 h q8h ^h) or Quinidine (10 mg of base/kg ^g infused over 1–2 h, followed by 1.2 mg of base/kg per hour ^h with electrocardiographic monitoring) |

^aVery few areas now have chloroquine-sensitive malaria (Fig. 116-2).
^bIn areas where the partner drug to artesunate is known to be effective.
^cFixed-dose coformulated combinations are available.
^dTetracycline and doxycycline should not be given to pregnant women or to children <8 years of age.
^eOral treatment should be substituted as soon as the patient recovers sufficiently to take fluids by mouth.
^fArtesunate is the drug of choice when available. The data from large studies in Southeast Asia showed a 35% reduction in mortality rate from that with quinine. Severe malaria in children in high-transmission settings has different characteristics; thus trials are ongoing in Africa comparing artesunate with quinine to determine whether there is a survival benefit in African children.
^gA loading dose should not be given if therapeutic doses of quinine or quinidine have definitely been administered in the previous 24 h. Some authorities recommend a lower dose of quinidine.
^hInfusions can be given in 0.9% saline and 5% or 10% dextrose in water. Infusion rates for quinine and quinidine should be carefully controlled.
Note: G6PD, glucose-6-phosphate dehydrogenase.

total plasma concentrations of 8–15 mg/L for quinine and 3.5–8.0 mg/L for quinidine are effective and do not cause serious toxicity. The systemic clearance and apparent volume of distribution of these alkaloids are

markedly reduced and plasma protein binding is increased in severe malaria, so that the blood concentrations attained with a given dose are higher. If the patient remains seriously ill or in acute renal failure for >2 days,

TABLE 116-7

PROPERTIES OF ANTIMALARIAL DRUGS

| DRUG(S) | PHARMACOKINETIC PROPERTIES | ANTIMALARIAL ACTIVITY | MINOR TOXICITY | MAJOR TOXICITY |
|--|--|--|--|--|
| Quinine, quinidine | Good oral and IM absorption (quinine); Cl and V_d reduced, but plasma protein binding (principally to α -1 acid glycoprotein) increased (90%) in malaria; quinine $t_{1/2}$: 16 h in malaria, 11 h in healthy persons; quinidine $t_{1/2}$: 13 h in malaria, 8 h in healthy persons | Acts mainly on trophozoite blood stage; kills gametocytes of <i>P. vivax</i> , <i>P. ovale</i> , and <i>P. malariae</i> (but not <i>P. falciparum</i>); no action on liver stages | <i>Common</i> : “Cinchonism”: tinnitus, high-tone hearing loss, nausea, vomiting, dysphoria, postural hypotension; ECG QT_c interval prolongation (quinine usually by <10% but quinidine by up to 25%) <i>Rare</i> : Diarrhea, visual disturbance, rashes <i>Note</i> : Very bitter taste | <i>Common</i> : Hypoglycemia <i>Rare</i> : Hypotension, blindness, deafness, cardiac arrhythmias, thrombocytopenia, hemolysis, hemolytic-uremic syndrome, vasculitis, cholestatic hepatitis, neuromuscular paralysis <i>Note</i> : Quinidine more cardiotoxic |
| Chloroquine | Good oral absorption, very rapid IM and SC absorption; complex pharmacokinetics; enormous Cl and V_d (unaffected by malaria); blood concentration profile determined by distribution processes in malaria; $t_{1/2}$: 1–2 months | As for quinine but acts slightly earlier in asexual cycle | <i>Common</i> : Nausea, dysphoria, pruritus in dark-skinned patients, postural hypotension <i>Rare</i> : Accommodation difficulties, keratopathy, rash <i>Note</i> : Bitter taste, well tolerated | <i>Acute</i> : Hypotensive shock (parenteral), cardiac arrhythmias, neuropsychiatric reactions <i>Chronic</i> : Retinopathy (cumulative dose, >100 g), skeletal and cardiac myopathy |
| Amodiaquine | Good oral absorption; largely converted to active metabolite desethylamodiaquine | As for chloroquine | Nausea (tastes better than chloroquine) | Agranulocytosis; hepatitis, mainly with prophylactic use |
| Mefloquine | Adequate oral absorption; no parenteral preparation; $t_{1/2}$: 14–20 days (shorter in malaria) | As for quinine | Nausea, giddiness, dysphoria, fuzzy thinking, sleeplessness, nightmares, sense of dissociation | Neuropsychiatric reactions, convulsions, encephalopathy |
| Tetracycline, doxycycline ^a | Excellent absorption; $t_{1/2}$: 8 h for tetracycline, 18 h for doxycycline | Weak antimalarial activity; should not be used alone for treatment | Gastrointestinal intolerance, deposition in growing bones and teeth, photosensitivity, moniliasis, benign intracranial hypertension | Renal failure in patients with impaired renal function (tetracycline) |
| Halofantrine ^b | Highly variable absorption related to fat intake; $t_{1/2}$: 1–3 days (active desbutyl metabolite $t_{1/2}$: 3–7 days) | As for quinine | Diarrhea | Cardiac conduction disturbances; atrioventricular block; ECG QT_c interval prolongation; potentially lethal ventricular tachyarrhythmias |

(Continued)

TABLE 116-7 (CONTINUED)

| PROPERTIES OF ANTIMALARIAL DRUGS | | | | |
|--|--|--|--|--|
| DRUG(S) | PHARMACOKINETIC PROPERTIES | ANTIMALARIAL ACTIVITY | MINOR TOXICITY | MAJOR TOXICITY |
| Artemisinin and derivatives (artemether, artesunate) | Good oral absorption, slow and variable absorption of IM artemether; artesunate and artemether biotransformed to active metabolite dihydroartemisinin; all drugs eliminated very rapidly; $t_{1/2}$: <1 h | Broader stage specificity and more rapid than other drugs; no action on liver stages; kills all but fully mature gametocytes of <i>P. falciparum</i> | Reduction in reticulocyte count (but not anemia) | Anaphylaxis, urticaria, fever |
| Pyrimethamine | Good oral absorption, variable IM absorption; $t_{1/2}$: 4 days | For blood stages, acts mainly on mature forms; causal prophylactic | Well tolerated | Megaloblastic anemia, pancytopenia, pulmonary infiltration |
| Proguanil (chloroguanide) | Good oral absorption; biotransformed to active metabolite cycloguanil; $t_{1/2}$: 16 h; biotransformation reduced by oral contraceptive use and in pregnancy | Causal prophylactic; not used alone for treatment | Well tolerated; mouth ulcers and rare alopecia | Megaloblastic anemia in renal failure |
| Primaquine | Complete oral absorption; active compound not known; $t_{1/2}$: 7 h | Radical cure; eradicates hepatic forms of <i>P. vivax</i> and <i>P. ovale</i> ; kills all stages of gametocyte development of <i>P. falciparum</i> | Nausea, vomiting, diarrhea, abdominal pain, hemolysis, methemoglobinemia | Massive hemolysis in subjects with severe G6PD deficiency |
| Atovaquone | Highly variable absorption related to fat intake; $t_{1/2}$: 30–70 h | Acts mainly on trophozoite blood stage | None identified | None identified |
| Lumefantrine | Highly variable absorption related to fat intake; $t_{1/2}$: 3–4 days | As for quinine | None identified | None identified |

^a Tetracycline and doxycycline should not be given to pregnant women or to children <8 years of age.

^b Halofantrine should not be used by patients with long ECG QT_c intervals or known conduction disturbances or by those taking drugs that may affect ventricular repolarization, e.g., quinidine, quinine, mefloquine, chloroquine, neuroleptics, antiarrhythmics, tricyclic antidepressants, terfenadine, or astemizole.

Note: *Cl*, systemic clearance; *V_d*, total apparent volume of distribution; IM, intramuscular; SC, subcutaneous; ECG, electrocardiogram; G6PD, glucose-6-phosphate dehydrogenase.

maintenance doses of quinine or quinidine should be reduced by 30–50% to prevent toxic accumulation of the drug. The initial doses should never be reduced. If one of the artemisinin derivatives is given, dose reductions are unnecessary, even in renal failure. Exchange transfusion should be considered for severely ill patients, although the precise indications for this procedure have not been agreed upon. It has been recommended that—if safe and feasible—exchange should be considered for patients with severe malaria, but there is no clear evidence that this measure is beneficial. The role of prophylactic anticonvulsants is uncertain. If respiratory support is not available, then a full loading dose of phenobarbital (20 mg/kg) to prevent convulsions should not be given as it may cause respiratory arrest.

When the patient is unconscious, the blood glucose level should be measured every 4–6 h, and values <2.2 mmol/L (40 mg/dL) should mandate treatment with IV dextrose. All patients treated with IV quinine or quinidine should receive a continuous infusion of 5–10% dextrose. The parasite count and hematocrit level should be measured every 6–12 h. Anemia develops rapidly; if the hematocrit falls to <20%, then whole blood (preferably fresh) or packed cells should be transfused slowly, with careful attention to circulatory status. Renal function should be checked daily. Children presenting with severe anemia and acidotic breathing are often hypovolemic; in this situation, resuscitation with crystalloids or blood is indicated. Accurate assessment is vital. Management of fluid balance is difficult in severe malaria, particularly in adults, because of the thin dividing line between overhydration (leading to pulmonary edema) and underhydration (contributing to renal impairment). If necessary, central venous pressures should be measured and maintained in the low-normal range. As soon as the patient can take fluids, oral therapy should be substituted for parenteral treatment.

UNCOMPLICATED MALARIA Infections due to *P. vivax*, *P. malariae*, and *P. ovale* should be treated with oral chloroquine (total dose, 25 mg of base/kg). In much of the tropics, drug-resistant *P. falciparum* has been increasing in distribution, frequency, and intensity. Chloroquine-resistant *P. falciparum* is now present throughout most of the tropical world, and resistance to sulfadoxine/pyrimethamine is widespread and increasing. It is now accepted that, to prevent resistance, falciparum malaria should be treated with drug combinations and not with single drugs in endemic areas; the same rationale has been applied successfully to the treatment of tuberculosis and HIV/AIDS. This combination strategy is based on simultaneous use of two or more drugs with different modes of action: one is usually an artemisinin derivative (artesunate, artemether, or dihydroartemisinin) given for 3 days, and the other is usually a slower-acting antimalarial to which *P. falciparum* is sensitive. Artemisinin combination regimens now constitute first-line recommended treatment for falciparum malaria. In areas with multidrug-resistant falciparum malaria (parts of

Asia and South America), either artemether-lumefantrine or artesunate-mefloquine should be used. Although significant resistance to mefloquine has been documented in Thailand, Myanmar, Vietnam, Laos, and Cambodia (Fig. 116-10), mefloquine is usually effective against multidrug-resistant strains of *P. falciparum* outside these areas and, in combination with artesunate, achieves cure rates exceeding 90% nearly everywhere. Atovaquone-proguanil is also highly effective. In areas with more drug-sensitive isolates, atovaquone-proguanil, mefloquine, artesunate-amodiaquine, or artesunate sulfadoxine/pyrimethamine can be used, depending on the prevailing drug susceptibility pattern. These 3-day regimens are all well tolerated, although mefloquine is associated with increased rates of vomiting and dizziness. As second-line treatment for recrudescence following first-line therapy, a 7-day course of either artesunate or quinine plus tetracycline, doxycycline, or clindamycin is effective. Tetracycline and doxycycline cannot be given to pregnant women or to children <8 years of age. Oral quinine is extremely bitter and regularly produces cinchonism comprising tinnitus, high-tone deafness, nausea, vomiting, and dysphoria. Adherence is poor with the required 7-day regimens of quinine.

Patients should be monitored for vomiting for 1 h after the administration of any oral antimalarial drug. If there is vomiting, the dose should be repeated. Symptom-based treatment, with tepid sponging and acetaminophen administration, lowers fever and thereby reduces the

FIGURE 116-10

Mefloquine resistance in *Plasmodium falciparum* in South-east Asia: high-level mefloquine resistance (brown), low-level mefloquine resistance (red), and mefloquine sensitivity (failure rate, <20%; green). There is insufficient information for the other areas.

patient's propensity to vomit these drugs. Minor central nervous system reactions (nausea, dizziness, sleep disturbances) are common. The incidence of serious adverse neuropsychiatric reactions to mefloquine treatment is ~1 in 1000 in Asia but may be as high as 1 in 200 among Africans and Caucasians. All the antimalarial quinolines (chloroquine, mefloquine, and quinine) exacerbate the orthostatic hypotension associated with malaria, and all are tolerated better by children than by adults. Pregnant women, young children, patients unable to tolerate oral therapy, and nonimmune subjects (e.g., travelers) with suspected malaria should be evaluated carefully and hospitalization considered. If there is any doubt as to the identity of the infecting malarial species, treatment for falciparum malaria should be given. A negative blood smear does not rule out malaria; thick blood films should be checked 1 and 2 days later to exclude the diagnosis. Nonimmune patients receiving treatment for malaria should have daily parasite counts performed until negative thick films indicate clearance of the parasite. If the level of parasitemia does not fall below 25% of the admission value in 48 h or if parasitemia has not cleared by 7 days (and adherence is assured), drug resistance is likely and the regimen should be changed. If treatment failures occur with commonly used antimalarial agents, alternative drugs should be used.

To eradicate persistent liver stages and prevent relapse (radical treatment), primaquine (0.25–0.5 mg of base/kg, adult dose) should be given daily for 14 days to patients with *P. vivax* or *P. ovale* infections after laboratory tests for G6PD deficiency have proved negative. A total dose of 22.5–30 mg for an adult is recommended for infections acquired in Southeast Asia and Oceania. If the patient has a mild variant of G6PD deficiency, primaquine can be given in a dose of 0.75 mg of base/kg (45 mg maximum) once weekly for 6 weeks.

COMPLICATIONS

Acute Renal Failure If the level of BUN or creatinine rises despite adequate rehydration, fluid administration should be restricted to prevent volume overload. As in other forms of hypercatabolic acute renal failure, renal replacement is best performed early. Hemofiltration and hemodialysis are more effective than peritoneal dialysis and are associated with lower mortality. Some patients with renal impairment pass small volumes of urine sufficient to allow control of fluid balance; these cases can be managed conservatively if other indications for dialysis do not arise. Renal function usually improves within days, but full recovery may take weeks.

Acute Pulmonary Edema Patients should be positioned with the head of the bed at a 45° elevation and given oxygen and IV diuretics. Pulmonary artery occlusion pressures may be normal, indicating increased pulmonary capillary permeability. Positive-pressure ventilation should be started early if the immediate measures fail.

Hypoglycemia An initial slow injection of 50% dextrose (0.5 g/kg) should be followed by an infusion of 10% dextrose (0.10 g/kg per hour). The blood glucose

level should be checked regularly thereafter as recurrent hypoglycemia is common, particularly among patients receiving quinine or quinidine. In severely ill patients, hypoglycemia commonly occurs together with metabolic (lactic) acidosis and carries a poor prognosis.

Other Complications Patients who develop spontaneous bleeding should be given fresh blood and IV vitamin K. Convulsions should be treated with IV or rectal benzodiazepines and, if necessary, respiratory support. Aspiration pneumonia should be suspected in any unconscious patient with convulsions, particularly with persistent hyperventilation; IV antimicrobial agents and oxygen should be administered, and pulmonary toilet should be undertaken. Hypoglycemia or gram-negative septicemia should be suspected when the condition of any patient suddenly deteriorates for no obvious reason during antimalarial treatment. Systemic *Salmonella* infections are common complications among African children with falciparum malaria.

Antibiotics should be considered for severely ill patients not responding to antimalarial treatment.

PREVENTION

These are halcyon days for malaria prevention and control. New drugs have been discovered and developed; highly effective drugs, insecticide-treated nets, and insecticides for spraying dwellings are being purchased for endemic countries by the Global Fund to Fight HIV/AIDS, Tuberculosis, and Malaria and the President's Malaria Initiative; and even stronger support is being advocated by the Roll Back Malaria Partnership, the Global Health Council, and other supporters of malaria control and research. Still, the eradication of malaria is not yet feasible because of the widespread distribution of *Anopheles* breeding sites; the great number of infected persons; the continued use of ineffective antimalarial drugs; and inadequacies in human and material resources, infrastructure, and control programs. Malaria may be contained by judicious use of insecticides to kill the mosquito vector, rapid diagnosis, appropriate patient management, and—where effective and feasible—administration of intermittent presumptive treatment or chemoprophylaxis to high-risk groups. Malaria researchers are intensifying their efforts to gain a better understanding of parasite-human-mosquito interactions and to develop more effective control and prevention interventions. Despite the enormous investment in efforts to develop a malaria vaccine, no safe, effective, long-lasting vaccine is likely to be available for general use in the near future (Chap. 3). While there is promise for one or more malaria vaccines on the more distant horizon, prevention and control measures continue to rely on antivector and drug-use strategies.

PERSONAL PROTECTION AGAINST MALARIA

Simple measures to reduce the frequency of mosquito bites in malarious areas are very important. These measures include the avoidance of exposure to mosquitoes

at their peak feeding times (usually dusk and dawn) and throughout the night as well as the use of insect repellents containing DEET (10–35%) or picaridin (7%; if DEET is unacceptable), suitable clothing, and insecticide-impregnated bed nets or other materials. Widespread use of bed nets treated with residual pyrethroids reduces the incidence of malaria in areas where vectors bite indoors at night and has been shown to reduce mortality rates in western and eastern Africa.

CHEMOPROPHYLAXIS

(Table 116-8; <http://wwwn.cdc.gov/travel/content/Malaria-DrugsHC.aspx>; accessed September 13, 2007) Recommendations for prophylaxis depend on knowledge of local patterns of plasmodial drug sensitivity and the likelihood of acquiring malarial infection. When there is uncertainty, drugs effective against resistant *P. falciparum* should be used [atovaquone-proguanil (Malarone), doxycycline, mefloquine, or primaquine]. Chemoprophylaxis is never entirely reliable, and malaria should always be considered in the differential diagnosis of fever in patients who have traveled to endemic areas, even if they are taking prophylactic antimalarial drugs.

Pregnant women traveling to malarious areas should be warned about the potential risks. All pregnant women at risk in endemic areas should be encouraged to attend regular antenatal clinics. Mefloquine is the only drug advised for pregnant women traveling to areas with drug-resistant malaria; this drug is generally considered safe in the second and third trimesters of pregnancy, and the limited data on first-trimester exposure are reassuring. The safety of other prophylactic antimalarial agents in pregnancy has not been established. Antimalarial prophylaxis has been shown to reduce mortality rates among children between the ages of 3 months and 4 years in malaria-endemic areas; however, it is not a logistically or economically feasible option in many countries. The alternative—to give intermittent treatment doses [intermittent preventive treatment (IPT)]—shows promise for more widespread use in infants, young children, and pregnant women. Children born to nonimmune mothers in endemic areas (usually expatriates moving to malaria-endemic areas) should receive prophylaxis from birth.

Travelers should start taking antimalarial drugs 2 days to 1–2 weeks before departure so that any untoward reactions can be detected and so that therapeutic antimalarial blood concentrations will be present when needed (Table 116-8). Antimalarial prophylaxis should continue for 4 weeks after the traveler has left the endemic area, except if atovaquone-proguanil or primaquine has been taken; these drugs have significant activities against the liver stage of the infection (causal prophylaxis) and can be discontinued 1 week after departure from the endemic area. Presumptive self-treatment for malaria with atovaquone-proguanil (for 3 consecutive days) or another drug can be considered under special circumstances; medical advice on self-treatment should be sought before departure for malarious areas and as soon as possible after illness begins.

Atovaquone-proguanil (Malarone; 3.75/1.5 mg/kg or 250/100 mg, daily adult dose) is a fixed-combination, once-daily prophylactic agent that is very well tolerated

by adults and children, with fewer adverse gastrointestinal effects than chloroquine-proguanil and fewer adverse central nervous system effects than mefloquine. It is proguanil itself, rather than the antifolate metabolite cycloguanil, that acts synergistically with atovaquone. This combination is effective against all types of malaria, including multidrug-resistant falciparum malaria. Atovaquone-proguanil is best taken with food or a milky drink to optimize absorption. There are insufficient data on the safety of this regimen in pregnancy.

Mefloquine (250 mg of salt weekly, adult dose) has been widely used for malarial prophylaxis because it is usually effective against multidrug-resistant falciparum malaria and is reasonably well tolerated. Mild nausea, dizziness, fuzzy thinking, disturbed sleep patterns, vivid dreams, and malaise are relatively common. Approximately 1 in every 10,000 recipients develops an acute reversible neuropsychiatric reaction manifested by confusion, psychosis, convulsions, or encephalopathy. The role of mefloquine prophylaxis during pregnancy remains uncertain; in studies in Africa, mefloquine prophylaxis was found to be effective and safe during pregnancy. However, in one study from Thailand, treatment of malaria with mefloquine was associated with an increased risk of stillbirth.

Daily administration of doxycycline (100 mg daily, adult dose) is an effective alternative to atovaquone-proguanil or mefloquine. Doxycycline is generally well tolerated but may cause vulvovaginal thrush, diarrhea, and photosensitivity and cannot be used by children <8 years old or by pregnant women.

Chloroquine remains the drug of choice for the prevention of infection with drug-sensitive *P. falciparum* (now found in very few areas of the world) and with the other human malarial species (although chloroquine-resistant *P. vivax* has been reported from parts of eastern Asia, Oceania, and Central and South America). Chloroquine is generally well tolerated, although some patients cannot take the drug because of malaise, headache, visual symptoms (from reversible keratopathy), gastrointestinal intolerance, or (in dark-skinned patients) pruritus. A concomitant filarial infection may provoke or aggravate chloroquine-induced pruritus. Chloroquine is considered safe in pregnancy. With chronic administration for >5 years, a characteristic dose-related retinopathy may develop, but this condition is rare at the doses used for antimalarial prophylaxis. Idiosyncratic or allergic reactions are also rare. Skeletal and cardiac myopathy are potential problems with protracted prophylactic use; they are more likely to occur with the high doses used in the treatment of rheumatoid arthritis. Neuropsychiatric reactions and skin rashes are unusual. When used continuously, amodiaquine, a related aminoquinoline, is associated with a high risk of agranulocytosis (~1 person in 2000) and hepatotoxicity (~1 person in 16,000) and should not be used for prophylaxis.

Primaquine (0.5 mg of base/kg or 30 mg, daily adult dose taken with food) has proved safe and effective in the prevention of drug-resistant falciparum and vivax malaria in adults. This drug can be considered for persons who are traveling to areas with or without drug-resistant *P. falciparum* and who are intolerant to other recommended

TABLE 116-8

DRUGS USED IN THE PROPHYLAXIS OF MALARIA

| DRUG | USAGE | ADULT DOSE | PEDIATRIC DOSE | COMMENTS |
|--|--|---|--|--|
| Atovaquone/proguanil (Malarone) | Prophylaxis in areas with chloroquine- or mefloquine-resistant <i>Plasmodium falciparum</i> | 1 adult tablet PO ^a | 5–8 kg: 1/2 pediatric tablet ^b daily ≥8–10 kg: 3/4 pediatric tablet daily ≥10–20 kg: 1 pediatric tablet daily ≥20–30 kg: 2 pediatric tablets daily ≥30–40 kg: 3 pediatric tablets daily ≥40 kg: 1 adult tablet daily | Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 7 days after leaving such areas. Atovaquone-proguanil is contraindicated in persons with severe renal impairment (creatinine clearance rate <30 mL/min). It is not recommended for children weighing <5 kg, pregnant women, or women breast-feeding infants weighing <5 kg. Atovaquone/proguanil should be taken with food or a milky drink. |
| Chloroquine phosphate (Aralen and generic) | Prophylaxis only in areas with chloroquine-sensitive <i>P. falciparum</i> ^c | 300 mg of base (500 mg of salt) PO once weekly | 5 mg/kg of base (8.3 mg of salt/kg) PO once weekly, up to a maximum adult dose of 300 mg of base | Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious areas and for 4 weeks after leaving such areas. Chloroquine phosphate may exacerbate psoriasis. |
| Doxycycline (many brand names and generic) | Prophylaxis in areas with chloroquine- or mefloquine-resistant <i>P. falciparum</i> ^c | 100 mg PO qd | ≥8 years of age: 2 mg/kg, up to adult dose | Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious areas and for 4 weeks after leaving such areas. Doxycycline is contraindicated in children <8 years of age and in pregnant women. |
| Hydroxychloroquine sulfate (Plaquenil) | An alternative to chloroquine for primary prophylaxis only in areas with chloroquine-sensitive <i>P. falciparum</i> ^c | 310 mg of base (400 mg of salt) PO once weekly | 5 mg of base/kg (6.5 mg of salt/kg) PO once weekly, up to maximum adult dose of 310 mg of base | Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious areas and for 4 weeks after leaving such areas. Hydroxychloroquine may exacerbate psoriasis. |
| Mefloquine (Lariam and generic) | Prophylaxis in areas with chloroquine-resistant <i>P. falciparum</i> | 228 mg of base (250 mg of salt) PO once weekly | ≤9 kg: 4.6 mg of base/kg (5 mg of salt/kg) PO once weekly 10–19 kg: 1/4 tablet once weekly 20–30 kg: 1/2 tablet once weekly 31–45 kg: 3/4 tablet once weekly ≥46 kg: 1 tablet once weekly | Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious areas and for 4 weeks after leaving such areas. Mefloquine is contraindicated in persons allergic to this drug or related compounds (e.g., quinine and quinidine) and in persons with active or recent depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Use with caution in persons with psychiatric disturbances or a history of depression. Mefloquine is not recommended for persons with cardiac conduction abnormalities. |
| Primaquine | An option for prophylaxis in special circumstances | 30 mg of base (52.6 mg of salt) PO qd | 0.5 mg of base/kg (0.8 mg of salt/kg) PO qd, up to adult dose; should be taken with food | Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious areas and for 7 days after leaving such areas. Primaquine is contraindicated in persons with G6PD1 deficiency. It is also contraindicated during pregnancy and in lactation unless the infant being breast-fed has a documented normal G6PD level. Use in consultation with malaria experts. |
| Primaquine | Used for presumptive anti-relapse therapy (terminal prophylaxis) to decrease risk of relapses of <i>P. vivax</i> and <i>P. ovale</i> . | 30 mg of base (52.6 mg of salt) PO qd for 14 days after departure from the malarious area | 0.5 mg of base/kg (0.8 mg of salt/kg), up to adult dose, PO qd for 14 days after departure from the malarious area | This therapy is indicated for persons who have had prolonged exposure to <i>P. vivax</i> and/or <i>P. ovale</i> . It is contraindicated in persons with G6PD1 deficiency as well as during pregnancy and in lactation unless the infant being breast-fed has a documented normal G6PD level. |

^a An adult tablet contains 250 mg of atovaquone and 100 mg of proguanil hydrochloride.^b A pediatric tablet contains 62.5 mg of atovaquone and 25 mg of proguanil hydrochloride.^c Very few areas now have chloroquine-sensitive malaria (Fig. 116-2).Source: CDC: <http://www.cdc.gov/travel/content/MalariaDrugsHC.aspx>, accessed September 13, 2007.

drugs. Abdominal pain and oxidant hemolysis—the principal adverse effects—are not common as long as the drug is taken with food and is not given to G6PD-deficient persons. Primaquine should not be given to pregnant women or neonates. Travelers must be tested for G6PD deficiency and be shown to have a level in the normal range before receiving primaquine. In G6PD deficiency, primaquine can cause hemolysis that is sometimes fatal.

In the past, the dihydrofolate reductase inhibitors pyrimethamine and proguanil (chloroguanide) have been administered widely, but the rapid selection of resistance in both *P. falciparum* and *P. vivax* has limited their use. Whereas antimalarial quinolines such as chloroquine act on the erythrocyte stage of parasitic development, the dihydrofolate reductase inhibitors also inhibit preerythrocytic growth in the liver (causal prophylaxis) and development in the mosquito (sporontocidal activity). Proguanil is safe and well tolerated, although mouth ulceration occurs in ~8% of persons using this drug; it is considered safe for antimalarial prophylaxis in pregnancy. The prophylactic use of the combination of pyrimethamine and sulfadoxine is not recommended because of an unacceptable incidence of severe toxicity, principally exfoliative dermatitis and other skin rashes, agranulocytosis, hepatitis, and pulmonary eosinophilia (incidence, 1:7000; fatal reactions, 1:18,000). The combination of pyrimethamine with dapsone (0.2/1.5 mg/kg weekly; 12.5/100 mg, adult dose) is a third-line alternative available in some countries. Dapsone may cause methemoglobinemia and allergic reactions and (at higher doses) may pose a significant risk of agranulocytosis. Proguanil and the pyrimethamine-dapsone combination are not available in the United States.

Because of the increasing spread and intensity of antimalarial drug resistance (Figs. 116–2 and 116–10), the Centers for Disease Control and Prevention (CDC; <http://www.cdc.gov/malaria/index.htm>), which recommends a daily dose of atovaquone-proguanil for all travelers, maintains an updated 24-h travel and malaria information audiotape that can be accessed by touch-tone telephone (877-FYI-TRIP). Regional and disease-specific documents may

be requested from the CDC Fax Information Service (888-232-3299). Consultation for the evaluation of prophylaxis failures or treatment of malaria can be obtained from state and local health departments and the CDC Malaria Hotline (770-488-7788) or the CDC Emergency Operations Center (770-488-7100).

CHAPTER 117

BABESIOSIS

Jeffrey A. Gelfand ■ Edouard Vannier

Babesiosis is an emerging infection transmitted by ticks and caused by intraerythrocytic protozoa of the genus *Babesia*. Wild and domestic animals are natural reservoirs of *Babesia* species. Only in the past 50 years has *Babesia*

been appreciated to be a pathogen in humans. Usually a mild flulike illness in young and healthy people, babesiosis may develop into a life-threatening malaria-like syndrome in asplenic, immunocompromised, or elderly patients.

ETIOLOGY AND NATURAL CYCLE

In the northeastern United States, *Babesia microti* is transmitted to humans by the hard-bodied tick *Ixodes scapularis* (*I. dammini*). In the fall, adult ticks feed primarily on white-tailed deer. Deer are incompetent reservoirs for *B. microti* but are essential for the maintenance of *I. scapularis*. Adult ticks overwinter and lay eggs in the spring. The eggs hatch into larvae in late July. In August and September, larvae become infected as they feed on *B. microti*-infected white-footed mice. In the spring of the following year, larvae molt into nymphs that remain infected with *B. microti* (transstadial transmission). Early in the summer, these nymphs feed on white-footed mice that become reservoirs of *B. microti*. Transmission of *B. microti* to humans is incidental and occurs primarily at the nymphal stage.

In Europe, *I. ricinus* is regarded as the main vector for infection of humans with *B. divergens*, a pathogen of cattle. *B. divergens* is maintained in the life cycle of the tick by transstadial and transovarial transmission. Nymphs and adults are considered the primary vectors in bovine and human babesiosis.

As ticks feed, *Babesia*-infected red blood cells (RBCs) accumulate in their gut. Gametes fuse into zygotes that translocate across the epithelium, enter the hemolymph, and become kinetes. Some kinetes reach salivary acini and undergo hypertrophy to become dormant sporoblasts. Upon attachment of the tick to the host, sporogony is initiated. In the last hours of feeding, sporozoites are deposited in the host dermis. Once in the blood, sporozoites invade erythrocytes to become trophozoites (see Fig. 118-9). Trophozoites undergo asynchronous schizogony, resulting in the budding of two or four merozoites. Tetrads ("Maltese crosses") are pathognomonic of *B. microti* and other small *Babesia* species (e.g., *B. duncani*) but are seen only rarely in blood smears during infection.

EPIDEMIOLOGY

United States

Babesiosis due to *B. microti* is an emerging infection in the United States. Most of the documented cases have occurred in coastal southern New England (from eastern Connecticut to Cape Cod, MA) and the chain of islands off the coast, particularly Nantucket Island and Martha's Vineyard (MA); Block Island (RI); and eastern Long Island, Shelter Island, and Fire Island (NY). Several cases have been reported from upstate New York, New Jersey, and Pennsylvania and from the upper Midwest (Wisconsin, Minnesota). Because babesiosis is not a notifiable disease in every state and asymptomatic infection is common, the incidence of *B. microti* infection is greatly underestimated. In New York state alone, >800 cases have been reported in the past decade. In Washington state and northern California, nine cases have been attributed to *B. duncani* (isolates WA1 and CA5), *B. duncani*-type parasites (WA2 and CA6), and other closely related babesial parasites (CA1-4). These organisms are antigenically distinct from *B. microti* and belong to the clade of piroplasms found in dogs (*B. conradae*) and wild animals in the western United States. As asymptomatic infection may persist for months without detectable parasitemia, babesiosis may be transmitted by blood transfusion, especially in endemic

areas. More than 50 transfusion-transmitted cases have been attributed to *B. microti* and two to *B. duncani* (WA1 and WA2). Neonatal babesiosis is rare and has been acquired by vertical transmission, blood transfusion, or tick bite. Lastly, *B. divergens*-like parasites have been implicated in three cases of acute babesiosis (one each in Missouri, Kentucky, and Washington state).

Other Countries

Babesiosis is rare in Europe, with half of >35 cases documented in France and the British Isles.

In addition to the original case from Croatia, cases have been reported from the central Alpine region (Austria, Italy, Switzerland) and from southern Europe (Spain, Portugal). Most cases have involved asplenic patients and have been attributed to *B. divergens*. *B. microti* has been implicated in only a handful of cases, although serologic evidence of *B. microti* infection has emerged from Switzerland and midwestern Germany. A study of two patients from Austria and Italy has identified *Babesia* EU1 as a novel pathogen that belongs to the *B. divergens* clade and is closely related to *B. odocoilei*, a parasite of white-tailed deer.

Sporadic cases of human babesiosis have been described in Mexico, Colombia, the Canary Islands, Ivory Coast, Egypt, Mozambique, South Africa, and India. Cases due to *B. microti*-like piroplasms have been reported from Taiwan and Japan.

CLINICAL PRESENTATION

Infections with *B. microti* vary in severity. Asymptomatic infection or self-limiting flulike illness occurs in ~25% of adults and ~50% of children. The incubation period lasts 1–6 weeks. Onset is gradual. The most common manifestations are fever (intermittent or sustained, with temperatures sometimes reaching 40°C), fatigue, malaise, shaking chills, sweats, myalgias, and arthralgias. Less frequent symptoms include shortness of breath, headache, anorexia, and nausea. Malaise, myalgias, arthralgias, and shortness of breath may help differentiate babesiosis from other febrile illnesses. Fever is the salient feature on physical examination. Mild splenomegaly and hepatomegaly may be noted. Jaundice is rare.

Low hematocrit, low hemoglobin, and hemoglobinuria are consistent with hemolytic anemia. The parasitemia level is usually 1–10% in immunocompetent hosts but can reach 85% in asplenic patients. Reticulocyte counts are elevated, white blood cell (WBC) counts are normal or slightly low, and thrombocytopenia is common. Levels of liver enzymes (including alkaline phosphatase, lactate dehydrogenase, aspartate and alanine aminotransferases, and bilirubin) are elevated. With hemolysis, the serum haptoglobin concentration is low, and urinalysis may show hemoglobinuria and proteinuria.

Complications of babesiosis include acute respiratory failure, disseminated intravascular coagulation, congestive heart failure, and renal failure. *B. microti* infection may be fatal in 5–10% of cases in hospitalized patients. Severe anemia (hemoglobin concentration, <10 g/dL) and high-level parasitemia (>10%) are risk factors for complications. Alkaline phosphatase levels of >125 U/L, WBC counts of >5 × 10⁹/L, and male gender are strong predictors of severe

disease, as defined by death, hospitalization for >2 weeks, or admission to an intensive care unit for >2 days. Severe babesiosis is common among asplenic patients, patients co-infected with *Borrelia burgdorferi* (i.e., those with Lyme disease), persons >50 years of age, and individuals with comorbidities, including HIV infection, cancer, and other diseases associated with immunosuppression. Infection may recrudesce after splenectomy or immunosuppressive therapy.

Babesiosis due to *B. divergens* occurs most often in asplenic patients. After an incubation period of 1–3 weeks, disease suddenly appears. Hemoglobinuria—the presenting symptom—is followed by jaundice, persistent high fever (40°–41°C), myalgias, shaking chills, and drenching sweats. Babesiosis may evolve into a shocklike syndrome, with renal failure and pulmonary edema. The parasitemia level can reach 80%. Hemoglobin levels may plunge to 4–8 g/dL. The mortality rate remains high (42%).

Infections with *B. duncani* and related parasites range from asymptomatic to severe and are sometimes fatal.

DIAGNOSIS

A diagnosis of babesiosis should be considered for any symptomatic patient who resides or travels in endemic areas. The tick bite often goes unnoticed. Because symptoms are nonspecific, the diagnosis requires laboratory testing. Babesiosis is diagnosed by microscopic examination of Giemsa-stained thin blood smears (see Fig. 118-9). *Babesia* spp. appear annular, oval, or piriform. Ring forms are most common and do not contain the central brownish deposits (hemozoin) typical of *Plasmodium falciparum*. Tetrads are indicative of small babesial parasites, such as *B. microti* and *B. duncani*. An indirect immunofluorescent antibody test (IFAT) for *B. microti* is available from the Centers for Disease Control and Prevention. A serum IgG titer of

≥1:64 is diagnostic. The latter test has good predictive value for infection but must be interpreted in the clinical context; antibodies do not develop until at least 1 week into the illness, and serologic testing does not distinguish prior infection from active infection. Thus, IFAT is ideal for detection of past or persistent infection but not of fulminant acute infection. Antibodies to *B. microti* do not react with *B. divergens* or *B. duncani*. The persistence of low-grade infection is best diagnosed by polymerase chain reaction (PCR)–based amplification of the babesial 18S rRNA gene in blood samples. As primers are species-specific, this assay is a valuable adjunct in the diagnosis of babesiosis.

Rx Treatment: BABESIOSIS

(See Table 117-1) Whether *B. microti* infection should be treated depends on the clinical context. Asymptomatic infections need not be treated, but if *Babesia* organisms continue to be seen on blood smear or by PCR for >3 months, treatment should be considered. Symptomatic infections should not be treated if blood smear and PCR are both negative for *Babesia*. If *Babesia* is detected in blood samples from symptomatic patients, treatment should be initiated.

A combination of atovaquone and azithromycin, given for 7–10 days, constitutes initial therapy for non-life-threatening (mild) babesiosis due to *B. microti*. For immunocompromised patients, higher doses of azithromycin (600–1000 mg/d) than those listed in the table are used. A combination of clindamycin and quinine is given for 7–10 days to patients with severe *B. microti* babesiosis; whenever possible, clindamycin should be given IV rather than PO. Partial or complete RBC exchange

TABLE 117-1

ANTIBIOTIC REGIMENS FOR THE TREATMENT OF BABESIOSIS

| ORGANISM | SEVERITY | ADULTS | CHILDREN |
|---------------------|--------------------------------|---|--|
| <i>B. microti</i> | Mild ^a | Atovaquone (750 mg q12h PO) <i>plus</i> Azithromycin (500–1000 mg/d PO on day 1, 250 mg/d PO thereafter) | Atovaquone (20 mg/kg q12h PO; maximum, 750 mg/dose) <i>plus</i> Azithromycin [10 mg/kg qd PO on day 1 (maximum, 500 mg/dose), 5 mg/kg qd PO thereafter (maximum, 250 mg/dose)] |
| | | Clindamycin (300–600 mg q6h IV or 600 mg q8h PO) <i>plus</i> Quinine (650 mg q6–8h PO) <i>plus</i> Consider RBC exchange transfusion Immediate complete RBC exchange transfusion <i>plus</i> Clindamycin (600 mg q6–8h IV) <i>plus</i> Quinine (650 mg q8h PO) | Clindamycin (7–10 mg/kg q6–8h IV or 7–10 mg/kg q6–8h PO; maximum, 600 mg/dose) <i>plus</i> Quinine (8 mg/kg q8h PO; maximum, 650 mg/dose) <i>plus</i> Consider RBC exchange transfusion Immediate complete RBC exchange transfusion <i>plus</i> Clindamycin (7–10 mg/kg q6–8h IV; maximum, 600 mg/dose) <i>plus</i> Quinine (8 mg/kg q8h PO; maximum, 650 mg/dose) |

^a Treatment duration: 7–10 days.

^b Treatment duration: generally 7–10 days, but may vary.

Note: RBC, red blood cell.

transfusion is advised in severe babesiosis, which is defined as a parasitemia level of >10%; significant hemolysis; or renal, hepatic, or pulmonary compromise. Treatment failures have been described with the recommended medical regimens. Other combination therapies may be used. A combination of azithromycin and quinine was effective in two patients with infection refractory to clindamycin plus quinine. One patient with AIDS and chronic babesiosis was treated successfully with a combination of clindamycin, doxycycline, and azithromycin after becoming allergic to quinine.

In patients with mild *B. microti* babesiosis, symptoms should improve within the first 48 h of therapy and should resolve within 3 months. In patients with severe babesiosis, hematocrit and parasitemia should be monitored each day or every other day until symptoms recede and the parasitemia level is <5%. Re-treatment may be required if the babesial parasite or amplifiable babesial DNA is detected for >3 months after initial therapy, but routine testing is not needed for immunocompetent patients who are asymptomatic. Underlying immunodeficiency (such as malignancy or HIV infection) should be considered in patients with severe or prolonged episodes of babesiosis.

There is increasing evidence that immunosuppressed patients may need treatment for considerably longer periods.

Patients with babesiosis should be evaluated for Lyme disease (Chap. 166) and human granulocytotropic anaplasmosis (Chap. 167), as all three infections may be acquired from the same tick vector. In endemic areas for these infections, relevant antimicrobial therapy should be considered when an intercurrent infection is strongly suspected.

B. divergens infection is often severe and progresses rapidly. The recommended treatment is immediate complete blood exchange transfusion and medical therapy with IV clindamycin plus oral quinine. Exchange transfusion ensures a complete and rapid removal of parasitized RBCs, RBC debris, and inflammatory mediators. Although

uninfected RBCs are introduced by exchange transfusion, anemia may persist for >1 month. If so, additional transfusion is needed.

PREVENTION

Individuals who live or travel in endemic areas, especially those at increased risk for severe babesiosis, should be advised to avoid tick exposure by wearing protective clothing (long sleeves/long pants, with pants tucked into socks); applying tick repellents (such as DEET) to clothing; and limiting outdoor activities, especially between May and September, when infection risk is highest. Thorough skin examination after outdoor exposure allows removal of ticks within 24 h of attachment—i.e., before transmission can occur.

CHAPTER 118

ATLAS OF BLOOD SMEARS OF MALARIA AND BABESIOSIS

Nicholas J. White ■ Joel G. Berman

Four species of blood protozoan parasites cause human malaria: the potentially lethal and often drug-resistant *Plasmodium falciparum*; the relapsing parasites *P. vivax* and *P. ovale*; and *P. malariae*, which can persist at low densities for years. Occasional infections in individuals who have been

in tropical forests may be caused by monkey parasites—notably, *P. knowlesi*.

The malaria parasites are readily seen under the microscope (×1000 magnification) in thick and thin blood smears stained with supravital dyes (e.g., Giemsa's, Field's,

FIGURE 118-1

Thin blood films of *Plasmodium falciparum*. **A.** Young trophozoites. **B.** Old trophozoites. **C.** Pigment in polymorphonuclear cells and trophozoites. **D.** Mature schizonts. **E.** Female gametocytes. **F.** Male gametocytes. Wright's, Leishman's). Thin film smears are shown in Figs. 118-1 to 118-4; thick film smears are shown in Figs. 118-5 to 118-8. The morphologic characteristics of the parasites are summarized in Table 118-1. In the thick film, lysis of red blood cells by water leaves the stained white cells and parasites, allowing detection of densities as low as 50 parasites/ μ L. This degree of sensitivity is up to 100 times greater than that of the thin

film, in which the red cells are fixed and the malaria parasites are seen inside the cells. The thin film is better for speciation and provides useful prognostic information in severe falciparum malaria. Several findings are associated with increased mortality risk: high parasite counts, more mature parasites (>20% containing visible malaria pigment), and phagocytosed malaria pigment in >5% of neutrophils.

TABLE 118-1
MORPHOLOGIC CHARACTERISTICS OF HUMAN MALARIA PARASITES

| | <i>P. FALCIPARUM</i> | <i>P. VIVAX</i> | <i>P. OVALE</i> | <i>P. MALARIAE</i> |
|-------------------|--|---|---|---|
| Asexual parasites | Usually only fine blue ring forms (some resembling stereo headsets) are seen. Parasitemia level may exceed 2%. | Irregular, large, fairly thick rings become highly pleomorphic as the parasite grows. Parasitemia level is low. | Regular, dense ring enlarges to compact, blue, mature trophozoite (rectangular or band-form). Parasitemia level is low. | Dense, thick rings mature to dense, round trophozoites. Parasitemia level is low. |
| Schizonts | Rare in peripheral blood; 8–32 merozoites, dark brown-black pigment | Common; 12–18 merozoites, orange-brown pigment | 8–14 merozoites, brown or black pigment | 8–10 merozoites, dark brown or black pigment |
| Gametocytes | Banana-shaped; male: light blue; female: darker blue; a few scattered blue-black pigment granules in cytoplasm | Round or oval; male: round, pale blue; female: oval, dark blue; triangular nucleus, a few orange pigment granules | Large, round, dense, and blue (like <i>P. malariae</i>), but prominent James’s dots; brown pigment | Large, oval; male: pale blue; female: dense blue; large black pigment granules |
| RBC changes | RBCs are normal in size. As the parasite matures, the RBC cytoplasm becomes pale, the cells become crenated, and a few small red dots may appear over the cytoplasm (Maurer’s clefts). | RBCs are enlarged. Pale red Schüffner’s dots increase in number as the parasite matures. | RBCs become oval with tufted ends. Red James’s dots are prominent. | RBCs are normal in size and shape. No red dots are seen. |

Note: RBC, red blood cell.

CHAPTER 119

LEISHMANIASIS

Barbara L. Herwaldt

The term *leishmaniasis* encompasses multiple clinical syndromes. Most notable are visceral, cutaneous, and mucosal leishmaniasis, which result from infection of macrophages throughout the reticuloendothelial system, in the dermis, and in the naso-oropharyngeal mucosa, respectively.

Leishmaniasis, a vector-borne disease caused by obligate intracellular protozoa, is characterized by vast diversity and by specificity within that diversity. The disease is endemic in focal areas of ~90 countries in the tropics, subtropics, and southern Europe, in settings that range from deserts to rain forests and from rural to urban areas. Infection in humans is caused by ~20 *Leishmania* species (*Leishmania* and *Viannia* subgenera) (Table 119-1), which are transmitted by ~30 species of phlebotomine sandflies (*Phlebotomus* [Old World] and *Lutzomyia* [New World]). Amid this diversity, particular parasite, vector, and host species maintain the transmission cycle in a given setting.

Both the diversity and the specificity of the disease confound attempts to generalize about any aspect of leishmaniasis, including control measures and clinical management. The multitudinous possible combinations of *Leishmania* species/strains, syndromes, and geographic areas—modified by host factors and immunoinflammatory responses—may be associated with clinically relevant differences, such as diverse manifestations of infection and diverse responses to particular therapies. It is essential that clinicians understand the dangers associated with extrapolating data from one setting to another and the importance of individualizing patient care, with expert consultation.

LIFE CYCLE AND IMMUNOREGULATION

Leishmania parasites, which target and persist in tissue macrophages, are transmitted by the bite of female phlebotomine sandflies. While probing for a blood meal, sandflies regurgitate the parasite's flagellated promastigote stage into the host's skin; sandfly salivary components with immunomodulating effects have been shown to promote experimental infection. Promastigotes bind to receptors on macrophages, are phagocytized, and transform within phagolysosomes into nonflagellated amastigotes (Fig. 119-1), which replicate and infect additional macrophages. Amastigotes ingested by sandflies transform back into infective promastigotes. Other modes of transmission include congenital and parenteral (e.g., by blood transfusion or needle sharing).

Leishmaniasis is viewed as a model system for exploring immunoregulatory responses to intracellular pathogens. Murine models of *L. major* infection exemplify the T_H1/T_H2 paradigm, in which polarized T_H1 and T_H2 responses govern resistance and susceptibility, respectively. Production of interferon γ (IFN- γ) by T_H1 and natural killer cells confers resistance; interleukin (IL) 12 induces naïve T cells to differentiate into T_H1 cells and induces T cells and natural killer cells to produce IFN- γ . In contrast, expansion of IL-4-producing T_H2 cells and IL-10 mediate susceptibility.

Although the immunoregulatory responses are more complex and less polarized in humans than in inbred mice, key principles are evident. The immunoinflammatory response is central to pathogenesis, healing is associated

FIGURE 119-1

Amastigotes (the tissue stage of *Leishmania* parasites) in a Giemsa-stained impression smear of tissue from a patient with cutaneous leishmaniasis. Amastigotes are oval or egg shaped and ~2–4 μm in length. Their internal organelles include a nucleus (larger arrow) and rod-shaped kinetoplast (smaller arrow). In particular, the kinetoplast, a specialized mitochondrial structure that contains extranuclear DNA, should be visualized. The extracellular amastigotes probably were released from macrophages during manipulation of the specimen. Magnification: $\times 1000$, obtained using a $\times 100$ oil-immersion objective. TABLE 119-1

LEISHMANIA SPECIES THAT CAUSE DISEASE IN HUMANS

| SPECIES ^a | CLINICAL SYNDROME ^b | GEOGRAPHIC DISTRIBUTION ^c |
|---|--------------------------------|--|
| Subgenus <i>Leishmania</i> | | |
| <i>L. donovani</i> complex | | |
| <i>L. donovani</i> sensu stricto | VL (PKDL, OWCL) | China, Indian subcontinent (southern Asia), southwestern Asia, Ethiopia, ^d Kenya, Somalia, Sudan, Uganda; possibly sporadic elsewhere in sub-Saharan Africa |
| <i>L. infantum</i> sensu stricto ^e | VL (OWCL) | China, central and southwestern Asia, Middle East, southern Europe, northern Africa, Ethiopia, ^d Sudan; sporadic elsewhere in sub-Saharan Africa |
| <i>L. chagasi</i> ^e | VL (NWCL) | Central and South America |
| <i>L. mexicana</i> complex | | |
| <i>L. mexicana</i> | NWCL (DCL) | Mexico, Central and South America; sporadic in Texas and Oklahoma |
| <i>L. amazonensis</i> | NWCL (ML, DCL, VL) | Panama and South America |
| <i>L. tropica</i> | OWCL (VL) ^f | Central Asia, India, Pakistan, southwestern Asia, Middle East, Turkey, Greece, northern Africa, Ethiopia, ^d Kenya, Namibia |
| <i>L. major</i> | OWCL | Central Asia, India, Pakistan, southwestern Asia, Middle East, Turkey, northern Africa, Sahel region of north-central Africa, Ethiopia, ^d Sudan, Kenya |
| <i>L. aethiopica</i> | OWCL (DCL) | Ethiopia, ^d Kenya, Uganda |
| Subgenus <i>Viannia</i> | | |
| <i>L. (V.) braziliensis</i> | NWCL (ML) | Central and South America |
| <i>L. (V.) guyanensis</i> | NWCL (ML) | South America |
| <i>L. (V.) panamensis</i> | NWCL (ML) | Central America, Venezuela, Colombia, Ecuador, Peru |
| <i>L. (V.) peruviana</i> | NWCL ^g | Peru (western slopes of Andes) |

^aSpecies other than those listed here have been reported to infect humans.

^bDCL, diffuse cutaneous leishmaniasis; ML, mucosal leishmaniasis; NWCL, New World (American) cutaneous leishmaniasis; OWCL, Old World cutaneous leishmaniasis; PKDL, post-kala-azar dermal leishmaniasis; VL, visceral leishmaniasis. Clinical syndromes less frequently associated with the various species are shown in parentheses.

^cThe geographic distribution is highly focal within countries/regions, and the order in which areas are listed does not reflect the level of endemicity. (See text for further information.) The geographic distribution of cases evaluated in countries such as the United States reflects travel and immigration patterns.

^dCutaneous and visceral leishmaniasis also are endemic in parts of Eritrea, but the causative species have not been well established.

^e*L. infantum* and *L. chagasi* are considered synonymous.

^f*L. tropica* also causes leishmaniasis recidivans and viscerotropic leishmaniasis.

^gThe cutaneous leishmaniasis syndrome caused by this species is called *uta*.

with activation of macrophages to kill intracellular amastigotes, and persistent infection is characteristic. Although the correlates of immunity are not fully defined and may differ between treated and untreated persons, nonsterile cure is a mixed blessing: quiescent parasites may help the host maintain a protective T cell-mediated immune response but may also serve as a source for activation of latent or clinically cured infection if the protective mechanisms fail.

EPIDEMIOLOGY, PREVENTION, AND CONTROL

Leishmaniasis is endemic or emerging in focal areas of ~90 countries in Asia, the Middle East, southern Europe, and Africa (Old World disease) and the Americas (New World disease) (Table 119-1).

Upwards of several hundred thousand cases of visceral leishmaniasis and 1–1.5 million cases of cutaneous leishmaniasis occur annually. Leishmaniasis is associated with the loss of ~2.4 million disability-adjusted life-years.

More than 90% of the world's cases of visceral leishmaniasis occur in three regions: (1) southern Asia or the Indian subcontinent, particularly in Bihar State in north-eastern India and in foci in Bangladesh and Nepal; (2) eastern Africa (Sudan and neighboring countries); and (3) the Americas, particularly in periurban areas of northeastern Brazil. The predominant etiologic agents are *L. donovani* in southern Asia and eastern Africa and *L. infantum*/*L. chagasi* elsewhere in the Old and New Worlds. These organisms can also cause cutaneous leishmaniasis.

More than 90% of the world's cases of cutaneous leishmaniasis occur in Afghanistan (Fig. 119-2), Algeria, Iran, Iraq, Pakistan, Saudi Arabia, and Syria (Old World)

**FIGURE 119-2**

People in Kabul, Afghanistan, standing in line for hours on a bitterly cold day in February 1997 at a treatment center for cutaneous leishmaniasis. Kabul is experiencing a prolonged epidemic of anthroponotic cutaneous leishmaniasis caused by *Leishmania tropica*. Photograph courtesy of D. Ashford and reprinted with permission from Elsevier Science (Lancet 350:1009, 1997).

and in Brazil and Peru (New World). The predominant etiologic agents are *L. tropica*, *L. major*, and *L. aethiopica* (Old World) and species of the *L. mexicana* complex and the *Viannia* subgenus (New World).

In general, prevention and control measures are difficult to sustain and must be tailored to the setting. Vaccine strategies are being explored. Vector characteristics contribute to the focality of transmission in time and place and have implications for preventive measures. Sandflies are nocturnal (i.e., most active from dusk to dawn), have a limited flight range (usually remaining within a few hundred meters of their breeding site), and are small (about one-third the size of mosquitoes). Personal protective measures include minimizing nocturnal outdoor activities, wearing protective clothing, and applying insect repellent to exposed skin. In settings with domiciliary transmission, spraying dwellings with residual-action insecticides and using bed nets treated with long-lasting insecticides may be protective.

Most transmission cycles traditionally have been classified as zoonotic, except for the anthroponotic cycles of *L. donovani* (in southern Asia and potentially in eastern Africa) and *L. tropica*. However, some zoonotic cycles may be partially anthroponotic (and vice versa), and transmission patterns can evolve (e.g., from predominantly sylvatic to include domiciliary transmission) in the context of environmental and epidemiologic changes.

If transmission is exclusively or partially anthroponotic, treatment of infected persons can serve as a control mea-

sure, and suboptimal treatment can lead to dissemination of drug resistance. In southern Asia, which arguably carries ~70% of the global burden of visceral leishmaniasis, transmission of *L. donovani* is anthroponotic and largely intra- or peridomiciliary. In 2005, India, Nepal, and Bangladesh resolved to collaborate to reduce the annual incidence of visceral leishmaniasis to <1 case per 10,000 persons by the year 2015. For areas where canids are reservoir hosts (*L. infantum*/*L. chagasi*—endemic regions), various control strategies are being explored (e.g., insecticide-impregnated dog collars and vaccine candidates).

CLINICAL MANIFESTATIONS AND DIFFERENTIAL DIAGNOSIS

VISCERAL LEISHMANIASIS

The general term *visceral leishmaniasis* encompasses a broad spectrum of severity and manifestations, with a chronic, subacute, or acute onset and an incubation period of weeks, months, or sometimes years. In contrast, the term *kala-azar* typically is reserved for advanced, life-threatening disease. Although *kala-azar* means black [*kala*] fever [*azar*] in Hindi, darkening of the skin is uncommon. The classic manifestations of advanced disease include prolonged fever; cachexia (malnutrition being both a risk factor for and a sequela of visceral leishmaniasis); hepatosplenomegaly (with splenomegaly usually predominant and the spleen sometimes massive); anemia; leukopenia (neutropenia, marked eosinopenia, and relative lymphocytosis and monocytosis); thrombocytopenia, sometimes associated with bleeding; hypergammaglobulinemia (chiefly IgG, from polyclonal B cell activation); and hypoalbuminemia. The differential diagnosis includes tropical and infectious diseases that cause fever or organomegaly (e.g., typhoid fever, subacute bacterial endocarditis, miliary tuberculosis, brucellosis, histoplasmosis, tropical splenomegaly syndrome, and schistosomiasis) and myeloproliferative diseases (e.g., leukemia and lymphoma).

Post-kala-azar dermal leishmaniasis (PKDL) is a syndrome characterized by skin lesions (including macules, papules, nodules, and patches) that are typically most prominent on the face and that develop during or after therapy for visceral leishmaniasis. In Sudan, PKDL is noted in ~50% of patients from 0 to 6 months after therapy and usually heals spontaneously. In contrast, in India, PKDL is noted in ~5–10% of patients, occurring several years after treatment and usually requiring further therapy. PKDL can be confused with miliaria rubra, syphilis, yaws, and leprosy.

The diagnosis of visceral leishmaniasis should be considered for HIV-infected patients who have ever been in leishmaniasis-endemic areas and have manifestations consistent with visceral infection. The leishmanial infection may have been acquired recently (e.g., from a contaminated syringe) or may represent activation of latent infection acquired in the distant past; most co-infected patients with clinically evident visceral infection have CD4+ T lymphocyte counts of <200/ μ L.

Most cases of *Leishmania*-HIV co-infection have been reported from southern Europe (particularly Spain, France,

Italy, and Portugal). Whereas antiretroviral therapy has decreased the incidence of clinically manifest leishmanial infection in Europe, increasing numbers of co-infected cases are being reported in resource-poor countries.

CUTANEOUS LEISHMANIASIS

Typically, the incubation period of cutaneous leishmaniasis ranges from weeks to months. Lesions progress from papules to plaques (which can be smooth or scaly and develop central ulceration; Fig. 119-3) to atrophic scars. The spectrum includes papulonodular, nodular, and noduloulcerative lesions. Multiple primary lesions, satellite lesions, regional adenopathy, nodular lymphangitis, secondary bacterial infection, and thick hemorrhagic crusts or verrucous (wart-like) scale are variably present. Both active and healed lesions can cause considerable morbidity. Spontaneous resolution does not preclude reactivation of infection, dissemination to mucous membranes (see below), or reinfection.

Cutaneous leishmaniasis can be confused with tropical, traumatic, and venous-stasis ulcers; foreign-body reactions; myiasis; infected insect bites; impetigo, ecthyma, and pyoderma gangrenosum; superficial and deep fungal, mycobacterial, and spirochetal infections; and cutaneous sarcoidosis and neoplasms.

The polyparasitic and oligoparasitic ends of the disease spectrum are represented by diffuse cutaneous leishmaniasis (DCL) and leishmaniasis recidivans, respectively. DCL, which typically is caused by *L. aethiopica* (Old World) and *L. mexicana* species (New World), develops in the context of *Leishmania*-specific anergy and is manifested by chronic, disseminated, nonulcerative lesions, with abundant parasites but few lymphocytes. DCL should be differentiated from benign disseminated cutaneous leishmaniasis, lepromatous leprosy, and PKDL. Leishmaniasis recidivans, which most characteristically is caused by *L. tropica*, is a hyperergic variant with scarce parasites. It resembles lupus vulgaris and is characterized by a chronic,

solitary plaque (typically on the cheek) that heals centrally but slowly expands at the periphery.

MUCOSAL LEISHMANIASIS

Traditionally, the term *mucosal leishmaniasis* (or *espundia*) refers to a potentially disfiguring sequela of New World cutaneous leishmaniasis that results from dissemination of parasites from the skin to the naso-oropharyngeal mucosa. Mucosal leishmaniasis is caused by species in the *Viannia* subgenus [especially *L. (V.) braziliensis* and *L. (V.) panamensis* but also *L. (V.) guyanensis*] and by *L. amazonensis* (Table 119-1).

The magnitudes and the determinants (both parasite- and host-related) of the risks for mucosal dissemination and mucosal disease are poorly defined. Overall risk estimates for mucosal disease typically are $\leq 5\%$ ($\sim 1\text{--}10\%$). The risk appears to be higher in South America and southern Central America than in *L. Viannia*-endemic regions further north (e.g., in Guatemala and Mexico). Mucosal and cutaneous lesions can be noted concomitantly or appear decades apart. Mucosal disease typically is noted within several years after the resolution of the original cutaneous lesions, which usually were not treated or were treated suboptimally.

The initial manifestations of mucosal disease typically are persistent, unusual nasal symptoms (e.g., epistaxis and stuffiness), with erythema and edema of the nasal mucosa, which can be followed by progressive, ulcerative destruction of the naso-oropharyngeal mucosa and surrounding tissues in the context of a hyperactive immune response. The differential diagnosis includes other infectious diseases (e.g., rhinoscleroma, paracoccidioidomycosis, histoplasmosis, leprosy, syphilis, and tertiary yaws), sarcoidosis, neoplasms, and mucosal ulceration from cocaine use.

DIAGNOSIS

PRINCIPLES AND PERSPECTIVE

Leishmaniasis often is diagnosed presumptively by clinical and epidemiologic criteria. Definitive diagnosis requires demonstration of the parasite in specimens from infected sites, which typically relies on classic microbiologic methods—i.e., detection of amastigotes by light microscopic examination of stained slides or detection of promastigotes by in vitro culture. In general, amastigotes, including their characteristic internal organelles (Fig. 119-1), are more easily recognizable on Giemsa-stained smears (e.g., thin smears of dermal scrapings or bone marrow aspirates and impression smears of biopsy specimens) than in tissue sections, particularly if organisms are rare.

Leishmania species can be distinguished by isoenzyme analysis of cultured promastigotes or determination of monoclonal antibody specificity. Molecular techniques of assorted types, with diverse genetic markers, are at various stages of development and validation for diagnosis of leishmaniasis and identification of species. Analyses of the genomes and the proteome profiles of *Leishmania* species may lead to novel diagnostic approaches.

FIGURE 119-3

Ulcerative skin lesions with raised outer borders on the arm of a patient with New World (American) cutaneous leishmaniasis acquired in Costa Rica. (Photograph courtesy of D. A. Light; with permission.)

Immunologic diagnostic methods include serologic assays and tests for *Leishmania*-specific cell-mediated immunity (e.g., skin testing for delayed-type hypersensitivity reactions). The utility of such methods depends in part on the syndrome. Most serologic assays do not reliably distinguish active from quiescent infection. No leishmanin skin-test preparation has been approved for use in the United States.

VISCERAL LEISHMANIASIS

Patients with advanced visceral leishmaniasis commonly have relatively heavy parasite burdens and high-level antibody responses that are not protective but are useful diagnostically; skin-test reactivity develops after recovery. Aspirates and biopsy specimens (e.g., of spleen, bone marrow, liver, or lymph node) are useful for parasitologic confirmation by traditional and molecular methods. Although the diagnostic yield is highest for splenic aspirates (>95%), bone marrow aspiration is safer.

In the appropriate setting, seropositivity is often the diagnostic standard. Although test performance can vary by region, approaches that offer the potential for improved field applicability include direct agglutination testing with freeze-dried antigen and immunochromatographic dipstick testing of fingerstick blood for antibody to recombinant antigens or synthetic peptides (e.g., rK39). In addition, assays for detection of leishmanial antigen in urine are being evaluated.

The sensitivity of serologic methods is lower in HIV-infected patients than in persons not infected with HIV (~50% vs. >90%). In contrast, the parasites may be abundant in typical sites (e.g., bone marrow), in atypical sites (e.g., gastrointestinal tissue), and in circulating monocytes—a circumstance that facilitates parasitologic diagnosis. The sensitivities of peripheral-blood smear and buffy-coat culture are ~50% and ~70%, respectively. PCR may be even more sensitive.

CUTANEOUS AND MUCOSAL LEISHMANIASIS

Aspirates and biopsy specimens of skin lesions and lymph nodes are useful for parasitologic confirmation of cutaneous and mucosal leishmaniasis by traditional and molecular methods. Parasitologic confirmation of mucosal leishmaniasis—a pauciparasitic syndrome—by traditional methods can be difficult. Serologic testing usually is not helpful for patients with cutaneous leishmaniasis; except in patients with DCL and some patients with mucosal leishmaniasis, antibody is either undetectable or present at low levels. In contrast, skin-test reactivity usually develops during active infection except in patients with DCL.

treatment is indicated, the parenterally administered pentavalent antimonial (Sb^V) compounds sodium stibogluconate and meglumine antimonate have been the mainstays of therapy for more than half a century. Manifestations of toxicity (e.g., body aches, malaise, elevated aminotransferase levels, chemical pancreatitis, and electrocardiographic abnormalities) are commonly noted but usually do not limit therapy and are reversible.

Conventional amphotericin B deoxycholate and pentamidine isethionate, the traditional parenteral alternatives to Sb^V, were previously relegated to second-line status, largely because of less experience with their use for the treatment of leishmaniasis and greater concern about their induction of potentially serious or irreversible toxicities (e.g., renal impairment). Amphotericin B, which has high-level, broad-spectrum antileishmanial activity, has been upgraded to first-line status in settings in which its benefits outweigh its risks (e.g., for Sb^V-resistant visceral leishmaniasis).

Lipid formulations of amphotericin B passively target the agent to macrophage-rich organs, resulting in less renal and other toxicity and permitting the use of higher daily doses and shorter courses of therapy. Targeting of drug to the reticuloendothelial system is ideal for visceral leishmaniasis but may not be advantageous for other syndromes. For amphotericin B and other antileishmanial agents, various delivery/targeting mechanisms and formulations are being explored.

Although some alternative therapies may have utility in particular settings, even data from well-conducted clinical trials cannot necessarily be generalized to other contexts. Of particular note, data from the many clinical trials of therapy for visceral leishmaniasis in foci in north-eastern India are not necessarily directly applicable to visceral leishmaniasis caused by *L. donovani* in other foci in southern Asia or elsewhere (e.g., eastern Africa) or to visceral infection caused by *L. infantum/chagasi*—let alone to other leishmanial syndromes.

Except for the development of resistance to Sb^V and pentamidine, Indian kala-azar typically is easier to treat than visceral leishmaniasis elsewhere: i.e., it is more responsive to therapy, even with lower total doses. Counterintuitively, visceral leishmaniasis often is easier to treat than cutaneous or mucosal leishmaniasis. Achieving adequate drug levels in the phagolysosomes of dermal and mucosal macrophages can be challenging, and the difficulty can be compounded by the fact that some dermatropic species are intrinsically less sensitive than *L. donovani* to particular drugs.

Some of these issues are exemplified by miltefosine, the first highly active oral agent for visceral leishmaniasis. Both experimental (in vitro) and clinical data indicate that *L. donovani* (the agent of Indian visceral leishmaniasis) is highly sensitive to miltefosine, whereas other species are variably responsive. In addition, the long half-life of the drug and suboptimal treatment predispose to the development of resistance. The most common side effects of therapy include gastrointestinal symptoms and reversible elevations in creatinine and aminotransferase levels. Miltefosine's teratogenicity in animals has

Rx Treatment: **LEISHMANIASIS**

PRINCIPLES AND PERSPECTIVE (Table 119-2)

Decisions about whether and how to treat leishmaniasis should be individualized. For cases in which systemic

TABLE 119-2

PARENTERAL AND ORAL DRUG REGIMENS FOR TREATMENT OF LEISHMANIASIS^a

| CLINICAL SYNDROME, DRUG | ROUTE OF ADMINISTRATION | REGIMEN |
|--|-------------------------|--|
| Visceral Leishmaniasis | | |
| Parenteral therapy | | |
| Pentavalent antimony ^b | IV, IM | 20 mg Sb ^V /kg qd for 28 days |
| Amphotericin B, lipid formulation ^c | IV | 2–5 mg/kg qd (total: usually ~15–21 mg/kg) |
| Amphotericin B (deoxycholate) | IV | 0.5–1 mg/kg qod or qd (total: usually ~15–20 mg/kg) |
| Paromomycin sulfate ^d | IV, IM | 15–20 mg/kg qd for ~21 days |
| Pentamidine isethionate | IV, IM | 4 mg/kg qod or thrice weekly for ~15–30 doses |
| Oral therapy | | |
| Miltefosine ^{d,e} | PO | 2.5 mg/kg qd for 28 days |
| Cutaneous Leishmaniasis | | |
| Parenteral therapy | | |
| Pentavalent antimony ^b | IV, IM | 20 mg Sb ^V /kg qd for 10–20 days (standard recommendation: 20 days) |
| Pentamidine isethionate | IV, IM | 2 mg/kg qod for 7 doses |
| Amphotericin B (deoxycholate) | IV | 0.5–1 mg/kg qod or qd (total: up to ~20 mg/kg) |
| Oral therapy | | |
| Fluconazole | PO | 200 mg qd for 6 weeks ^f |
| Ketoconazole | PO | 600 mg qd for 28 days ^f |
| Itraconazole | PO | 200 mg bid for 28 days ^f |
| Miltefosine ^{d,e} | PO | 2.5 mg/kg qd for 28 days |
| Mucosal Leishmaniasis | | |
| Pentavalent antimony ^b | IV, IM | 20 mg Sb ^V /kg qd for 28 days |
| Amphotericin B (deoxycholate) | IV | 1 mg/kg qod or qd (total: usually ~20–40 mg/kg) |
| Pentamidine isethionate | IV, IM | 2–4 mg/kg qod or thrice weekly for ≥15 doses |

^aSee text for additional details and perspective about the drugs and regimens in this table and about treatment of leishmaniasis in general. Some of the listed drugs are effective only against certain *Leishmania* species/strains and only in certain areas of the world. Classification of drugs/regimens in such categories as first-line, alternative, (in)effective, investigational, (un)available, and cost-prohibitive is highly dependent on the setting. Ranges shown for doses and durations of therapy reflect variability both in dosage regimens among clinical trials and in responsiveness in different settings. To maximize effectiveness and minimize toxicity, the listed regimens should be individualized according to the particularities of the case and in consultation with an expert. Children may need different dosage regimens. Except for liposomal amphotericin B (see footnote c), as of this writing, none of the drugs listed is licensed by the U.S. Food and Drug Administration (FDA) for the treatment of leishmaniasis per se.

^bThe Centers for Disease Control and Prevention (CDC) provides the pentavalent antimonial (Sb^V) compound sodium stibogluconate (Pentostam; Glaxo Operations UK Limited, Barnard Castle, United Kingdom; 100 mg Sb^V/mL) to U.S.-licensed physicians through the CDC Drug Service (404-639-3670) under an IND mechanism with the FDA. The other widely used Sb^V compound, meglumine antimonate (Glucantime; typically, ~85 mg Sb^V/mL), is available primarily in Spanish- and French-speaking areas of the world. Locally made (generic) Sb^V preparations may have different Sb^V concentrations and may vary in quality and safety.

^cThe lipid formulations of amphotericin B include liposomal amphotericin B and amphotericin B lipid complex. In 1997, the FDA approved the following regimen of liposomal amphotericin B for immunocompetent patients with visceral leishmaniasis: 3 mg/kg qd on days 1–5, 14, and 21, for a total of 21 mg/kg. For immunosuppressed patients, the approved regimen is 4 mg/kg qd on days 1–5, 10, 17, 24, 31, and 38, for a total of 40 mg/kg. Many alternative regimens have been proposed for immunocompetent patients in various regions of the world; the regimens vary with respect to total and daily doses, number of doses, and intervals between doses. See text for perspective on the use of lipid formulations of amphotericin B for treatment of cutaneous and mucosal leishmaniasis.

^dNot commercially available in the United States as of this writing.

^eMiltefosine, which is teratogenic in animals, should not be used to treat pregnant women. Women of child-bearing age should use effective birth control during treatment and for 2 months thereafter. See text regarding the treatment of mucosal leishmaniasis.

^fAdult dosage.

implications for its use in women of child-bearing age (Table 119-2).

VISCERAL LEISHMANIASIS The primary goal of treatment for visceral leishmaniasis is to prevent death. Highly effective antileishmanial therapy is essential, as is supportive care (e.g., therapy for malnutrition,

anemia, bleeding, and intercurrent infections). In most regions, Sb^V therapy remains highly effective. However, use of an alternative agent should be considered if high-level Sb^V resistance is prevalent or if non-Sb^V therapy is advantageous for other reasons (e.g., duration, cost, or tolerability). In general, most patients feel better and become afebrile during the first week of therapy;

resolution of splenomegaly and hematologic abnormalities may require weeks or months.

In northeastern India, districts of Bihar State north of the Ganges River constitute the epicenter of the epidemic of Sb^V resistance, which is spreading—to varying degrees—to contiguous areas of India and southern Nepal. Conventional amphotericin B has become first-line therapy where Sb^V and pentamidine are no longer effective. Lipid formulations of amphotericin B, which are cost-prohibitive where they are most needed, are increasingly being used in southern Europe.

The anthroponotic transmission of *L. donovani* in southern Asia is both a blessing and a curse: a blessing because treatment can serve as a control measure, and a curse because suboptimal treatment can and does lead to the development and dissemination of drug resistance and thereby to the elimination of drugs from the limited armamentarium and to the demise of patients who cannot afford or access the few alternatives. In this context, the oral agent miltefosine, which is registered for commercial use in India and some other countries, has great potential but also is highly vulnerable. The advent of oral therapy translates into unsupervised outpatient treatment, in which patients buy the quantity of drug they can afford and prematurely stop therapy when their supply is depleted or their symptoms are alleviated. Unless protective measures are implemented (e.g., with directly observed or multidrug therapy), drug resistance almost assuredly will develop and spread. The oral agent sitamaquine, an 8-amino-quinoline, is being field-tested in various regions but appears to have a narrow therapeutic window and can cause nephrotoxicity.

The aminoglycoside paromomycin (the chemical equivalent of aminosidine) is a candidate parenteral agent for use alone or in drug combinations. To date, the rates of response in field tests have been variable; response rates may be higher in India than in eastern Africa.

Patients who are co-infected with HIV may initially respond well to standard therapy but typically experience more toxicity. Antiretroviral therapy delays but does not prevent relapses. Consensus approaches to treatment and secondary prophylaxis have not been established.

CUTANEOUS LEISHMANIASIS Decisions about clinical management of cutaneous leishmaniasis should be based on consideration of goals (e.g., accelerating the healing of skin lesions, decreasing morbidity, decreasing risks for local and mucosal dissemination and relapse), parasite factors (e.g., tissue tropisms and drug sensitivities), and the extent to which the lesions are of concern or are bothersome because of their location (e.g., on the face or near joints), number, size, persistence, or other features (e.g., nodular lymphangitis). When optimal effectiveness is important, parenteral Sb^V therapy is generally recommended. The first sign of a clinical response typically is decreasing induration, and relapses usually are noted first at the margins of healed lesions.

Although clinical trials of conventional amphotericin B for cutaneous leishmaniasis have not been conducted and standard dosage regimens have not been established, this agent almost assuredly is highly and broadly effective, albeit potentially toxic. Conflicting, limited data are available for lipid formulations. Pentamidine was effective in Colombia [predominantly against *L. (V.) panamensis*] but not in Peru [against *L. (V.) braziliensis*].

The effectiveness of the oral agent miltefosine is species and strain dependent. For example, this drug has been effective against *L. (V.) panamensis* in Colombia but ineffective against *L. (V.) braziliensis* in Guatemala. At best, azoles have shown modest activity against particular species in isolated studies—e.g., ketoconazole and itraconazole against *L. mexicana* in Guatemala, ketoconazole against *L. (V.) panamensis* in Panama, and fluconazole against *L. major* in Saudi Arabia. Itraconazole has been ineffective against *L. (V.) panamensis* in Colombia.

Local therapy can be considered for some cases without demonstrable local dissemination or risk of mucosal dissemination (e.g., for relatively benign lesions caused by *L. mexicana* or *L. major*). Examples of approaches being used or evaluated in some settings include intralesional Sb^V, various formulations of paromomycin ointments, topical immunomodulators, thermotherapy, and cryotherapy.

MUCOSAL LEISHMANIASIS The traditional treatment options for mucosal leishmaniasis include Sb^V and conventional amphotericin B; conflicting, limited data are available for lipid formulations of the latter drug. The response rates approach those for cutaneous leishmaniasis if mucosal disease is detected and treated at early stages, whereas advanced disease may be unresponsive or relapse repeatedly. Oral miltefosine therapy shows promise, on the basis of a clinical trial in Bolivia. Adjunctive immunotherapy is being evaluated. Concomitant glucocorticoid therapy is indicated if respiratory compromise develops after initiation of therapy.

CHAPTER 120

TRYPANOSOMIASIS

Louis V. Kirchhoff

The genus *Trypanosoma* contains many species of protozoans. *Trypanosoma cruzi*, the cause of Chagas' disease in the Americas, and the two trypanosome subspecies that cause human African trypanosomiasis, *Trypanosoma brucei gambiense* and *T. brucei rhodesiense*, are the only members of the genus that cause disease in humans.

CHAGAS' DISEASE

DEFINITION

Chagas' disease, or American trypanosomiasis, is a zoonosis caused by the protozoan parasite *T. cruzi*. Acute Chagas' disease is usually a mild febrile illness that results from initial infection with the organism. After spontaneous resolution of the acute illness, most infected persons remain for life in the indeterminate phase of chronic Chagas' disease, which is characterized by subpatent parasitemia, easily detectable antibodies to *T. cruzi*, and an absence of symptoms. In a minority of chronically infected patients, cardiac and gastrointestinal lesions develop that can result in serious morbidity and even death.

LIFE CYCLE AND TRANSMISSION

T. cruzi is transmitted among its mammalian hosts by hematophagous triatomine insects, often called *reduviid bugs*. The insects become infected by sucking blood from animals or humans who have circulating parasites. Ingested organisms multiply in the gut of the triatomines, and infective forms are discharged with the feces at the time of subsequent blood meals. Transmission to a second vertebrate host occurs when breaks in the skin, mucous membranes, or conjunctivae become contaminated with bug feces that contain infective parasites. *T. cruzi* can also be transmitted by the transfusion of blood donated by infected persons, by organ transplantation, from mother to fetus, and in laboratory accidents.

PATHOLOGY

An indurated inflammatory lesion called a *chagoma* often appears at the parasites' portal of entry. Local histologic changes include the presence of parasites within leukocytes and cells of subcutaneous tissues and the development of interstitial edema, lymphocytic infiltration, and reactive hyperplasia of adjacent lymph nodes. After dissemination of the organisms through the lymphatics and

the bloodstream, muscles (including the myocardium) may become heavily parasitized (**Fig. 120-1**). The characteristic pseudocysts present in sections of infected tissues are intracellular aggregates of multiplying parasites.

In the minority of persons with chronic *T. cruzi* infections who develop related clinical manifestations, the heart is the organ most commonly affected. Changes include thinning of the ventricular walls, biventricular enlargement, apical aneurysms, and mural thrombi. Widespread lymphocytic infiltration, diffuse interstitial fibrosis, and atrophy of myocardial cells are often apparent, but parasites are difficult to find in myocardial tissue. Conduction-system involvement often affects the right branch and the left anterior branch of the bundle of His. In chronic Chagas' disease of the gastrointestinal tract (megadisease), the esophagus and colon may exhibit varying degrees of dilatation. On microscopic examination, focal inflammatory lesions with lymphocytic infiltration are seen, and the number of neurons in the myenteric plexus may be markedly reduced. Accumulating experimental evidence implicates the persistence of parasites and the accompanying chronic inflammation—rather than autoimmune mechanisms—as the basis for the pathology in patients with chronic *T. cruzi* infection.

FIGURE 120-1

Trypanosoma cruzi in the heart muscle of a child who died of acute Chagas' myocarditis. An infected myocyte containing several dozen *T. cruzi* amastigotes is in the center of the field (hematoxylin and eosin, $\times 900$).

T. cruzi is found only in the Americas. Wild and domestic mammals harboring *T. cruzi* and infected triatomines are found in spotty distributions from the southern United States to southern Argentina. Humans become involved in the cycle of transmission when infected vectors take up residence in the primitive wood, adobe, and stone houses common in much of Latin America. Thus human *T. cruzi* infection is a health problem primarily among the poor in rural areas of Mexico and Central and South America. Most new *T. cruzi* infections in rural settings occur in children, but the incidence is unknown because most cases go undiagnosed. Historically, transfusion-associated transmission of *T. cruzi* has been a serious public health problem in many endemic countries. However, with some notable exceptions, transmission by this route has been markedly reduced as effective programs for the screening of donated blood have been implemented. Several dozen patients with HIV and chronic *T. cruzi* infections who underwent acute recrudescence of the latter have been described. These patients generally presented with *T. cruzi* brain abscesses, a manifestation of the illness that does not occur in immunocompetent persons. Currently, it is estimated that 12 million people are chronically infected with *T. cruzi* and that 25,000 deaths due to the illness occur each year. Of chronically infected persons, 10–30% eventually develop symptomatic cardiac lesions or gastrointestinal disease. The resulting morbidity and mortality make Chagas' disease the most important parasitic disease burden in Latin America.

In recent years, the rate of *T. cruzi* transmission has decreased markedly in several endemic countries as a result of successful programs involving vector control, blood-bank screening, and education of at-risk populations. A major program begun in 1991 in the "southern cone" nations of South America (Uruguay, Paraguay, Bolivia, Brazil, Chile, and Argentina) has provided the framework for much of this progress. Uruguay and Chile were certified transmission-free in the late 1990s, and Brazil was declared free of transmission in 2006. Transmission has been reduced markedly in Argentina as well. Similar control programs have been initiated in the countries of northern South America and in the Central American nations.

Acute Chagas' disease is rare in the United States. Five cases of autochthonous transmission and five instances of transmission by blood transfusion have been reported. Moreover, *T. cruzi* was transmitted to five recipients of organs from three *T. cruzi*-infected donors. Two of these recipients became infected through cardiac transplants. Acute Chagas' disease has not been reported in tourists returning to the United States from Latin America, although two such instances have been reported in Europe. In contrast, the prevalence of chronic *T. cruzi* infections in the United States has increased considerably in recent years. Data from the 2000 census indicate that >12 million immigrants from Chagas'-endemic countries currently live in the United States, ~8 million of whom are Mexicans. The prevalence of *T. cruzi* infection in

Mexico is 0.5–1.0%, and most of the 4 million immigrants from Chagas'-endemic nations who are not Mexicans come from countries in which the prevalence of *T. cruzi* infection is greater than it is in Mexico. The total number of *T. cruzi*-infected persons living in the United States can be estimated reasonably to be 80,000–120,000. The number of instances of transfusion-associated transmission in this country is likely to be considerably greater than the number reported. Screening of the U.S. blood supply for evidence of *T. cruzi* infection has recently begun (see "Diagnosis" later in the chapter).

CLINICAL COURSE

The first signs of acute Chagas' disease develop at least 1 week after invasion by the parasites. When the organisms enter through a break in the skin, an indurated area of erythema and swelling (the chagoma), accompanied by local lymphadenopathy, may appear. *Romaña's sign*—the classic finding in acute Chagas' disease, which consists of unilateral painless edema of the palpebrae and periocular tissues—can result when the conjunctiva is the portal of entry (Fig. 120-2). These initial local signs may be followed by malaise, fever, anorexia, and edema of the face and lower extremities. A morbilliform rash may also appear. Generalized lymphadenopathy and hepatosplenomegaly may develop. Severe myocarditis develops rarely; most deaths in acute Chagas' disease are due to heart failure. Neurologic signs are not common, but meningoencephalitis occurs occasionally. The acute symptoms resolve spontaneously in virtually all patients, who then enter the asymptomatic or indeterminate phase of chronic *T. cruzi* infection.

FIGURE 120-2

Romaña's sign in an Argentinean patient with acute *T. cruzi* infection. (Courtesy of Dr. Humberto Lugones, Centro de Chagas, Santiago del Estero, Argentina; with permission.)

Symptomatic chronic Chagas' disease becomes apparent years or even decades after the initial infection. The heart is commonly involved, and symptoms are caused by rhythm disturbances, dilated cardiomyopathy, and thromboembolism. Right bundle-branch block is a common electrocardiographic abnormality, but other types of atrioventricular block, premature ventricular contractions, and tachy- and bradyarrhythmias occur frequently. Cardiomyopathy often results in right-sided or biventricular heart failure. Embolization of mural thrombi to the brain or other areas may take place. Patients with megaesophagus suffer from dysphagia, odynophagia, chest pain, and regurgitation. Aspiration can occur (especially during sleep) in patients with severe esophageal dysfunction, and repeated episodes of aspiration pneumonitis are common. Weight loss, cachexia, and pulmonary infection can result in death. Patients with megacolon are plagued by abdominal pain and chronic constipation, and advanced megacolon can cause obstruction, volvulus, septicemia, and death.

DIAGNOSIS

The diagnosis of acute Chagas' disease requires the detection of parasites. Microscopic examination of fresh anticoagulated blood or of the buffy coat is the simplest way to see the motile organisms. Parasites also can be seen in Giemsa-stained thin and thick blood smears. Microhematocrit tubes containing acridine orange as a stain can be used for the same purpose. When repeated attempts to visualize the organisms are unsuccessful, polymerase chain reaction (PCR) or hemoculture in special media can be performed. When used by experienced personnel, all of these methods yield positive results in a high proportion of cases of acute Chagas' disease. Hemoculture has the disadvantage of taking several weeks to give positive results. Serologic testing plays no role in diagnosing acute Chagas' disease.

Chronic Chagas' disease is diagnosed by the detection of specific antibodies that bind to *T. cruzi* antigens. Demonstration of the parasite is not of primary importance. In Latin America, ~20 assays are commercially available, including several based on recombinant antigens. Unfortunately, these tests have varying levels of sensitivity and specificity, and false-positive reactions are a particular problem—typically with samples from patients who have other infectious and parasitic diseases or autoimmune disorders. In addition, confirmatory testing has presented a persistent challenge. For these reasons, it is generally recommended that specimens be tested in at least two assays and that well-characterized positive and negative comparison samples be included in each run. The radioimmune precipitation assay (Chagas' RIPA) is a highly sensitive and specific confirmatory method for detecting antibodies to *T. cruzi* [approved under the Clinical Laboratory Improvement Amendment (CLIA) and available in the author's laboratory]. In December 2006, the U.S. Food and Drug Administration (FDA) approved a test to screen blood and organ donors for *T. cruzi* infection (Ortho *T. cruzi* ELISA Test System, Ortho-Clinical Diagnostics, Raritan, NJ). In late

January 2007, the American Red Cross and Blood Systems, Inc.—blood-collection agencies that together account for ~65% of the U.S. blood supply—initiated screening of all the donations they process for *T. cruzi*. The Chagas' RIPA is being used as the confirmatory assay. Data generated during the first 2 months of screening suggest that if 65% of the blood supply continues to be tested, ~1500 Ortho-reactive donors will be identified annually, ~350 of whom will be RIPA-positive; these figures reflect an overall prevalence of ~1 in 30,000 donors. The use of PCR assays to detect *T. cruzi* DNA in chronically infected persons has been studied extensively. The sensitivity of this approach has not been shown to be reliably greater than that of serology, and no PCR assays are commercially available.

Rx Treatment: CHAGAS' DISEASE

Therapy for Chagas' disease is unsatisfactory. For many years, only two drugs—nifurtimox and benznidazole—have been available for this purpose. Unfortunately, both drugs lack efficacy and often cause severe side effects.

In acute Chagas' disease, nifurtimox markedly reduces the duration of symptoms and parasitemia and decreases the mortality rate. Nevertheless, limited studies have shown that only ~70% of acute infections are cured parasitologically by a full course of treatment. Despite its limitations, treatment with nifurtimox should be initiated as early as possible in acute Chagas' disease. Common adverse effects of nifurtimox include abdominal pain, anorexia, nausea, vomiting, and weight loss. Neurologic reactions to the drug may include restlessness, disorientation, insomnia, twitching, paresthesia, polyneuritis, and seizures. These symptoms usually disappear when the dosage is reduced or treatment is discontinued. The recommended daily dosage is 8–10 mg/kg for adults, 12.5–15 mg/kg for adolescents, and 15–20 mg/kg for children 1–10 years of age. The drug should be given orally in four divided doses each day, and therapy should be continued for 90–120 days. Nifurtimox is available from the Drug Service of the Centers for Disease Control and Prevention (CDC) in Atlanta (telephone number, 770-639-3670).

The efficacy of benznidazole is similar to that of nifurtimox; a cure rate of 90% among congenitally infected infants treated before their first birthday has been reported. Adverse effects include peripheral neuropathy, rash, and granulocytopenia. The recommended oral dosage is 5 mg/kg per day for 60 days. Benznidazole is generally considered the drug of choice in Latin America.

The question of whether patients in the indeterminate or chronic symptomatic phase of Chagas' disease should be treated with nifurtimox or benznidazole has been debated for years. The fact that parasitologic cure rates in chronically infected persons may be <10% is central to this controversy. There is no convincing evidence from properly controlled trials that treatment of adults with long-standing *T. cruzi* infections with either

of the drugs is beneficial. The current consensus of Latin American authorities is that all *T. cruzi*-infected persons up to 18 years old should be given benznidazole or nifurtimox.

The usefulness of allopurinol, fluconazole, and itraconazole for the treatment of acute Chagas' disease has been studied in laboratory animals and to a lesser extent in humans. None of these drugs has exhibited a level of anti-*T. cruzi* activity that warrants its use in patients. Several newer antifungal azoles have shown promise in animal studies but have not yet been tested in humans.

Patients who develop cardiac and/or gastrointestinal disease in association with *T. cruzi* infection should be referred to appropriate subspecialists for further evaluation and treatment. Cardiac transplantation is an option for patients with end-stage chagasic cardiopathies, and >100 such transplantations have been done in Brazil and the United States. The survival rate among Chagas' disease cardiac transplant recipients is higher than that among persons receiving cardiac transplants for other reasons. This better outcome may be due to the fact that lesions are limited to the heart in most patients with symptomatic chronic Chagas' disease.

PREVENTION

Since drug therapy is unsatisfactory and vaccines are not available, the control of *T. cruzi* transmission in endemic countries must depend on reduction of domiciliary vector populations by spraying of insecticides, improvements in housing, and education of at-risk persons. As noted above, these measures, coupled with serologic screening of blood donors, have markedly reduced transmission of the parasite in many endemic countries. Tourists would be wise to avoid sleeping in dilapidated houses in rural areas of endemic countries. Mosquito nets and insect repellent provide additional protection.

In view of the possibly serious consequences of chronic *T. cruzi* infection, it would be prudent for all immigrants from endemic regions living in the United States to be tested for evidence of infection. Identification of persons harboring the parasite would permit periodic electrocardiographic monitoring, which can be important because pacemakers benefit some patients who develop ominous rhythm disturbances. The possibility of congenital transmission is yet another justification for screening. Guidance for the evaluation and long-term monitoring of *T. cruzi*-infected persons is being developed by staff at the CDC.

Laboratory personnel should wear gloves and eye protection when working with *T. cruzi* and infected vectors.

SLEEPING SICKNESS

DEFINITION

Sleeping sickness, or human African trypanosomiasis (HAT), is caused by flagellated protozoan parasites that belong to the *T. brucei* complex and are transmitted to

humans by tsetse flies. In untreated patients, the trypanosomes first cause a febrile illness that is followed months or years later by progressive neurologic impairment and death.

THE PARASITES AND THEIR TRANSMISSION

The East African (*rhodesiense*) and the West African (*gambiense*) forms of sleeping sickness are caused, respectively, by two trypanosome subspecies: *T. brucei rhodesiense* and *T. brucei gambiense*. These subspecies are morphologically indistinguishable but cause illnesses that are epidemiologically and clinically distinct (Table 120-1). The parasites are transmitted by blood-sucking tsetse flies of the genus *Glossina*. The insects acquire the infection when they ingest blood from infected mammalian hosts. After many cycles of multiplication in the midgut of the vector, the parasites migrate to the salivary glands. Their transmission takes place when they are inoculated into a mammalian host during a subsequent blood meal. The injected trypanosomes multiply in the blood (Fig. 120-3) and other extracellular spaces and evade immune destruction for long periods by undergoing antigenic variation, a process driven by gene switching in which the antigenic structure of the organisms' surface coat of glycoproteins changes periodically.

PATHOGENESIS AND PATHOLOGY

A self-limited inflammatory lesion (trypanosomal chancre) may appear a week or so after the bite of an infected

TABLE 120-1
COMPARISON OF WEST AFRICAN AND EAST AFRICAN TRYPANOSOMIASIS

| POINT OF COMPARISON | WEST AFRICAN (GAMBIENSE) | EAST AFRICAN (RHODESIENSE) |
|---------------------------------|-------------------------------|--|
| Organism | <i>T. b. gambiense</i> | <i>T. b. rhodesiense</i> |
| Vectors | Tsetse flies (palpalis group) | Tsetse flies (morsitans group) |
| Primary reservoir | Humans | Antelope and cattle |
| Human illness | Chronic (late CNS disease) | Acute (early CNS disease) |
| Duration of illness | Months to years | <9 months |
| Lymphadenopathy | Prominent | Minimal |
| Parasitemia | Low | High |
| Diagnosis by rodent inoculation | No | Yes |
| Epidemiology | Rural populations | Workers in wild areas, rural populations, tourists in game parks |

tsetse fly. A systemic febrile illness then evolves as the parasites are disseminated through the lymphatics and bloodstream. Systemic HAT without central nervous system (CNS) involvement is generally referred to as *stage I disease*. In this stage, widespread lymphadenopathy and splenomegaly reflect marked lymphocytic and histiocytic proliferation and invasion of morular cells, which are plasmacytes that may be involved in the production of IgM. Enderteritis, with perivascular infiltration of both parasites and lymphocytes, may develop in lymph nodes and the spleen. Myocarditis develops frequently in patients with stage I disease and is especially common in *T. b. rhodesiense* infections.

Hematologic manifestations that accompany stage I HAT include moderate leukocytosis, thrombocytopenia, and anemia. High levels of immunoglobulins, consisting primarily of polyclonal IgM, are a constant feature, and heterophile antibodies, antibodies to DNA, and rheumatoid factor are often detected. High levels of antigen-antibody complexes may play a role in the tissue damage and increased vascular permeability that facilitate dissemination of the parasites.

Stage II disease involves invasion of the CNS. The presence of trypanosomes in perivascular areas is accompanied by intense infiltration of mononuclear cells. Abnormalities in cerebrospinal fluid (CSF) include increased pressure, elevated total protein concentration, and pleocytosis. In addition, trypanosomes are frequently found in CSF.

EPIDEMIOLOGY

The trypanosomes that cause sleeping sickness are found only in Africa. Approximately 50 million persons are at risk of acquiring HAT, and tens of thousands of new cases occur every year. Precise data are not available because health statistics are often incomplete in the developing countries where HAT is endemic.

Sleeping sickness has undergone a resurgence in recent years, with major epidemics in the Sudan, Ivory Coast, Chad, the Central African Republic, and several other endemic countries.

Humans are the only reservoir of *T. b. gambiense*, which occurs in widely distributed foci in tropical rain forests of Central and West Africa. *Gambiense* trypanosomiasis is primarily a problem in rural populations; tourists rarely become infected. Trypanotolerant antelope species in savanna and woodland areas of Central and East Africa are the principal reservoir of *T. b. rhodesiense*. Cattle can also be infected with this and other trypanosome species but generally succumb to the infection. Since risk results for the most part from contact with tsetse flies that feed on wild animals, humans acquire *T. b. rhodesiense* infection only incidentally, usually while visiting or working in areas where infected game and vectors are present. Roughly one or two patients with HAT acquired in East African game parks (and typically caused by *T. b. rhodesiense*) are reported to the CDC each year.

CLINICAL COURSE

A painful trypanosomal chancre appears in some patients at the site of inoculation of the parasite. Hematogenous and lymphatic dissemination (stage I disease) is marked by the onset of fever. Typically, bouts of high temperatures lasting several days are separated by afebrile periods. Lymphadenopathy is prominent in *T. b. gambiense* trypanosomiasis. The nodes are discrete, movable, rubbery, and nontender. Cervical nodes are often visible, and enlargement of the nodes of the posterior cervical triangle, or *Winterbottom's sign*, is a classic finding. Pruritus and maculopapular rashes are common. Inconstant findings include malaise, headache, arthralgias, weight loss, edema, hepatosplenomegaly, and tachycardia. The differential diagnosis of stage I HAT includes many diseases that are common in the tropics and are associated with fevers. HIV infection, malaria, and typhoid fever are common in populations at risk for HAT and need to be considered.

CNS invasion (stage II disease) is characterized by the insidious development of protean neurologic manifestations that are accompanied by progressive abnormalities in the CSF. A picture of progressive indifference and daytime somnolence develops (hence the designation "sleeping sickness"), sometimes alternating with restlessness and insomnia at night. A listless gaze accompanies a loss of spontaneity, and speech may become halting and indistinct. Extraparallel signs may include choreiform movements, tremors, and fasciculations. Ataxia is frequent, and the patient may appear to have Parkinson's disease, with a shuffling gait, hypertonia, and tremors. In the final phase, progressive neurologic impairment ends in coma and death.

The most striking difference between the West African and East African trypanosomiasis is that the latter illness tends to follow a more acute course. Typically, in tourists with *T. b. rhodesiense* disease, systemic signs of infection, such as fever, malaise, and headache, appear

1116 before the end of the trip or shortly after the return home. Persistent tachycardia unrelated to fever is common early in the course of *T. b. rhodesiense* trypanosomiasis, and death may result from arrhythmias and congestive heart failure before CNS disease develops. In general, untreated *T. b. rhodesiense* trypanosomiasis leads to death in a matter of weeks to months, often without a clear distinction between the hemolymphatic and CNS stages. In contrast, *T. b. gambiense* disease can smolder for many months or even for years.

DIAGNOSIS

A definitive diagnosis of HAT requires detection of the parasite. If a chancre is present, fluid should be expressed and examined directly by light microscopy for the highly motile trypanosomes. The fluid also should be fixed and stained with Giemsa. Material obtained by needle aspiration of lymph nodes early in the illness should be examined similarly. Examination of wet preparations and Giemsa-stained thin and thick films of serial blood samples is also useful. If parasites are not seen initially in blood, efforts should be made to concentrate the organisms; the simplest method involves the use of microhematocrit tubes containing acridine orange. In these tubes the parasites are separated from blood cells by centrifugation and are easily seen under light microscopy because of the stain. Alternatively, the buffy coat from 10–15 mL of anticoagulated blood can be examined directly under a microscope. The likelihood of finding parasites in blood is higher in stage I than in stage II disease and in patients infected with *T. b. rhodesiense* rather than *T. b. gambiense*. Trypanosomes may also be seen in material aspirated from the bone marrow; the aspirate can be inoculated into liquid culture medium, as can blood, buffy coat, lymph node aspirates, and CSF. Finally, *T. b. rhodesiense* infection can be detected by inoculation of these specimens into mice or rats, which—when positive—results in patent parasitemias in a week or two. Although this method is highly sensitive for the detection of *T. b. rhodesiense*, it does not detect *T. b. gambiense* because of host specificity.

It is essential to examine CSF from all patients in whom HAT is suspected. Abnormalities in the CSF that may be associated with stage II disease include an increase in the CSF mononuclear cell count as well as increases in opening pressure and in levels of total protein and IgM. Trypanosomes may be seen in the sediment of centrifuged CSF. Any CSF abnormality in a patient in whom trypanosomes have been found at other sites must be viewed as pathognomonic for CNS involvement and thus must prompt specific treatment for CNS disease. In patients with CSF pleocytosis in whom parasites are not found, tuberculous meningitis and HIV-associated CNS infections such as cryptococcosis should be considered in the differential diagnosis.

A number of serologic assays are available to aid in the diagnosis of HAT, but their variable sensitivity and specificity mandate that decisions about treatment be based on demonstration of the parasite. These tests are of

value for epidemiologic surveys. PCR assays for detecting African trypanosomes in humans have been developed, but none is commercially available.

Rx Treatment:
SLEEPING SICKNESS

The drugs used for treatment of HAT are suramin, pentamidine, eflornithine, and the organic arsenical melarsoprol. In the United States these drugs can be obtained from the CDC. Therapy for HAT must be individualized on the basis of the infecting subspecies, the presence or absence of CNS disease, adverse reactions, and occasionally drug resistance. The choices of drugs for the treatment of HAT are summarized in Table 120-2.

Suramin is highly effective against stage I East African disease. However, it can cause serious adverse effects and must be administered under the close supervision of a physician. A 100- to 200-mg IV test dose should be given to detect hypersensitivity. The dosage for adults is 20 mg/kg on days 1, 5, 12, 18, and 26. The drug is given by slow IV infusion of a freshly prepared 10% aqueous solution. Approximately 1 patient in 20,000 has an immediate, severe, and potentially fatal reaction to the drug, developing nausea, vomiting, shock, and seizures. Less severe reactions include fever, photophobia, pruritus, arthralgias, and skin eruptions. Renal damage is the most common important adverse effect of suramin. Transient proteinuria often appears during treatment. A urinalysis should be done before each dose, and treatment should be discontinued if proteinuria increases or if casts and red cells appear in the sediment. Suramin should not be given to patients with renal insufficiency.

Eflornithine is highly effective for treatment of both stages of West African trypanosomiasis. In the trials on which the FDA based its approval, this agent cured >90% of 600 patients with stage II disease. The recommended treatment schedule is 400 mg/kg per day, given intravenously in four divided doses, for 2 weeks. Adverse reactions include diarrhea, anemia, thrombocytopenia, seizures, and hearing loss. The high dosage and duration

of therapy required are disadvantages that make widespread use of eflornithine difficult.

Pentamidine is the first-line drug for patients with stage I West African HAT. The dose for both adults and children is 4 mg/kg per day, given intramuscularly or intravenously, for 10 days. Frequent, immediate adverse reactions include nausea, vomiting, tachycardia, and hypotension. These reactions are usually transient and do not warrant cessation of therapy. Other adverse reactions include nephrotoxicity, abnormal liver function tests, neutropenia, rashes, hypoglycemia, and sterile abscesses.

The arsenical melarsoprol is the drug of choice for the treatment of East African trypanosomiasis with CNS involvement and is an alternative agent for stage II West African disease. Melarsoprol cures both stages of the disease and therefore is also indicated for the treatment of stage I disease in patients who fail to respond to or cannot tolerate suramin or pentamidine. However, because of its relatively high toxicity, melarsoprol is never the first choice for the treatment of stage I disease. For East African disease, the drug should be given to adults in three courses of 3 days each. The dosage is 2–3.6 mg/kg per day, given intravenously in three divided doses for 3 days, followed 1 week later by 3.6 mg/kg per day, also in three divided doses and for 3 days. The latter course is repeated 7 days later. In debilitated patients, suramin is administered for 2–4 days before therapy with melarsoprol is initiated; an 18-mg initial dose of the latter drug, followed by progressive increases to the standard dose, has been recommended. For children, a total of 18–25 mg/kg should be given over 1 month. An IV starting dose of 0.36 mg/kg should be increased gradually to a maximum of 3.6 mg/kg at 1- to 5-day intervals, for a total of 9 or 10 doses. The regimen for West African disease is 2.2 mg/kg per day, given intravenously for 10 days.

Melarsoprol is highly toxic and should be administered with great care. To reduce the likelihood of drug-induced encephalopathy, all patients receiving melarsoprol should be given prednisolone at a dose of 1 mg/kg (up to 40 mg) per day, beginning 1–2 days before the first dose of melarsoprol and continuing through the last dose. Without prednisolone prophylaxis, the incidence of reactive encephalopathy has been reported to be as high as 18% in some series. Clinical manifestations of reactive encephalopathy include high fever, headache, tremor, impaired speech, seizures, and even coma and death. Treatment with melarsoprol should be discontinued at the first sign of encephalopathy but

may be restarted cautiously at lower doses a few days after signs have resolved. Extravasation of the drug results in intense local reactions. Vomiting, abdominal pain, nephrotoxicity, and myocardial damage can occur.

PREVENTION

HAT poses complex public-health and epizootic problems in Africa. Considerable progress has been made in some areas through control programs that focus on eradication of vectors and drug treatment of infected humans; however, there is no consensus on the best approach to solving the overall problem, and major epidemics continue to occur. Individuals can reduce their risk of acquiring trypanosomiasis by avoiding areas known to harbor infected insects, by wearing protective clothing, and by using insect repellent. Chemoprophylaxis is not recommended, and no vaccine is available to prevent transmission of the parasites.

CHAPTER 121

TOXOPLASMA INFECTIONS

Lloyd H. Kasper

DEFINITION

Toxoplasmosis is caused by infection with the obligate intracellular parasite *Toxoplasma gondii*. Acute infection acquired after birth may be asymptomatic but frequently results in the chronic persistence of cysts in the host's tissues. In both acute and chronic toxoplasmosis, the parasite is responsible for clinically evident disease, including lymphadenopathy, encephalitis, myocarditis, and pneumonitis. Congenital toxoplasmosis is an infection of newborns that results from the transplacental passage of parasites from an infected mother to the fetus. These infants usually are asymptomatic at birth but later manifest a wide range of signs and symptoms, including chorioretinitis, strabismus, epilepsy, and psychomotor retardation.

ETIOLOGY

T. gondii is an intracellular coccidian that infects both birds and mammals. There are two distinct stages in the life cycle of *T. gondii* (Fig. 121-1). In the *nonfeline* stage, tissue cysts that contain bradyzoites or sporulated oocysts are ingested by an intermediate host (e.g., a human, mouse, sheep, pig, or bird). The cyst is rapidly digested by the acidic-pH gastric secretions. Bradyzoites or sporozoites are released, enter the small-intestinal epithelium, and transform into rapidly dividing tachyzoites. The tachyzoites can infect and replicate in all mammalian cells except red blood cells. Once attached to the host cell, the parasite penetrates the cell and forms a parasitophorous vacuole within which it divides. Parasite replication continues until the number of parasites

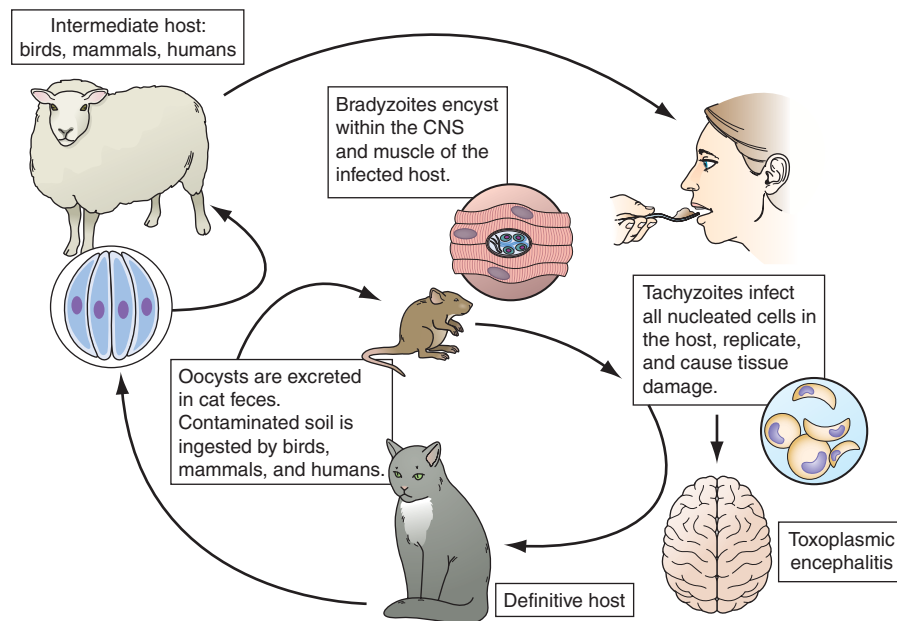

FIGURE 121-1

Life cycle of *Toxoplasma gondii*. The cat is the definitive host in which the sexual phase of the cycle is completed. Oocysts shed in cat feces can infect a wide range of animals, including birds, rodents, grazing domestic animals, and humans. The bradyzoites found in the muscle of food animals may infect humans who eat insufficiently cooked

meat products, particularly lamb and pork. Although human disease can take many forms, congenital infection and encephalitis from reactivation of latent infection in the brains of immunosuppressed persons are the most important manifestations. CNS, central nervous system. (Courtesy of Dominique Buzoni-Gatel, Institut Pasteur, Paris; with permission.)

within the cell approaches a critical mass and the cell ruptures, releasing parasites that infect adjoining cells.

As a result of this process, an infected organ soon shows evidence of cytopathology. Most tachyzoites are eliminated by the host's humoral and cell-mediated immune responses. Tissue cysts containing many bradyzoites develop 7–10 days after systemic tachyzoite infection. These tissue cysts occur in various host organs but persist principally within the central nervous system (CNS) and muscle. The development of this chronic stage completes the nonfeline portion of the life cycle. Active infection in the immunocompromised host is most likely to be due to the spontaneous release of encysted parasites that undergo rapid transformation into tachyzoites within the CNS.

The principal (*feline*) stage in the life cycle takes place in the cat (the definitive host) and its prey. The parasite's sexual phase is defined by the formation of oocysts within the feline host. This enteroepithelial cycle begins with the ingestion of the bradyzoite tissue cysts and culminates (after several intermediate stages) in the production of gametes. Gamete fusion produces a zygote, which envelops itself in a rigid wall and is secreted in the feces as an unsporulated oocyst. After 2–3 days of exposure to air at ambient temperature, the noninfectious oocyst sporulates to produce eight sporozoite progeny. The sporulated oocyst can be ingested by an intermediate host, such as a person emptying a cat's litter box or a pig rummaging in a barnyard. It is in the intermediate host that *T. gondii* completes its life cycle.

EPIDEMIOLOGY

T. gondii infects a wide range of mammals and birds. Its seroprevalence depends on the locale and the age of the population. Generally, hot arid climatic conditions are associated with a low prevalence of infection. In the United States and most European countries, the seroprevalence increases with age and exposure. For example, in the United States, 5–30% of individuals 10–19 years old and 10–67% of those >50 years old have serologic evidence of exposure; seroprevalence increases by ~1% per year. In Central America, France, Turkey, and Brazil, the seroprevalence is higher. There may be as many as 2100 cases of toxoplasmic encephalitis (TE) each year in the United States.

TRANSMISSION

Oral Transmission

The principal source of human *Toxoplasma* infection remains uncertain. Transmission usually takes place by the oral route and can be attributable to ingestion of either sporulated oocysts from contaminated soil or bradyzoites from undercooked meat. During acute feline infection, a cat may excrete as many as 100 million parasites per day. These very stable sporozoite-containing oocysts are highly infectious and may remain viable for many years in the soil. Humans infected during a well-documented outbreak of oocyst-transmitted infection develop stage-specific antibodies to the oocyst/sporozoite.

Children and adults also can acquire infection from tissue cysts containing bradyzoites. The ingestion of a single cyst is all that is required for human infection. Undercooking or insufficient freezing of meat is an important source of infection in the developed world. In the United States, 10–20% of lamb products and 25–35% of pork products show evidence of cysts that contain bradyzoites. The incidence in beef is much lower—perhaps as low as 1%. Direct ingestion of bradyzoite cysts in these various meat products leads to acute infection.

Transmission via Blood or Organs

In addition to oral transmission, direct transmission of the parasite by blood or organ products during transplantation takes place at a low rate. Viable parasites can be cultured from refrigerated anticoagulated blood, which may be a source of infection in individuals receiving blood transfusions. *T. gondii* infection also has been reported in kidney and heart transplant recipients who were uninfected before transplantation.

Transplacental Transmission

About one-third of all women who acquire infection with *T. gondii* during pregnancy transmit the parasite to the fetus; the remainder give birth to normal, uninfected babies. Of the various factors that influence fetal outcome, gestational age at the time of infection is the most critical (see below). Few data support a role for recrudescent maternal infection as the source of congenital disease. Thus, women who are seropositive before pregnancy usually are protected against acute infection and do not give birth to congenitally infected neonates.

The following general guidelines can be used to evaluate congenital infection. There is essentially no risk if the mother becomes infected ≥ 6 months before conception. If infection is acquired <6 months before conception, the likelihood of transplacental infection increases as the interval between infection and conception decreases. In pregnancy, if the mother becomes infected during the first trimester, the incidence of transplacental infection is lowest (~15%), but the disease in the neonate is most severe. If maternal infection occurs during the third trimester, the incidence of transplacental infection is greatest (65%), but the infant is usually asymptomatic at birth. Infected infants who are normal at birth may have a higher incidence of learning disabilities and chronic neurologic sequelae than uninfected children. Only a small proportion (20%) of women infected with *T. gondii* develop clinical signs of infection. Often the diagnosis is first appreciated when routine postconception serologic tests show evidence of specific antibody.

PATHOGENESIS

Upon the host's ingestion of either tissue cysts containing bradyzoites or oocysts containing sporozoites, the parasites are released from the cysts by a digestive process. Bradyzoites are resistant to the effect of pepsin and invade the host's gastrointestinal tract. Within enterocytes (or other gut-associated cells), the parasites undergo

morphologic transformation, giving rise to invasive tachyzoites. These tachyzoites induce a parasite-specific secretory IgA response. From the gastrointestinal tract, parasites are disseminated to a variety of organs, particularly lymphatic tissue, skeletal muscle, myocardium, retina, placenta, and the CNS. At these sites, the parasite infects host cells, replicates, and invades the adjoining cells. In this fashion, the hallmarks of the infection develop: cell death and focal necrosis surrounded by an acute inflammatory response.

In the immunocompetent host, both the humoral and the cellular immune responses control infection; parasite virulence and tissue tropism may be strain specific. Tachyzoites are sequestered by a variety of immune mechanisms, including induction of parasitocidal antibody, activation of macrophages with radical intermediates, production of interferon γ (IFN- γ), and stimulation of cytotoxic T lymphocytes of the CD8+ phenotype. These antigen-specific lymphocytes are capable of killing both extracellular parasites and target cells infected with parasites. As tachyzoites are cleared from the acutely infected host, tissue cysts containing bradyzoites begin to appear, usually within the CNS and the retina. In the immunocompromised or fetal host, the immune factors necessary to control the spread of tachyzoite infection are lacking. This altered immune state allows the persistence of tachyzoites and gives rise to progressive focal destruction that results in organ failure (i.e., necrotizing encephalitis, pneumonia, and myocarditis).

Persistence of infection with cysts containing bradyzoites is common in the immunocompetent host. This lifelong infection usually remains subclinical. Although bradyzoites are in a slow metabolic phase, cysts do degenerate and rupture within the CNS. This degenerative process, with the development of new bradyzoite-containing cysts, is the most probable source of recrudescent infection in immunocompromised individuals and the most likely stimulus for the persistence of antibody titers in the immunocompetent host.

PATHOLOGY

Cell death and focal necrosis due to replicating tachyzoites induce an intense mononuclear inflammatory response in any tissue or cell type infected. Tachyzoites rarely can be visualized by routine histopathologic staining of these inflammatory lesions. However, immunofluorescent staining with parasitic antigen-specific antibodies can reveal either the organism itself or evidence of antigen. In contrast to this inflammatory process caused by tachyzoites, bradyzoite-containing cysts cause inflammation only at the early stages of development, and even this inflammation may be a response to the presence of tachyzoite antigens. Once the cysts reach maturity, the inflammatory process can no longer be detected, and the cysts remain immunologically quiescent within the brain matrix until they rupture.

Lymph Nodes

During acute infection, lymph node biopsy demonstrates characteristic findings, including follicular hyperplasia and

irregular clusters of tissue macrophages with eosinophilic cytoplasm. Granulomas rarely are evident in these specimens. Although tachyzoites are not usually visible, they can be sought either by subinoculation of infected tissue into mice, with resultant disease, or by polymerase chain reaction (PCR). PCR amplification of DNA fragments representing either p30 (SAG-1) or p22 (SAG-2) surface antigen or B1 antigen is an effective and sensitive assay for establishing lymph node infection by tachyzoites.

Eyes

In the eye, infiltrates of monocytes, lymphocytes, and plasma cells may produce uni- or multifocal lesions. Granulomatous lesions and chorioretinitis can be observed in the posterior chamber after acute necrotizing retinitis. Other ocular complications include iridocyclitis, cataracts, and glaucoma.

Central Nervous System

During CNS involvement, both focal and diffuse meningoencephalitis can be documented, with evidence of necrosis and microglial nodules. Necrotizing encephalitis in patients without AIDS is characterized by small diffuse lesions with perivascular cuffing in contiguous areas. In the AIDS population, polymorphonuclear leukocytes may be present in addition to monocytes, lymphocytes, and plasma cells. Cysts containing bradyzoites frequently are found contiguous with the necrotic tissue border. As stated previously, it is estimated that there are as many as 2100 cases of TE in the United States each year.

Lungs and Heart

Among patients with AIDS who die of toxoplasmosis, 40–70% have involvement of the lungs and heart. Interstitial pneumonitis can develop in neonates and immunocompromised patients. Thickened and edematous alveolar septa infiltrated with mononuclear and plasma cells are apparent. This inflammation may extend to the endothelial walls. Tachyzoites and bradyzoite-containing cysts have been observed within the alveolar membrane. Superimposed bronchopneumonia can be caused by other microbial agents. Cysts and aggregates of parasites in cardiac muscle tissue are evident in patients with AIDS who die of toxoplasmosis. Focal necrosis surrounded by inflammatory cells is associated with hyaline necrosis and disrupted myocardial cells. Pericarditis is associated with toxoplasmosis in some patients.

Gastrointestinal Tract

Acute infection in certain strains of inbred mice (B6) results in lethal ileitis within 7–9 days. This inflammatory bowel disease has been recognized in several mammalian species, including pigs and nonhuman primates. The association between human inflammatory bowel disease and either acute or recurrent *Toxoplasma* infection has not been established.

Other Sites

Pathologic changes during disseminated infection are similar to those described for the lymph nodes, eyes, and CNS. In patients with AIDS, the skeletal muscle, pancreas, stomach, and kidneys can be involved, with necrosis, invasion by inflammatory cells, and (rarely) tachyzoites detectable by routine staining. Large necrotic lesions may cause direct tissue destruction. In addition, secondary effects from acute infection of these various organs, including pancreatitis, myositis, and glomerulonephritis, have been reported.

HOST IMMUNE RESPONSE

Acute *Toxoplasma* infection evokes a cascade of protective immune responses in the immunocompetent host. *Toxoplasma* enters the host at the gut mucosal level and evokes a mucosal immune response that includes the production of antigen-specific secretory IgA. Titers of serum IgA antibody directed at p30 (SAG-1) are a useful marker for congenital and acute toxoplasmosis. Milk-whey IgA from acutely infected mothers contains a high titer of antibody to *T. gondii* and can block infection of enterocytes in vitro. In mice, IgA intestinal secretions directed at the parasite are abundant and are associated with the induction of mucosal T cells.

Within the host, *T. gondii* rapidly induces detectable levels of both IgM and IgG serum antibodies. Monoclonal gammopathy of the IgG class can occur in congenitally infected infants. IgM levels may be increased in newborns with congenital infection. The polyclonal IgG antibodies evoked by infection are parasitocidal in vitro in the presence of serum complement and are the basis for the Sabin-Feldman dye test. However, cell-mediated immunity is the major protective response evoked by the parasite during host infection. Macrophages are activated after phagocytosis of antibody-opsonized parasites. This activation can lead to death of the parasite by either an oxygen-dependent or an oxygen-independent process. If the parasite is not phagocytosed and enters the macrophage by active penetration, it continues to replicate, and this replication may represent the mechanism for transport and dissemination to distant organs. *Toxoplasma* stimulates a robust interleukin (IL) 12 response by human dendritic cells. The requirement for costimulation via CD40/154 has been established. The CD4+ and CD8+ T-cell responses are antigen-specific and further stimulate the production of a variety of important lymphokines that expand the T-cell and natural killer cell repertoire. *T. gondii* is a potent inducer of a T_H1 phenotype, with IL-12 and IFN- γ playing an essential role in the control of the parasites' growth in the host. Regulation of the inflammatory response is at least partially under the control of a T_H2 response that includes the production of IL-4 and IL-10 in seropositive individuals. Both asymptomatic patients and those with active infection may have a depressed CD4+ to CD8+ ratio. This shift may be correlated with a disease syndrome but is not necessarily correlated with disease outcome. Human T-cell clones of both the CD4+ and the CD8+ phenotypes are cytolytic against parasite-infected macrophages.

These T-cell clones produce cytokines that are "microbistatic." IL-18, IL-7, and IL-15 upregulate the production of IFN- γ and may be important during acute and chronic infection. The effect of IFN- γ may be paradoxical, with stimulation of a host downregulatory response as well.

Although in patients with AIDS *T. gondii* infection is believed to be recrudescent, determination of antibody titers is not helpful in establishing reactivation. Because of the severe depletion in CD4+ T cells, quite frequently there is no observed increase in antibody titer during exacerbation of infection. T cells from AIDS patients with reactivation of toxoplasmosis fail to secrete both IFN- γ and IL-2. This alteration in the production of these critical immune cytokines contributes to the persistence of infection. *Toxoplasma* infection frequently develops late in the course of AIDS, when the loss of T-cell-dependent protective mechanisms, particularly CD8+ T cells, becomes most pronounced.

CLINICAL MANIFESTATIONS

In persons whose immune systems are intact, acute toxoplasmosis is usually asymptomatic and self-limited. This condition can go unrecognized in 80–90% of adults and children with acquired infection. The asymptomatic nature of this infection makes diagnosis difficult in mothers infected during pregnancy. In contrast, the wide range of clinical manifestations in congenitally infected children includes severe neurologic complications such as hydrocephalus, microcephaly, mental retardation, and chorioretinitis. If prenatal infection is severe, multiorgan failure and subsequent intrauterine fetal death can occur. In children and adults, chronic infection can persist throughout life, with little consequence to the immunocompetent host.

Toxoplasmosis in Immunocompetent Patients

The most common manifestation of acute toxoplasmosis is cervical lymphadenopathy. The nodes may be single or multiple, are usually nontender, are discrete, and vary in firmness. Lymphadenopathy also may be found in suboccipital, supraclavicular, inguinal, and mediastinal areas. Generalized lymphadenopathy occurs in 20–30% of symptomatic patients. Between 20 and 40% of patients with lymphadenopathy also have headache, malaise, fatigue, and fever [usually with a temperature of <40°C (<104°F)]. A smaller proportion of symptomatic individuals have myalgia, sore throat, abdominal pain, maculopapular rash, meningoencephalitis, and confusion. Rare complications associated with infection in the normal immune host include pneumonia, myocarditis, encephalopathy, pericarditis, and polymyositis. Symptoms associated with acute infection usually resolve within several weeks, although the lymphadenopathy may persist for some months. In one epidemic, toxoplasmosis was diagnosed correctly in only 3 of the 25 patients who consulted physicians. If toxoplasmosis is considered in the differential diagnosis, routine laboratory and serologic screening should precede node biopsy.

The results of routine laboratory studies are usually unremarkable except for minimal lymphocytosis, an elevated erythrocyte sedimentation rate, and a nominal increase in liver aminotransferases. Evaluation of cerebrospinal fluid (CSF) in cases with evidence of encephalopathy or meningoencephalitis shows an elevation of intracranial pressure, mononuclear pleocytosis (10–50 cells/mL), a slight increase in protein concentration, and (occasionally) an increase in the gamma globulin level. PCR amplification of the *Toxoplasma* DNA target sequence in CSF may be beneficial. The CSF of chronically infected individuals is normal.

Infection of Immunocompromised Patients

Patients with AIDS and those receiving immunosuppressive therapy for lymphoproliferative disorders are at greatest risk for developing acute toxoplasmosis. This predilection may be due either to reactivation of latent infection or to acquisition of parasites from exogenous sources such as blood or transplanted organs. In individuals with AIDS, >95% of cases of TE are believed to be due to recrudescent infection. In most of these cases, encephalitis develops when the CD4+ T-cell count falls below 100/μL. In immunocompromised hosts, the disease may be rapidly fatal if untreated. Thus accurate diagnosis and initiation of appropriate therapy are necessary to prevent fulminant infection.

Toxoplasmosis is a principal opportunistic infection of the CNS in persons with AIDS. Although geographic origin may be related to frequency of infection, it has no correlation with the severity of disease in immunocompromised hosts. Individuals with AIDS who are seropositive for *T. gondii* are at very high risk for encephalitis. In the United States, about one-third of the 15–40% of adult AIDS patients who are latently infected with *T. gondii* develop TE.

The signs and symptoms of acute toxoplasmosis in immunocompromised patients principally involve the CNS (Fig. 121-2). More than 50% of patients with clinical manifestations have intracerebral involvement. Clinical findings at presentation range from nonfocal to focal dysfunction. CNS findings include encephalopathy, meningoencephalitis, and mass lesions. Patients may present with altered mental status (75%), fever (10–72%), seizures (33%), headaches (56%), and focal neurologic findings (60%), including motor deficits, cranial nerve palsies,

movement disorders, dysmetria, visual-field loss, and aphasia. Patients who present with evidence of diffuse cortical dysfunction develop evidence of focal neurologic disease as infection progresses. This altered condition is due not only to the necrotizing encephalitis caused by direct invasion by the parasite but also to secondary effects, including vasculitis, edema, and hemorrhage. The onset of infection can range from an insidious process over several weeks to an acute confusional state with fulminant focal deficits, including hemiparesis, hemiplegia, visual-field defects, localized headache, and focal seizures.

Although lesions can occur anywhere in the CNS, the areas most often involved appear to be the brainstem, basal ganglia, pituitary gland, and corticomedullary junction. Brainstem involvement gives rise to a variety of neurologic dysfunctions, including cranial nerve palsy, dysmetria, and ataxia. With basal ganglionic infection, patients may develop hydrocephalus, choreiform movements, and choreoathetosis. Because *Toxoplasma* usually causes encephalitis, meningeal involvement is uncommon, and thus CSF findings may be unremarkable or may include a modest increase in cell count and in protein—but not glucose—concentration.

Cerebral toxoplasmosis must be differentiated from other opportunistic infections or tumors in the CNS of AIDS patients. The differential diagnosis includes herpes simplex encephalitis, cryptococcal meningitis, progressive multifocal leukoencephalopathy, and primary CNS lymphoma. Involvement of the pituitary gland can give rise to panhypopituitarism and hyponatremia from inappropriate secretion of vasopressin (antidiuretic hormone). AIDS-dementia complex may present as cognitive impairment, attention loss, and altered memory. Brain biopsy in patients who have been treated for TE but who continue to exhibit neurologic dysfunction often fails to identify organisms.

Autopsies of *Toxoplasma*-infected patients have demonstrated the involvement of multiple organs, including the lungs, gastrointestinal tract, pancreas, skin, eyes, heart, and liver. *Toxoplasma* pneumonia can be confused with *Pneumocystis* pneumonia (PcP). Respiratory involvement usually presents as dyspnea, fever, and a nonproductive cough and may rapidly progress to acute respiratory failure with hemoptysis, metabolic acidosis, hypotension, and (occasionally) disseminated intravascular coagulation. Histopathologic studies demonstrate necrosis and a mixed

FIGURE 121-2

Toxoplasmic encephalitis in a 36-year-old patient with AIDS. The multiple lesions are demonstrated by magnetic resonance scanning (T1 weighted with gadolinium enhancement). (Courtesy of Clifford Eskey, Dartmouth Hitchcock Medical Center, Hanover, NH; with permission.)

cellular infiltrate. The presence of organisms is a helpful diagnostic indicator, but organisms can also be found in healthy tissue. Infection of the heart is usually asymptomatic but can be associated with cardiac tamponade or biventricular failure. Infections of the gastrointestinal tract and the liver have been documented.

Congenital Toxoplasmosis

Between 400 and 4000 infants born each year in the United States are affected by congenital toxoplasmosis. Infection of the placenta leads to hematogenous infection of the fetus. As stated earlier, the proportion of fetuses that become infected increases but the clinical severity of the infection declines as gestation proceeds. Persistence of *T. gondii* can ultimately result in reactivation and further damage decades later. Factors associated with relatively severe disabilities include delays in diagnosis and in initiation of therapy, neonatal hypoxia and hypoglycemia, profound visual impairment (see “Ocular Infection,” below), uncorrected hydrocephalus, and increased intracranial pressure. If treated appropriately, upwards of 70% of children have normal developmental, neurologic, and ophthalmologic findings at follow-up evaluations. Treatment for 1 year with pyrimethamine and a sulfonamide is tolerated with minimal toxicity (see “Treatment” later in the chapter).

Ocular Infection

Infection with *T. gondii* is estimated to cause 35% of all cases of chorioretinitis in the United States and Europe. Most ocular involvement is believed to be due to congenital infection, with a very low incidence following acquired infection. Between 1 and 3% of all patients with AIDS develop debilitating chorioretinitis due to *T. gondii*. A variety of ocular manifestations are documented, including blurred vision, scotoma, photophobia, and eye pain. Macular involvement occurs with loss of central vision, and nystagmus is secondary to poor fixation. Involvement of the extraocular muscles may lead to disorders of convergence and to strabismus. Ophthalmologic examination should be undertaken in newborns with suspected congenital infection. As the inflammation resolves, vision improves, but episodic flare-ups of chorioretinitis, which progressively destroy retinal tissue and lead to glaucoma, are common.

The ophthalmologic examination reveals yellow-white, cotton-like patches with indistinct margins of hyperemia. As the lesions age, white plaques with distinct borders and black spots within the retinal pigment become more apparent. Lesions usually are located near the posterior pole of the retina; they may be single but are more commonly multiple. Congenital lesions may be unilateral or bilateral and show evidence of massive chorioretinal degeneration with extensive fibrosis. Surrounding these areas of involvement are a normal retina and vasculature. In patients with AIDS, retinal lesions are often large, with diffuse retinal necrosis, and include both free tachyzoites and cysts containing bradyzoites. Toxoplasmic chorioretinitis may be a prodrome to the development of encephalitis.

DIAGNOSIS

Tissue and Body Fluids

The differential diagnosis of acute toxoplasmosis can be made by appropriate culture, serologic testing, and PCR (Table 121-1). Although difficult, the isolation of *T. gondii* from blood or other body fluids can be accomplished after subinoculation of the sample into the peritoneal cavity of mice. Mice should be tested for organisms in the peritoneal fluid 6–10 days after inoculation. If no parasites are found in the mouse’s peritoneal fluid, its anti-*Toxoplasma* serum titer can be evaluated 4–6 weeks after inoculation. Isolation of *T. gondii* from the patient’s body fluids reflects acute infection, whereas isolation from biopsied tissue is an indication only of the presence of tissue cysts and should not be misinterpreted as evidence of acute toxoplasmosis. Persistent parasitemia in patients with latent, asymptomatic infection is rare. Histologic examination of lymph nodes may suggest the characteristic changes described above. Demonstration of tachyzoites in lymph nodes establishes the diagnosis

TABLE 121-1

DIFFERENTIAL LABORATORY DIAGNOSIS OF TOXOPLASMOSIS

| CLINICAL SETTING | ALTERNATIVE DIAGNOSIS | DISTINGUISHING CHARACTERISTICS |
|--|--|--------------------------------|
| Mononucleosis syndrome | Epstein-Barr virus | Serologic test |
| | Cytomegalovirus | Serologic test |
| | HIV | Serologic test |
| Congenital infection | Cytomegalovirus | Viral culture |
| | Herpes simplex virus | Viral culture |
| | Rubella virus | Viral culture/serologic test |
| | Syphilis | Serologic test |
| | Listeriosis | Bacterial culture |
| Retinochoroiditis in immuno-competent individual | Tuberculosis | Bacterial culture |
| | Syphilis | Serologic test |
| | Histoplasmosis | Serologic test/culture |
| Retinochoroiditis in AIDS | Cytomegalovirus | Viral culture/PCR |
| | Syphilis | Serologic test |
| | Herpes simplex virus | Viral culture/PCR |
| | Varicella-zoster virus | Viral culture/PCR |
| | Fungal infection | Culture |
| CNS lesions in AIDS | Lymphoma or metastatic tumor | Tissue biopsy |
| | Brain abscess | Bacterial culture |
| | Progressive multifocal leukoencephalopathy | PCR |
| | Fungal/mycobacterial infection | Biopsy and culture |

of acute toxoplasmosis. Like subinoculation into mice, histologic demonstration of cysts containing bradyzoites confirms prior infection with *T. gondii* but is nondiagnostic for acute infection.

Serology

The procedures just described have great diagnostic value but are limited by difficulties encountered either in the growth of parasites in vivo or in the identification of tachyzoites by histochemical methods. Serologic testing has become the routine method of diagnosis. A wide range of serologic tests that can be used to measure antibody to *T. gondii* are available commercially.

Diagnosis of acute infection with *T. gondii* can be established by detection of the simultaneous presence of IgG and IgM antibodies to *Toxoplasma* in serum. The presence of circulating IgA favors the diagnosis of an acute infection. The Sabin-Feldman dye test, the indirect fluorescent antibody test, and the enzyme-linked immunosorbent assay (ELISA) all satisfactorily measure circulating IgG antibody to *Toxoplasma*. Positive IgG titers (>1:10) can be detected as early as 2–3 weeks after infection. These titers usually peak at 6–8 weeks and decline slowly to a new baseline level that persists for life. It is necessary to measure the serum IgM titer in concert with the IgG titer to better establish the time of infection. The methods currently available for this determination are the double-sandwich IgM-ELISA and the IgM-immunosorbent assay (IgM-ISAGA). Both of these assays are specific and sensitive, and their use precludes the false-positive results associated with tests for rheumatoid factor and antinuclear antibody. The double-sandwich IgA-ELISA is more sensitive than the IgM-ELISA for detecting congenital infection in the fetus and newborn.

Recently, the results obtained with PCR have suggested high sensitivity, specificity, and clinical utility in the diagnosis of TE in resource-poor settings.

Molecular Diagnostics

Molecular approaches can directly detect *T. gondii* in biologic samples independent of the serologic response. Specific molecular analysis for either the B1 gene or the 529-bp sequence is useful. Real-time PCR is a promising technique that can provide quantitative results. Isolates can be genotyped and polymorphic sequences can be obtained, with the consequent identification of the precise strain. Knowledge of the correct sequence is important in studies on the correlation of clinical signs and symptoms of disease with the *T. gondii* genotype.

The Immunocompetent Adult or Child

For the patient who presents with lymphadenopathy only, a positive IgM titer is an indication of acute infection—and an indication for therapy, if that is clinically warranted (see “Treatment” later in the chapter). The serum IgM titer should be determined again in 3 weeks. An elevation in the IgG titer without an increase in the IgM titer suggests that infection is present but is not

acute. If there is a borderline increase in either IgG or IgM, the titers should be reassessed in 3–4 weeks.

The Immunocompromised Host

A presumptive clinical diagnosis of TE in patients with AIDS is based on clinical presentation, history of exposure (as evidenced by positive serology), and radiologic evaluation. To detect latent infection with *T. gondii*, HIV-infected persons should be tested for IgG antibody to *Toxoplasma* soon after HIV infection is diagnosed. When these criteria are used, the predictive value is as high as 80%. More than 97% of patients with AIDS and toxoplasmosis have IgG antibody to *T. gondii* in serum. IgM serum antibody usually is not detectable. Attempts to evaluate rising IgG titers or to determine whether IgM is present are not productive. Serologic evidence of infection virtually always precedes the development of TE. It is therefore important to determine the *Toxoplasma* antibody status of all patients infected with HIV. Antibody titers may range from negative to 1:1024 in patients with AIDS and TE. Fewer than 3% of patients have no demonstrable antibody to *Toxoplasma* at diagnosis. Intrathecal antibody to *T. gondii* may be present; determination of the titer may help identify prior infection.

Patients with TE have focal or multifocal abnormalities demonstrable by CT or MRI. Neuroradiologic evaluation should include double-dose contrast CT of the head. By this test, single and frequently multiple contrast-enhancing lesions (<2 cm) may be identified. MRI usually demonstrates multiple lesions located in both hemispheres, with the basal ganglia and corticomedullary junction most commonly involved; MRI provides a more sensitive evaluation of the efficacy of therapy than does CT (Fig. 121-2). These findings are not pathognomonic of *Toxoplasma* infection, since 40% of CNS lymphomas are multifocal and 50% are ring-enhancing. For both MRI and CT scans, the rate of false-negative results is ~10%. The finding of a single lesion on an MRI scan increases the likelihood of primary CNS lymphoma (in which solitary lesions are four times more likely than in TE) and strengthens the argument for the performance of a brain biopsy. A therapeutic trial of anti-*Toxoplasma* medications is frequently used to assess the diagnosis. Treatment of presumptive TE with pyrimethamine plus clindamycin results in quantifiable clinical improvement in >50% of patients by day 3. By day 7, >90% of treated patients show evidence of improvement. In contrast, if patients fail to respond or have lymphoma, clinical signs and symptoms worsen by day 7. Patients in this category require brain biopsy with or without a change in therapy. This procedure can now be performed by a stereotactic CT-guided method that reduces the potential for complications. Brain biopsy for *T. gondii* identifies organisms in 50–75% of cases. PCR amplification of genetic material of the parasite found in the CSF may prove diagnostically beneficial in the future.

Now used in some centers, single-photon emission CT (SPECT) has been touted as a definitive means of detecting or ruling out *Toxoplasma* infection when a

CNS lesion is suspected. In the future, SPECT may well be widely used for this purpose.

As in other conditions, the radiologic response may lag behind the clinical response. Resolution of lesions may take from 3 weeks to 6 months. Some patients show clinical improvement despite worsening radiographic findings.

Congenital Infection

The issue of concern when a pregnant woman has evidence of recent *T. gondii* infection is obviously whether the fetus is infected. PCR analysis of the amniotic fluid for the B1 gene of *T. gondii* has replaced fetal blood sampling. Serologic diagnosis is based on the persistence of IgG antibody or a positive IgM titer after the first week of life (a time frame that excludes placental leak). The IgG determination should be repeated every 2 months. An increase in IgM beyond the first week of life is indicative of acute infection. However, up to 25% of infected newborns may be seronegative and have normal routine physical examinations. Thus assessment of the eye and the brain, with ophthalmologic testing, CSF evaluation, and radiologic studies, is important in establishing the diagnosis.

Ocular Toxoplasmosis

Because of the congenital nature of ocular toxoplasmosis, the serum antibody titer may not correlate with the presence of active lesions in the fundus. In general, a positive IgG titer (measured in undiluted serum if necessary) in conjunction with typical lesions establishes the diagnosis. Antibody production is expressed in terms of the Goldmann-Witmer coefficient (C), in which $C = [\text{anti-Toxoplasma IgG (aqueous humor/serum)}] / [\text{total IgG (serum/aqueous humor)}]$. The positive cutoff of 3 is the generally accepted discrimination level. The sensitivity of this index as a diagnostic tool lies between 60 and 85%, with a specificity close to 90% in persons of European or North American origin. Confirmation of local specific antibody production in the eye indicates that the site of inflammatory activity is localized to this organ. However, two-thirds of patients without evidence of specific antibody production at initial clinical presentation later develop a detectable titer. If lesions are atypical and the titer is in the low-positive range, the diagnosis is presumptive. The parasitic antigen-specific polyclonal IgG assay as well as parasitic antigen-specific PCR may facilitate the diagnosis. Accordingly, the clinical diagnosis of ocular toxoplasmosis can be supported in 60–90% of cases by laboratory tests, depending on the time of anterior chamber puncture and the panel of antibody analyses used. In the remaining cases, the possibility of a falsely negative laboratory diagnosis or of an incorrect clinical diagnosis cannot be clarified further.

R_x Treatment: TOXOPLASMOSIS

CONGENITAL INFECTION Congenitally infected neonates are treated with daily oral pyrimethamine

(0.5–1 mg/kg) and sulfadiazine (100 mg/kg) for 1 year. In addition, therapy with spiramycin (100 mg/kg per day) plus prednisone (1 mg/kg per day) is efficacious for congenital infection.

INFECTION IN IMMUNOCOMPETENT PATIENTS

Immunologically competent adults and older children who have only lymphadenopathy do not require specific therapy unless they have persistent, severe symptoms. Patients with ocular toxoplasmosis should be treated for 1 month with pyrimethamine plus either sulfadiazine or clindamycin. Prenatal antibiotic therapy can reduce the number of infants severely affected by *Toxoplasma* infection.

INFECTION IN IMMUNOCOMPROMISED PATIENTS

Primary Prophylaxis Patients with AIDS should be treated for acute toxoplasmosis; in immunocompromised patients, toxoplasmosis is rapidly fatal if untreated. Before the introduction of antiretroviral therapy (ART), the median survival time was >1 year for patients who could tolerate treatment for TE. Despite their toxicity, the drugs used to treat TE were required for survival prior to ART. The incidence of TE has declined as survival of patients with HIV infection has increased as a result of ART.

In Africa, many patients are diagnosed with HIV infection only after developing opportunistic infections such as TE. Hence, the optimal management of these opportunistic infections is important if the benefits of subsequent ART are to be realized. AIDS patients who are seropositive for *T. gondii* and who have a CD4+ T-lymphocyte count of <100/μL should receive prophylaxis against TE. A recent Cochrane analysis of clinical trials of TE treatment failed to document the superiority of any one regimen. Of the currently available agents, trimethoprim-sulfamethoxazole (TMP-SMX) appears to be an effective alternative for TE in resource-poor settings where the preferred combination of pyrimethamine plus sulfadiazine is not available. The daily dose of TMP-SMX recommended as the preferred regimen for PcP prophylaxis (one double-strength tablet) is effective against TE. If patients cannot tolerate TMP-SMX, the recommended alternative is dapsone-pyrimethamine, which is also effective against PcP. Atovaquone with or without pyrimethamine also can be considered. Prophylactic monotherapy with dapsone, pyrimethamine, azithromycin, clarithromycin, or aerosolized pentamidine is probably insufficient. AIDS patients who are seronegative for *Toxoplasma* and are not receiving prophylaxis for PcP should be retested for IgG antibody to *Toxoplasma* if their CD4+ T-cell count drops to <100/μL. If seroconversion has taken place, then the patient should be given prophylaxis as described above.

Discontinuing Primary Prophylaxis Some current studies indicate that prophylaxis against TE can be discontinued in patients who have responded to ART

and whose CD4+ T-lymphocyte count has been $>200/\mu\text{L}$ for 3 months. Although patients with CD4+ T-lymphocyte counts of $<100/\mu\text{L}$ are at greatest risk for developing TE, the risk that this condition will develop when the count has increased to 100–200/ μL has not been established. Thus, prophylaxis should indeed be discontinued only when the count has increased to $>200/\mu\text{L}$. Continued prophylaxis at a CD4+ count of $>200/\mu\text{L}$ has only a limited preventive effect against TE. Discontinuation of therapy reduces the pill burden; the potential for drug toxicity, drug interaction, or selection of drug-resistant pathogens; and cost. Prophylaxis should be recommenced if the CD4+ T-lymphocyte count again decreases to $<100\text{--}200/\mu\text{L}$.

Individuals who have completed initial therapy for TE should receive treatment indefinitely unless immune reconstitution, with a CD4+ T-cell count of $>200/\mu\text{L}$, occurs as a consequence of ART. Combination therapy with pyrimethamine plus sulfadiazine plus leucovorin is effective for this purpose. An alternative to sulfadiazine in this regimen is clindamycin. Unfortunately, only the combination of pyrimethamine plus sulfadiazine provides protection against PCP as well.

Discontinuing Secondary Prophylaxis (Chronic Maintenance Therapy) Patients receiving secondary prophylaxis for TE are at low risk for recurrence when they have completed initial therapy for TE, remain asymptomatic, and have a CD4+ T-lymphocyte count of $>200/\mu\text{L}$ for at least 6 months after ART. This recommendation is based on recent observations in a large cohort (381 patients) and is consistent with more extensive data indicating the safety of discontinuing secondary prophylaxis for other opportunistic infections during advanced HIV disease. Discontinuation of chronic maintenance therapy among these patients appears reasonable. A repeat MRI brain scan is recommended. Secondary prophylaxis should be reintroduced if the CD4+ T-lymphocyte count decreases to $<200/\mu\text{L}$.

PREVENTION

All HIV-infected persons, including those who lack IgG antibody to *Toxoplasma*, should be counseled regarding sources of *Toxoplasma* infection. The chances of primary infection with *Toxoplasma* can be reduced by not eating undercooked meat and by avoiding oocyst-contaminated material (i.e., a cat's litter box). Specifically, lamb, beef, and pork should be cooked to an internal temperature of 165°–170°F; from a more practical perspective, meat cooked until it is no longer pink inside usually satisfies this requirement. Hands should be washed thoroughly after work in the garden, and all fruits and vegetables should be washed. If the patient owns a cat, the litter

box should be cleaned or changed daily, preferably by an HIV-negative, nonpregnant person; alternatively, patients should wash their hands thoroughly after changing the litter box. Patients should be encouraged to keep their cats inside and not to adopt or handle stray cats. Cats should be fed only canned or dried commercial food or well-cooked table food, not raw or undercooked meats. Patients need not be advised to part with their cats or to have their cats tested for toxoplasmosis. Blood intended for transfusion into *Toxoplasma*-seronegative immunocompromised individuals should be screened for antibody to *T. gondii*. Although such serologic screening is not routinely performed, seronegative women should be screened for evidence of infection several times during pregnancy if they are exposed to environmental conditions that put them at risk for infection with *T. gondii*. HIV-positive individuals should adhere closely to these preventive measures.

CHAPTER 122

PROTOZOAL INTESTINAL INFECTIONS AND TRICHOMONIASIS

Peter F. Weller

PROTOZOAL INFECTIONS

GIARDIASIS

Giardia lamblia (also known as *G. intestinalis*) is a cosmopolitan protozoal parasite that inhabits the small intestines of humans and other mammals.

Giardiasis is one of the most common parasitic diseases in both developed and developing countries worldwide, causing both endemic and epidemic intestinal disease and diarrhea.

Life Cycle and Epidemiology

(Fig. 122-1) Infection follows the ingestion of environmentally hardy cysts, which excyst in the small intestine, releasing flagellated trophozoites (Fig. 122-2) that multiply by binary fission. *Giardia* remains a pathogen of the proximal small bowel and does not disseminate hematogenously. Trophozoites remain free in the lumen or attach to the mucosal epithelium by means of a ventral sucking disk. As a trophozoite encounters altered conditions, it forms a morphologically distinct cyst, which is the stage of the parasite usually found in the feces. Trophozoites may be present and even predominate in loose or watery stools, but it is the resistant cyst that survives outside the body and is responsible for transmission. Cysts do not tolerate heating, desiccation, or continued exposure to feces but do remain viable for months in cold fresh water. The number of cysts excreted varies widely but can approach 10^7 per gram of stool.

Ingestion of as few as 10 cysts is sufficient to cause infection in humans. Because cysts are infectious when excreted, person-to-person transmission occurs where fecal hygiene is poor. Giardiasis, as symptomatic or asymptomatic infections, is especially prevalent in day-care centers; person-to-person spread also takes place in other institutional settings with poor fecal hygiene and during anal-oral contact. If food is contaminated with *Giardia* cysts after cooking or preparation, food-borne transmission can occur. Waterborne transmission accounts for episodic infections (e.g., in campers and travelers) and for major epidemics in metropolitan areas. Surface water, ranging from mountain streams to large municipal reservoirs, can become contaminated with fecally derived *Giardia* cysts; outmoded water systems are subject to cross-contamination from leaking sewer lines. The efficacy

FIGURE 122-1

Life cycle of *Giardia*. (Reprinted from RL Guerrant et al: *Tropical Infectious Disease: Principles, Pathogens and Practice*, 2d ed, 2006, p 987, with permission from Elsevier Science.)

of water as a means of transmission is enhanced by the small infectious inoculum of *Giardia*, the prolonged survival of cysts in cold water, and the resistance of cysts to killing by routine chlorination methods that are adequate

**FIGURE 122-2**Flagellated, binucleate *Giardia* trophozoite.

for controlling bacteria. Viable cysts can be eradicated from water by either boiling or filtration. In the United States, *Giardia* (like *Cryptosporidium*; see below) is a common cause of waterborne epidemics of gastroenteritis. *Giardia* is common in developing countries, and infections may be acquired by travelers.

The importance of animal reservoirs as sources of infection for humans is unclear. *Giardia* parasites morphologically similar to those in humans are found in many mammals, including beavers from reservoirs implicated in epidemics, dogs, and cats.

Giardiasis, like cryptosporidiosis, creates a significant economic burden because of the costs incurred in the installation of water filtration systems required to prevent waterborne epidemics, in the management of epidemics that involve large communities, and in the evaluation and treatment of endemic infections.

Pathophysiology

The reasons that some, but not all, infected patients develop clinical manifestations and the mechanisms by which *Giardia* causes alterations in small-bowel function are largely unknown. Although trophozoites adhere to the epithelium, they do not cause invasive or locally destructive alterations. The lactose intolerance and, in a minority of infected adults and children, significant malabsorption that develop are clinical signs of the loss of brush-border enzyme activities. In most infections, the morphology of the bowel is unaltered; however, in a few cases (usually in chronically infected, symptomatic patients), the histopathologic findings (including flattened villi) and the clinical manifestations resemble those of tropical sprue and gluten-sensitive enteropathy. The pathogenesis of diarrhea in giardiasis is not known.

The natural history of *Giardia* infection varies markedly. Infections may be aborted, transient, recurrent, or chronic. Parasite as well as host factors may be important in determining the course of infection and disease. Both cellular and humoral responses develop in human infections, but their precise roles in the control of infection and/or disease are unknown. Because patients with hypogammaglobulinemia

suffer from prolonged, severe infections that are poorly responsive to treatment, humoral immune responses appear to be important. The greater susceptibility of the young than of the old and of newly exposed persons than of chronically exposed populations suggests that at least partial protective immunity may develop. *Giardia* isolates vary genotypically, biochemically, and biologically, and variations among isolates may contribute to different courses of infection.

Clinical Manifestations

Disease manifestations of giardiasis range from asymptomatic carriage to fulminant diarrhea and malabsorption. Most infected persons are asymptomatic, but in epidemics the proportion of symptomatic cases may be higher. Symptoms may develop suddenly or gradually. In persons with acute giardiasis, symptoms develop after an incubation period that lasts at least 5–6 days and usually 1–3 weeks. Prominent early symptoms include diarrhea, abdominal pain, bloating, belching, flatus, nausea, and vomiting. Although diarrhea is common, upper intestinal manifestations such as nausea, vomiting, bloating, and abdominal pain may predominate. The duration of acute giardiasis is usually >1 week, although diarrhea often subsides. Individuals with chronic giardiasis may present with or without having experienced an antecedent acute symptomatic episode. Diarrhea is not necessarily prominent, but increased flatus, loose stools, sulfurous belching, and (in some instances) weight loss occur. Symptoms may be continual or episodic and can persist for years. Some persons who have relatively mild symptoms for long periods recognize the extent of their discomfort only in retrospect. Fever, the presence of blood and/or mucus in the stools, and other signs and symptoms of colitis are uncommon and suggest a different diagnosis or a concomitant illness. Symptoms tend to be intermittent yet recurring and gradually debilitating, in contrast with the acute disabling symptoms associated with many enteric bacterial infections. Because of the less severe illness and the propensity for chronic infections, patients may seek medical advice late in the course of the illness; however, disease can be severe, resulting in malabsorption, weight loss, growth retardation, and dehydration. A number of extraintestinal manifestations have been described, such as urticaria, anterior uveitis, and arthritis; whether these are caused by giardiasis or concomitant processes is unclear.

Giardiasis can be severe in patients with hypogammaglobulinemia and can complicate other preexisting intestinal diseases, such as that occurring in cystic fibrosis. In patients with AIDS, *Giardia* can cause enteric illness that is refractory to treatment.

Diagnosis

(Table 122-1) Giardiasis is diagnosed by detection of parasite antigens in the feces or by identification of cysts in the feces or of trophozoites in the feces or small intestines. Cysts are oval, measure 8–12 $\mu\text{m} \times 7$ –10 μm , and characteristically contain four nuclei. Trophozoites are pear-shaped, dorsally convex, flattened parasites with

^aO+P, ova and parasites.

two nuclei and four pairs of flagella (Fig. 122-2). The diagnosis is sometimes difficult to establish. Direct examination of fresh or properly preserved stools as well as concentration methods should be used. Because cyst excretion is variable and may be undetectable at times, repeated examination of stool, sampling of duodenal fluid, and biopsy of the small intestine may be required to detect the parasite. Tests for parasitic antigens in stool are at least as sensitive and specific as good microscopic examinations and are easier to perform. All of these methods occasionally yield false-negative results.

Rx Treatment: **GIARDIASIS**

Cure rates with metronidazole (250 mg thrice daily for 5 days) are usually >90%. Tinidazole (2 g once by mouth) is reportedly more effective than metronidazole. Nitazoxanide (500 mg twice daily for 3 days) is an alternative agent for treatment of giardiasis. Paromomycin, an oral aminoglycoside that is not well absorbed, can be given to symptomatic pregnant patients, although information is limited on how effectively this agent eradicates infection.

Almost all patients respond to therapy and are cured, although some with chronic giardiasis experience delayed resolution of symptoms after eradication of *Giardia*. For many of the latter patients, residual symptoms probably reflect delayed regeneration of intestinal brush-border enzymes. Continued infection should be documented by stool examinations before treatment is repeated. Patients who remain infected after repeated treatments should be evaluated for reinfection through family members, close personal contacts, and environmental sources as well as for hypogammaglobulinemia. In cases refractory to multiple treatment courses, prolonged therapy with metronidazole (750 mg thrice daily for 21 days) has been successful.

Prevention

Although *Giardia* is extremely infectious, disease can be prevented by consumption of noncontaminated food and water and by personal hygiene when caring for infected children. Boiling or filtering potentially contaminated water prevents infection.

CRYPTOSPORIDIOSIS

The coccidian parasite *Cryptosporidium* causes diarrheal disease that is self-limited in immunocompetent human hosts but can be severe in persons with AIDS or other forms of immunodeficiency. Two species of *Cryptosporidium*, *C. hominis* and *C. parvum*, cause most human infections.

Life Cycle and Epidemiology

Cryptosporidium species are widely distributed in the world. Cryptosporidiosis is acquired by the consumption of oocysts (50% infectious dose: ~132 oocysts in nonimmune individuals), which excyst to liberate sporozoites that in turn enter and infect intestinal epithelial cells. The parasite's further development involves both asexual and sexual cycles, which produce forms capable of infecting other epithelial cells and of generating oocysts that are passed in the feces. *Cryptosporidium* species infect a number of animals, and *C. parvum* can spread from infected animals to humans. Since oocysts are immediately infectious when passed in feces, person-to-person transmission takes place in day-care centers and among household contacts and medical providers. Waterborne transmission (especially that of *C. hominis*) accounts for infections in travelers and for common-source epidemics. Oocysts are quite hardy and resist killing by routine chlorination. Both drinking water and recreational water (e.g., pools, waterslides) have been increasingly recognized as sources of infection.

Pathophysiology

Although intestinal epithelial cells harbor cryptosporidia in an intracellular vacuole, the means by which secretory diarrhea is elicited remain uncertain. No characteristic pathologic changes are found by biopsy. The distribution of infection can be spotty within the principal site of infection, the small bowel. Cryptosporidia are found in the pharynx, stomach, and large bowel of some patients and at times in the respiratory tract. Especially in patients with AIDS, involvement of the biliary tract can cause papillary stenosis, sclerosing cholangitis, or cholecystitis.

Clinical Manifestations

Asymptomatic infections can occur in both immunocompetent and immunocompromised hosts. In immunocompetent persons, symptoms develop after an incubation period of ~1 week and consist principally of watery nonbloody diarrhea, sometimes in conjunction with abdominal pain, nausea, anorexia, fever, and/or weight loss. In these hosts, the illness usually subsides after 1–2 weeks. In contrast, in immunocompromised hosts (especially those

with AIDS and CD4+ T cell counts $<100/\mu\text{L}$), diarrhea can be chronic, persistent, and remarkably profuse, causing clinically significant fluid and electrolyte depletion. Stool volumes may range from 1 to 25 L/d. Weight loss, wasting, and abdominal pain may be severe. Biliary tract involvement can manifest as midepigastic or right upper quadrant pain.

Diagnosis

(Table 122-1) Evaluation starts with fecal examination for small oocysts, which are smaller (4–5 μm in diameter) than the fecal stages of most other parasites. Because conventional stool examination for ova and parasites does not detect *Cryptosporidium*, specific testing must be requested. Detection is enhanced by evaluation of stools (obtained on multiple days) by several techniques, including modified acid-fast and direct immunofluorescent stains and enzyme immunoassays. Cryptosporidia can also be identified by light and electron microscopy at the apical surfaces of intestinal epithelium from biopsy specimens of the small bowel and, less frequently, the large bowel.

Treatment: CRYPTOSPORIDIOSIS

Nitazoxanide is approved by the U.S. Food and Drug Administration for the treatment of cryptosporidiosis and is available in tablet form for adults (500 mg twice daily for 3 days) and as an elixir for children. To date, however, this agent has not been effective for the treatment of HIV-infected patients, in whom improved immune status due to antiretroviral therapy can lead to amelioration of cryptosporidiosis. Otherwise, treatment includes supportive care with replacement of fluids and electrolytes and administration of antidiarrheal agents. Biliary tract obstruction may require papillotomy or T-tube placement. Prevention requires minimizing exposure to infectious oocysts in human or animal feces. Use of submicron water filters may minimize acquisition of infection from drinking water.

ISOSPORIASIS

The coccidian parasite *Isospora belli* causes human intestinal disease. Infection is acquired by the consumption of oocysts, after which the parasite invades intestinal epithelial cells and undergoes both sexual and asexual cycles of development. Oocysts excreted in stool are not immediately infectious but must undergo further maturation.

Although *I. belli* infects many animals, little is known about the epidemiology or prevalence of this parasite in humans. It appears to be most common in tropical and subtropical countries. Acute infections can begin abruptly with fever, abdominal pain, and watery nonbloody diarrhea and can last for weeks or months. In patients who have AIDS or are immunocompromised for other reasons, infections often are not self-limited but rather resemble cryptosporidiosis, with chronic, profuse watery diarrhea. Eosinophilia,

which is not found in other enteric protozoan infections, may be detectable. The diagnosis (Table 122-1) is usually made by detection of the large (~25- μm) oocysts in stool by modified acid-fast staining. Oocyst excretion may be low-level and intermittent; if repeated stool examinations are unrevealing, sampling of duodenal contents by aspiration or small-bowel biopsy (often with electron-microscopic examination) may be necessary.

Treatment: ISOSPORIASIS

Trimethoprim-sulfamethoxazole (TMP-SMX; 160/800 mg four times daily for 10 days, and for HIV-infected patients, then three times daily for 3 weeks) is effective. For patients intolerant of sulfonamides, pyrimethamine (50–75 mg/d) can be used. Relapses can occur in persons with AIDS and necessitate maintenance therapy with TMP-SMX (160/800 mg three times per week).

CYCLOSPORIASIS

Cyclospora cayetanensis, a cause of diarrheal illness, is globally distributed: illness due to *C. cayetanensis* has been reported in the United States, Asia, Africa, Latin America, and Europe. The epidemiology of this parasite has not yet been fully defined, but waterborne transmission and food-borne transmission by basil and imported raspberries have been recognized. The full spectrum of illness attributable to *Cyclospora* has not been delineated. Some patients may harbor the infection without symptoms, but many have diarrhea, flulike symptoms, and flatulence and belching. The illness can be self-limited, can wax and wane, or in many cases can involve prolonged diarrhea, anorexia, and upper gastrointestinal symptoms, with sustained fatigue and weight loss in some instances. Diarrheal illness may persist for >1 month. *Cyclospora* can cause enteric illness in patients infected with HIV.

The parasite is detectable in epithelial cells of small-bowel biopsy samples and elicits secretory diarrhea by unknown means. The absence of fecal blood and leukocytes indicates that disease due to *Cyclospora* is not caused by destruction of the small-bowel mucosa. The diagnosis (Table 122-1) can be made by detection of spherical 8- to 10- μm oocysts in the stool, although routine stool O and P examinations are not sufficient. Specific fecal examinations must be requested to detect the oocysts, which are variably acid-fast and are fluorescent when viewed with ultraviolet light microscopy. Cyclosporiasis should be considered in the differential diagnosis of prolonged diarrhea, with or without a history of travel by the patient to other countries.

Treatment: CYCLOSPORIASIS

Cyclosporiasis is treated with TMP-SMX (160/800 mg twice daily for 7 days). HIV-infected patients may experience relapses after such treatment and thus may require longer-term suppressive maintenance therapy.

MICROSPORIDIOSIS

Microsporidia are obligate intracellular spore-forming protozoa that infect many animals and cause disease in humans, especially as opportunistic pathogens in AIDS. Microsporidia are members of a distinct phylum, Microspora, which contains dozens of genera and hundreds of species. The various microsporidia are differentiated by their developmental life cycles, ultrastructural features, and molecular taxonomy based on ribosomal RNA. The complex life cycles of the organisms result in the production of infectious spores (Fig. 122-3). Currently, eight genera of microsporidia—*Encephalitozoon*, *Pleistophora*, *Nosema*, *Vittaforma*, *Trachipleistophora*, *Brachiola*, *Microsporidium*, and *Enterocytozoon*—are recognized as causes of human disease. Although some microsporidia are probably prevalent causes of self-limited or asymptomatic infections in immunocompetent patients, little is known about how microsporidiosis is acquired.

Microsporidiosis is most common among patients with AIDS, less common among patients with other types of immunocompromise, and rare among immunocompetent

hosts. In patients with AIDS, intestinal infections with *Enterocytozoon bienersi* and *Encephalitozoon* (formerly *Sep-tata*) *intestinalis* are recognized to contribute to chronic diarrhea and wasting; these infections are found in 10–40% of patients with chronic diarrhea. Both organisms have been found in the biliary tracts of patients with cholecystitis. *E. intestinalis* may also disseminate to cause fever, diarrhea, sinusitis, cholangitis, and bronchiolitis. In patients with AIDS, *Encephalitozoon hellem* has caused superficial keratoconjunctivitis as well as sinusitis, respiratory tract disease, and disseminated infection. Myositis due to *Pleistophora* has been documented. *Nosema*, *Vittaforma*, and *Microsporidium* have caused stromal keratitis associated with trauma in immunocompetent patients.

Microsporidia are small gram-positive organisms with mature spores measuring $0.5\text{--}2\text{ }\mu\text{m} \times 1\text{--}4\text{ }\mu\text{m}$. Diagnosis of microsporidial infections in tissue often requires electron microscopy, although intracellular spores can be visualized by light microscopy with hematoxylin and eosin, Giemsa, or tissue Gram's stain. For the diagnosis of intestinal microsporidiosis, modified trichrome or chromotrope

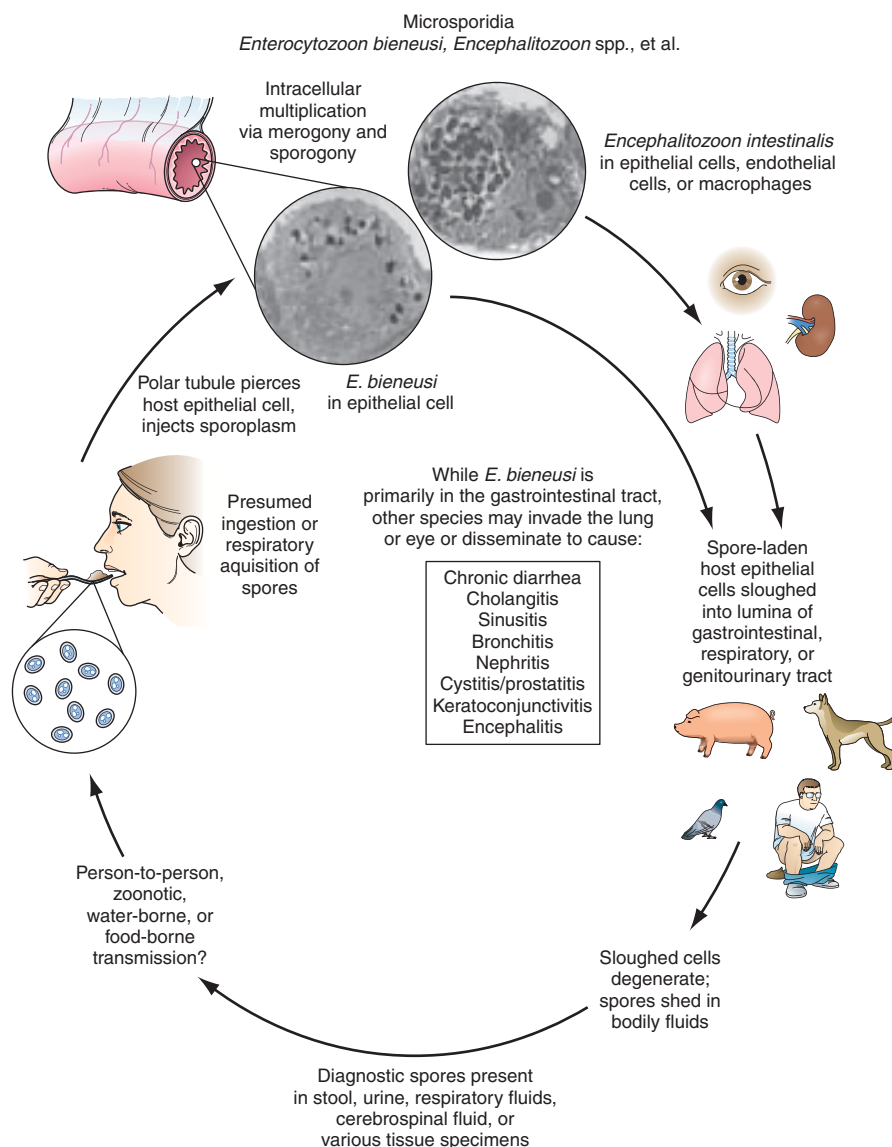

FIGURE 122-3

Life cycle of microsporidia. (Reprinted from RL Guerrant et al: *Tropical Infectious Disease: Principles, Pathogens and Practice*, 2d ed, 2006, p 1128, with permission from Elsevier Science.)

2R-based staining and Uvitex 2B or calcofluor fluorescent staining reveal spores in smears of feces or duodenal aspirates. Definitive therapies for microsporidial infections remain to be established. For superficial keratoconjunctivitis due to *E. hellem*, topical therapy with fumagillin suspension has shown promise (Chap. 113). For enteric infections with *E. bienersi* and *E. intestinalis* in HIV-infected patients, therapy with albendazole may be efficacious (Chap. 113).

OTHER INTESTINAL PROTOZOA

Balantidiasis

Balantidium coli is a large ciliated protozoal parasite that can produce a spectrum of large-intestinal disease analogous to amebiasis.

The parasite is widely distributed in the world. Since it infects pigs, cases in humans are more common where pigs are raised. Infective cysts can be transmitted from person to person and through water, but many cases are due to the ingestion of cysts derived from porcine feces in association with slaughtering, with use of pig feces for fertilizer, or with contamination of water supplies by pig feces.

Ingested cysts liberate trophozoites, which reside and replicate in the large bowel. Many patients remain asymptomatic, but some have persisting intermittent diarrhea, and a few develop more fulminant dysentery. In symptomatic individuals, the pathology in the bowel—both gross and microscopic—is similar to that seen in amebiasis, with varying degrees of mucosal invasion, focal necrosis, and ulceration. Balantidiasis, unlike amebiasis, does not spread hematogenously to other organs. The diagnosis is made by detection of the trophozoite stage in stool or sampled colonic tissue. Tetracycline (500 mg four times daily for 10 days) is an effective therapeutic agent.

Blastocystis Hominis Infection

B. hominis, while believed by some to be a protozoan capable of causing intestinal disease, remains an organism of uncertain pathogenicity. Some patients who pass *B. hominis* in their stools are asymptomatic, whereas others have diarrhea and associated intestinal symptoms. Diligent evaluation reveals other potential bacterial, viral, or protozoal causes of diarrhea in some but not all patients with symptoms. Because the pathogenicity of *B. hominis* is uncertain and because therapy for *Blastocystis* infection is neither specific nor uniformly effective, patients with prominent intestinal symptoms should be fully evaluated for other infectious causes of diarrhea. If diarrheal symptoms associated with *Blastocystis* are prominent, either metronidazole (750 mg thrice daily for 10 days) or TMP-SMX (160 mg/800 mg twice daily for 7 days) can be used.

Dientamoeba Fragilis Infection

D. fragilis is unique among intestinal protozoa in that it has a trophozoite stage but not a cyst stage. How trophozoites survive to transmit infection is not known. When symptoms develop in patients with *D. fragilis*

infection, they are generally mild and include intermittent diarrhea, abdominal pain, and anorexia. The diagnosis is made by the detection of trophozoites in stool; the lability of these forms accounts for the greater yield when fecal samples are preserved immediately after collection. Since fecal excretion rates vary, examination of several samples obtained on alternate days increases the rate of detection. Iodoquinol (650 mg three times daily for 20 days), paromomycin (25–35 mg/kg per day in three doses for 7 days), metronidazole (500–750 mg three times daily for 10 days), or tetracycline (500 mg four times daily for 10 days) is appropriate for treatment.

TRICHOMONIASIS

Various species of trichomonads can be found in the mouth (in association with periodontitis) and occasionally in the gastrointestinal tract. *Trichomonas vaginalis*—one of the most prevalent protozoal parasites in the United States—is a pathogen of the genitourinary tract and a major cause of symptomatic vaginitis.

LIFE CYCLE AND EPIDEMIOLOGY

T. vaginalis is a pear-shaped, actively motile organism that measures about $10 \times 7 \mu\text{m}$, replicates by binary fission, and inhabits the lower genital tract of females and the urethra and prostate of males. In the United States, it accounts for ~3 million infections per year in women. While the organism can survive for a few hours in moist environments and could be acquired by direct contact, person-to-person venereal transmission accounts for virtually all cases of trichomoniasis. Its prevalence is greatest among persons with multiple sexual partners and among those with other sexually transmitted diseases (Chap. 28).

CLINICAL MANIFESTATIONS

Many men infected with *T. vaginalis* are asymptomatic, although some develop urethritis and a few have epididymitis or prostatitis. In contrast, infection in women, which has an incubation period of 5–28 days, is usually symptomatic and manifests with malodorous vaginal discharge (often yellow), vulvar erythema and itching, dysuria or urinary frequency (in 30–50% of patients), and dyspareunia. These manifestations, however, do not clearly distinguish trichomoniasis from other types of infectious vaginitis.

DIAGNOSIS

Detection of motile trichomonads by microscopic examination of wet mounts of vaginal or prostatic secretions has been the conventional means of diagnosis. Although this approach provides an immediate diagnosis, its sensitivity for the detection of *T. vaginalis* is only ~50–60% in routine evaluations of vaginal secretions. Direct immunofluorescent antibody staining is more sensitive (70–90%) than wet-mount examinations. *T. vaginalis* can be recovered from the urethra of both males and females and is

detectable in males after prostatic massage. Culture of the parasite is the most sensitive means of detection; however, the facilities for culture are not generally available, and detection of the organism takes 3–7 days.

Rx Treatment: **TRICHOMONIASIS**

Metronidazole, given either as a single 2-g dose or in 500-mg doses twice daily for 7 days, is usually effective. Tinidazole (a single 2-g dose) is also effective. All sexual partners must be treated concurrently to prevent reinfection, especially from asymptomatic males. In males with persistent symptomatic urethritis after therapy for nongonococcal urethritis, metronidazole therapy should be considered for possible trichomoniasis. Alternatives to metronidazole for treatment during pregnancy are not readily available, although use of 100-mg clotrimazole vaginal suppositories nightly for 2 weeks may cure some infections in pregnant women. Reinfection often accounts for apparent treatment failures, but strains of *T. vaginalis* exhibiting high-level resistance to metronidazole have been encountered. Treatment of these resistant infections with higher oral doses, parenteral doses, or concurrent oral and vaginal doses of metronidazole or with tinidazole has been successful.

PART 3

HELMINTHIC INFECTIONS

CHAPTER 123

TRICHINELLA AND OTHER TISSUE NEMATODES

Peter F. Weller

Nematodes are elongated, symmetric roundworms. Parasitic nematodes of medical significance may be broadly classified as either predominantly intestinal or tissue nematodes. This chapter covers trichinellosis, visceral and ocular larva migrans, cutaneous larva migrans, cerebral

angiostrongyliasis, and gnathostomiasis. All are zoonotic infections caused by incidental exposure to infectious nematodes. The clinical symptoms of these infections are due largely to invasive larval stages that (except in the case of *Trichinella*) do not reach maturity in humans.

Trichinellosis develops after the ingestion of meat containing cysts of *Trichinella*—for example, pork or other meat from a carnivore. Although most infections are mild and asymptomatic, heavy infections can cause severe enteritis, periorbital edema, myositis, and (infrequently) death.

Life Cycle and Epidemiology

Eight species of *Trichinella* are recognized as causes of infection in humans. Two species are distributed worldwide: *T. spiralis*, which is found in a great variety of carnivorous and omnivorous animals, and *T. pseudospiralis*, which is found in mammals and birds.

T. nativa is present in Arctic regions and infects bears; *T. nelsoni* is found in equatorial eastern Africa, where it is common among felid predators and scavengers such as hyenas and bush pigs; and *T. britovi* is found in Europe, western Africa, and western Asia among carnivores but not among domestic swine. *T. murrelli* is present in North American game animals.

After human consumption of trichinous meat, encysted larvae are liberated by digestive acid and pepsin (Fig. 123-1). The larvae invade the small-bowel mucosa and mature into adult worms. After ~1 week, female worms release newborn larvae that migrate via the circulation to striated muscle. The larvae of all species except *T. pseudospiralis*, *T. papuae*, and *T. zimbabwensis* then encyst by inducing a radical transformation in the muscle cell architecture. Although host immune responses may help to expel intestinal adult worms, they have little effect on muscle-dwelling larvae.

Human trichinellosis is often caused by the ingestion of infected pork products and thus can occur in almost any location where the meat of domestic or wild swine is eaten. Human trichinellosis also may be acquired from the meat of other animals, including dogs (in parts of Asia and Africa), horses (in Italy and France), and bears and walrus (in northern regions). Although cattle (being herbivores) are not natural hosts of *Trichinella*, beef has been implicated in outbreaks when contaminated or adulterated with trichinous pork. Laws that prohibit the feeding of uncooked garbage to pigs have greatly reduced the transmission of trichinellosis in the United States. About 12 cases of trichinellosis are reported annually in this country, but most mild cases probably remain undiagnosed. Recent U.S. and Canadian outbreaks have been attributable to consumption of wild game (especially bear meat) and, less frequently, of pork.

Pathogenesis and Clinical Features

Clinical symptoms of trichinellosis arise from the successive phases of parasite enteric invasion, larval migration, and muscle encystment (Fig. 123-1). Most light infections (those with <10 larvae per gram of muscle) are asymptomatic, whereas heavy infections (which can involve >50 larvae per gram of muscle) can be life-threatening. Invasion of the gut by large numbers of parasites occasionally provokes diarrhea during the first week after infection. Abdominal pain, constipation, nausea, or vomiting also may be prominent.

Symptoms due to larval migration and muscle invasion begin to appear in the second week after infection. The

FIGURE 123-1

Life cycle of *Trichinella spiralis* (cosmopolitan); *nelsoni* (equatorial Africa); *britovi* (Europe, western Africa, western Asia); *nativa* (Arctic); *murrelli* (North America); *papuae* (Papua New Guinea); *zimbabwensis* (Tanzania); and *pseudospiralis* (cosmopolitan). [Reprinted from Guerrant RL et al (eds): *Tropical Infectious Diseases: Principles, Pathogens and Practice*, 2d ed, p 1218. © 2006, with permission from Elsevier Science.]

migrating *Trichinella* larvae provoke a marked local and systemic hypersensitivity reaction, with fever and hypereosinophilia. Periorbital and facial edema is common, as are hemorrhages in the subconjunctivae, retina, and nail beds (“splinter” hemorrhages). A maculopapular rash, headache, cough, dyspnea, or dysphagia sometimes develops. Myocarditis with tachyarrhythmias or heart failure—and, less commonly, encephalitis or pneumonitis—may develop and accounts for most deaths of patients with trichinellosis.

Upon onset of larval encystment in muscle 2–3 weeks after infection, symptoms of myositis with myalgias, muscle edema, and weakness develop, usually overlapping with the inflammatory reactions to migrating larvae. The most commonly involved muscle groups include the extraocular muscles; the biceps; and the muscles of the jaw, neck, lower back, and diaphragm. Peaking ~3 weeks after infection, symptoms subside only gradually during a prolonged convalescence. Uncommon infections with *T. pseudospiralis*, whose larvae do not encapsulate in muscles, elicit prolonged polymyositis-like illness.

Laboratory Findings and Diagnosis

Blood eosinophilia develops in >90% of patients with symptomatic trichinellosis and may peak at a level of >50% between 2 and 4 weeks after infection. Serum levels of muscle enzymes, including creatine phosphokinase, are elevated in most symptomatic patients. Patients should be questioned thoroughly about their consumption of pork or wild-animal meat and about illness in other individuals who ate the same meat. A presumptive clinical diagnosis can be based on fevers, eosinophilia, periorbital edema, and myalgias after a suspect meal. A rise in the titer of parasite-specific antibody, which usually does not occur until after the third week of infection, confirms the diagnosis. Alternatively, a definitive diagnosis requires surgical biopsy of at least 1 g of involved muscle; the yields are highest near tendon insertions. The fresh muscle tissue should be compressed between glass slides and examined microscopically (Fig. 123-2), because larvae may be overlooked by examination of routine histopathologic sections alone.

Rx Treatment: TRICHINELLOSIS

Most lightly infected patients recover uneventfully with bed rest, antipyretics, and analgesics. Glucocorticoids like prednisone (Table 123-1) are beneficial for severe myositis and myocarditis. Mebendazole and albendazole are active against enteric stages of the parasite, but their efficacy against encysted larvae has not been conclusively demonstrated.

Prevention

Larvae may be killed by cooking pork until it is no longer pink or by freezing it at –15°C for 3 weeks. However, Arctic *T. nativa* larvae in walrus or bear meat are relatively resistant and may remain viable despite freezing.

FIGURE 123-2

Trichinella larva encysted in a characteristic hyalinized capsule in striated muscle tissue. (Photo/Wadsworth Center, New York State Department of Health. Reprinted from CDC MMWR 53:606, 2004; public domain.)

VISCERAL AND OCULAR LARVA MIGRANS

Visceral larva migrans is a syndrome caused by nematodes that are normally parasitic for nonhuman host species. In humans, the nematode larvae do not develop into adult worms but instead migrate through host tissues and elicit eosinophilic inflammation. The more common form of visceral larva migrans is toxocariasis due to larvae of the canine ascarid *Toxocara canis*, less commonly to the feline ascarid *T. cati*, and even less commonly to the pig ascarid *Ascaris suum*. Rare cases with eosinophilic meningoencephalitis have been caused by the raccoon ascarid *Baylisascaris procyonis*.

Life Cycle and Epidemiology

The canine roundworm *T. canis* is distributed among dogs worldwide. Ingestion of infective eggs by dogs is followed by liberation of *Toxocara* larvae, which penetrate the gut wall and migrate intravascularly into canine tissues, where most remain in a developmentally arrested state. During pregnancy, some larvae resume migration in bitches and infect puppies prenatally (through transplacental transmission) or after birth (through suckling). Thus, in lactating bitches and puppies, larvae return to the intestinal tract and develop into adult worms, which produce eggs that are released in the feces. Humans acquire toxocariasis mainly by eating soil contaminated by puppy feces that contains infective *T. canis* eggs. Visceral larva migrans is most common among children who habitually eat dirt.

Pathogenesis and Clinical Features

Clinical disease most commonly afflicts preschool children. After humans ingest *Toxocara* eggs, the larvae hatch

THERAPY FOR TISSUE NEMATODE INFECTIONS

| INFECTION | SEVERITY | TREATMENT |
|-------------------------|------------------|---|
| Trichinellosis | Mild | Supportive |
| | Moderate | Albendazole (400 mg bid × 8–14 days) or Mebendazole (200–400 mg tid × 3 days, then 400 mg tid × 8–14 days) |
| | Severe | Add glucocorticoids (e.g., prednisone, 1 mg/kg qd × 5 days) |
| Visceral larva migrans | Mild to moderate | Supportive |
| | Severe | Glucocorticoids (as above) |
| | Ocular | Not fully defined; albendazole (800 mg bid for adults, 400 mg bid for children) with glucocorticoids × 5–20 days has been effective |
| Cutaneous larva migrans | | Ivermectin (single dose, 200 µg/kg) or Albendazole (200 mg bid × 3 days) |
| Angiostrongyliasis | Mild to moderate | Supportive |
| Gnathostomiasis | Severe | Glucocorticoids (as above) |
| | | Ivermectin (200 µg/kg per day × 2 days) or Albendazole (400 mg bid × 21 days) |

and penetrate the intestinal mucosa, from which they are carried by the circulation to a wide variety of organs and tissues. The larvae invade the liver, lungs, central nervous system (CNS), and other sites, provoking intense local eosinophilic granulomatous responses. The degree of clinical illness depends on larval number and tissue distribution, reinfection, and host immune responses. Most light infections are asymptomatic and may be manifest only by blood eosinophilia. Characteristic symptoms of visceral larva migrans include fever, malaise, anorexia and weight loss, cough, wheezing, and rashes. Hepatosplenomegaly is common. These features are often accompanied by extraordinary peripheral eosinophilia, which may approach 90%. Uncommonly, seizures or behavioral disorders develop. Rare deaths are due to severe neurologic, pneumonic, or myocardial involvement.

The ocular form of the larva migrans syndrome occurs when *Toxocara* larvae invade the eye. An eosinophilic granulomatous mass, most commonly in the posterior pole of the retina, develops around the entrapped larva. The retinal lesion can mimic retinoblastoma in appearance, and mistaken diagnosis of the latter condition can lead to unnecessary enucleation. The spectrum of eye involvement also includes endophthalmitis, uveitis, and chorioretinitis. Unilateral visual disturbances, strabismus, and eye pain are the most common presenting symptoms. In contrast to visceral larva migrans, ocular toxocariasis usually develops in older children or young adults with no history of pica; these patients seldom have eosinophilia or visceral manifestations.

Diagnosis

In addition to eosinophilia, leukocytosis and hypergammaglobulinemia may be evident. Transient pulmonary

infiltrates are apparent on chest x-rays of about half of patients with symptoms of pneumonitis. The clinical diagnosis can be confirmed by an enzyme-linked immunosorbent assay for toxocaral antibodies. Stool examination for parasite eggs, while important in the evaluation of unexplained eosinophilia, is worthless for toxocariasis, since the larvae do not develop into egg-producing adults in humans.

Treatment:
Rx VISCERAL AND OCULAR LARVA MIGRANS

The vast majority of *Toxocara* infections are self-limited and resolve without specific therapy. In patients with severe myocardial, CNS, or pulmonary involvement, glucocorticoids may be employed to reduce inflammatory complications. Available anthelmintic drugs, including mebendazole and albendazole, have not been shown conclusively to alter the course of larva migrans. Control measures include prohibiting dog excreta in public parks and playgrounds, deworming dogs, and preventing pica in children. Treatment of ocular disease is not fully defined, but the administration of albendazole in conjunction with glucocorticoids has been effective (Table 123-1).

CUTANEOUS LARVA MIGRANS

Cutaneous larva migrans (“creeping eruption”) is a serpiginous skin eruption caused by burrowing larvae of animal hookworms, usually the dog and cat hookworm *Ancylostoma braziliense*. The larvae hatch from eggs passed in dog and cat feces and mature in the soil. Humans

become infected after skin contact with soil in areas frequented by dogs and cats, such as areas underneath house porches. Cutaneous larva migrans is prevalent among children and travelers in regions with warm humid climates, including the southeastern United States.

After larvae penetrate the skin, erythematous lesions form along the tortuous tracks of their migration through the dermal-epidermal junction; the larvae advance several centimeters in a day. The intensely pruritic lesions may occur anywhere on the body and can be numerous if the patient has lain on the ground. Vesicles and bullae may form later. The animal hookworm larvae do not mature in humans and, without treatment, will die after an interval ranging from weeks to a couple of months, with resolution of skin lesions. The diagnosis is made on clinical grounds. Skin biopsies only rarely detect diagnostic larvae. Symptoms can be alleviated by ivermectin or albendazole (Table 123-1).

ANGIOSTRONGYLIASIS

Angiostrongylus cantonensis, the rat lungworm, is the most common cause of human eosinophilic meningitis (Fig. 123-3).

Life Cycle and Epidemiology

This infection occurs principally in Southeast Asia and the Pacific Basin but has spread to other areas of the world. *A. cantonensis* larvae produced by adult worms in the rat lung migrate to the gastrointestinal tract and are expelled with the feces. They develop into infective larvae in land snails and slugs. Humans acquire the infection by ingesting raw infected mollusks; vegetables contaminated by mollusk slime; or crabs, freshwater shrimp, and certain marine fish that have themselves eaten infected mollusks. The larvae then migrate to the brain.

Pathogenesis and Clinical Features

The parasites eventually die in the CNS, but not before initiating pathologic consequences that, in heavy infections, can result in permanent neurologic sequelae or death. Migrating larvae cause marked local eosinophilic inflammation and hemorrhage, with subsequent necrosis and granuloma formation around dying worms. Clinical symptoms develop 2–35 days after the ingestion of larvae. Patients usually present with an insidious or abrupt excruciating frontal, occipital, or bitemporal headache. Neck stiffness, nausea and vomiting, and paresthesias are also common. Fever, cranial and extraocular nerve palsies, seizures, paralysis, and lethargy are uncommon.

Laboratory Findings

Examination of cerebrospinal fluid (CSF) is mandatory in suspected cases and usually reveals an elevated opening pressure, a white blood cell count of 150–2000/ μ L, and an eosinophilic pleocytosis of >20%. The protein concentration is usually elevated and the glucose level normal. The larvae of *A. cantonensis* are only rarely seen in CSF. Peripheral-blood eosinophilia may be mild. The diagnosis is generally based on the clinical presentation of eosinophilic meningitis together with a compatible epidemiologic history.

Treatment: ANGIOSTRONGYLIASIS

Specific chemotherapy is not of benefit in angiostrongyliasis; larvicidal agents may exacerbate inflammatory brain lesions. Management consists of supportive measures, including the administration of analgesics, sedatives, and—in severe cases—glucocorticoids (Table 123-1). Repeated lumbar punctures with removal of CSF can relieve symptoms. In most patients,

FIGURE 123-3

Life cycle of *Angiostrongylus cantonensis* (rat lung worm). Also found in Southeast Asia, Pacific Islands, Cuba, Australia, Japan, China, Mauritius, and U.S. ports. [Reprinted from Guerrant RL et al (eds): *Tropical Infectious Diseases: Principles, Pathogens and Practice*, 2d ed, p 1225. (c) 2006, with permission from Elsevier Science.]

cerebral angiostrongyliasis has a self-limited course, and recovery is complete. The infection may be prevented by adequately cooking snails, crabs, and prawns and inspecting vegetables for mollusk infestation. Other parasitic or fungal causes of eosinophilic meningitis in endemic areas may include gnathostomiasis (see below), paragonimiasis (Chap. 126), schistosomiasis (Chap. 126), neurocysticercosis (Chap. 127), and coccidiodomycosis (Chap. 104).

GNATHOSTOMIASIS

Infection of human tissues with larvae of *Gnathostoma spinigerum* can cause eosinophilic meningoencephalitis, migratory cutaneous swellings, or invasive masses of the eye and visceral organs.

Life Cycle and Epidemiology

Human gnathostomiasis occurs in many countries and is notably endemic in Southeast Asia and parts of China and Japan. In nature, the mature adult worms parasitize the gastrointestinal tract of dogs and cats. First-stage larvae hatch from eggs passed into water and are ingested by *Cyclops* species (water fleas). Infective third-stage larvae develop in the flesh of many animal species (including fish, frogs, eels, snakes, chickens, and ducks) that have eaten either infected *Cyclops* or another infected second intermediate host. Humans typically acquire the infection by eating raw or undercooked fish or poultry. Raw fish dishes, such as *som fak* in Thailand and *sashimi* in Japan, account for many cases of human gnathostomiasis. Some cases in Thailand result from the local practice of applying frog or snake flesh as a poultice.

Pathogenesis and Clinical Features

Clinical symptoms are due to the aberrant migration of a single larva into cutaneous, visceral, neural, or ocular tissues. After invasion, larval migration may cause local inflammation, with pain, cough, or hematuria accompanied by fever and eosinophilia. Painful, itchy, migratory swellings may develop in the skin, particularly in the distal extremities or periorbital area. Cutaneous swellings usually last ~1 week but often recur intermittently over many years. Larval invasion of the eye can provoke a sight-threatening inflammatory response. Invasion of the CNS results in eosinophilic meningitis with myeloencephalitis, a serious complication due to ascending larval migration along a large nerve track. Patients characteristically present with agonizing radicular pain and paresthesias in the trunk or a limb, which are followed

shortly by paraplegia. Cerebral involvement, with focal hemorrhages and tissue destruction, is often fatal.

Diagnosis and Treatment

Cutaneous migratory swellings with marked peripheral eosinophilia, supported by an appropriate geographic and dietary history, generally constitute an adequate basis for a clinical diagnosis of gnathostomiasis. However, patients may present with ocular or cerebrospinal involvement without antecedent cutaneous swellings. In the latter case, eosinophilic pleocytosis is demonstrable (usually along with hemorrhagic or xanthochromic CSF), but worms are almost never recovered from CSF. Surgical removal of the parasite from subcutaneous or ocular tissue, though rarely feasible, is both diagnostic and therapeutic. Albendazole or ivermectin may be helpful (Table 123-1). At present, cerebrospinal involvement is managed with supportive measures and generally with a course of glucocorticoids. Gnathostomiasis can be prevented by adequate cooking of fish and poultry in endemic areas.

CHAPTER 124

INTESTINAL NEMATODES

Peter F. Weller ■ Thomas B. Nutman

More than a billion persons worldwide are infected with one or more species of intestinal nematodes. **Table 124-1** summarizes biologic and clinical features of infections due to the major intestinal parasitic nematodes. These parasites are most common in regions with poor fecal sanitation, particularly in resource-poor countries in the tropics and subtropics, but they have also been seen with increasing frequency among immigrants and refugees to resource-rich countries. Although nematode infections are not usually fatal, they contribute to malnutrition and diminished work capacity. It is interesting that these helminth infections may protect some individuals from allergic disease. Humans may on occasion be infected with nematode parasites that ordinarily infect animals; these zoonotic infections produce diseases such as trichostrongyliasis, anisakiasis, capillariasis, and abdominal angiostrongyliasis.

Intestinal nematodes are roundworms; they range in length from 1 mm to many centimeters when mature (Table 124-1). Their life cycles are complex and highly varied; some species, including *Strongyloides stercoralis* and *Enterobius vermicularis*, can be transmitted directly from person to person, while others, such as *Ascaris lumbricoides*, *Necator americanus*, and *Ancylostoma duodenale*, require a soil phase for development. Because most helminth parasites do not self-replicate, the acquisition of a heavy burden of adult worms requires repeated exposure to the parasite in its infectious stage, whether larva or egg. Hence, clinical disease, as opposed to asymptomatic infection, generally develops only with prolonged residence in an endemic area. In persons with marginal nutrition, intestinal helminth infections may impair growth and development. Eosinophilia and elevated serum IgE levels are features of many helminthic infections and, when unexplained, should always prompt a search for occult helminthiasis. Significant protective immunity to intestinal nematodes appears not to develop in humans, although mechanisms of parasite immune evasion and host immune responses to these infections have not been elucidated in detail.

ASCARIASIS

A. lumbricoides is the largest intestinal nematode parasite of humans, reaching up to 40 cm in length. Most infected individuals have low worm burdens and are asymptomatic. Clinical disease arises from larval

migration in the lungs or effects of the adult worms in the intestines.

Life Cycle

Adult worms live in the lumen of the small intestine. Mature female *Ascaris* worms are extraordinarily fecund, each producing up to 240,000 eggs a day, which pass with the feces. Ascarid eggs, which are remarkably resistant to environmental stresses, become infective after several weeks of maturation in the soil and can remain infective for years. After infective eggs are swallowed, larvae hatched in the intestine invade the mucosa, migrate through the circulation to the lungs, break into the alveoli, ascend the bronchial tree, and return via swallowing to the small intestine, where they develop into adult worms. Between 2 and 3 months elapse between initial infection and egg production. Adult worms live for 1–2 years.

Epidemiology

Ascaris is widely distributed in tropical and subtropical regions as well as in other humid areas, including the rural southeastern United States. Transmission typically occurs through fecally contaminated soil and is due either to a lack of sanitary facilities or to the use of human feces as fertilizer. With their propensity for hand-to-mouth fecal carriage, younger children are most affected. Infection outside endemic areas, though uncommon, can occur when eggs on transported vegetables are ingested.

Clinical Features

During the lung phase of larval migration, ~9–12 days after egg ingestion, patients may develop an irritating nonproductive cough and burning substernal discomfort that is aggravated by coughing or deep inspiration. Dyspnea and blood-tinged sputum are less common. Fever is usually reported. Eosinophilia develops during this symptomatic phase and subsides slowly over weeks. Chest x-rays may reveal evidence of eosinophilic pneumonitis (Löffler's syndrome), with rounded infiltrates a few millimeters to several centimeters in size. These infiltrates may be transient and intermittent, clearing after several weeks. Where there is seasonal transmission of the parasite, seasonal pneumonitis with eosinophilia may develop in previously infected and sensitized hosts.

MAJOR HUMAN INTESTINAL PARASITIC NEMATODES

| FEATURE | PARASITIC NEMATODE | | | | |
|--|--|---|--|--|---|

^aTime from infection to egg production by mature female worm.

In established infections, adult worms in the small intestine usually cause no symptoms. In heavy infections, particularly in children, a large bolus of entangled worms can cause pain and small-bowel obstruction, sometimes complicated by perforation, intussusception, or volvulus. Single worms may cause disease when they migrate into aberrant sites. A large worm can enter and occlude the biliary tree, causing biliary colic, cholecystitis, cholangitis, pancreatitis, or (rarely) intrahepatic abscesses. Migration of an adult worm up the esophagus can provoke coughing and oral expulsion of the worm. In highly endemic areas, intestinal and biliary ascariasis can rival acute appendicitis and gallstones as causes of surgical acute abdomen.

Laboratory Findings

Most cases of ascariasis can be diagnosed by microscopic detection of characteristic *Ascaris* eggs (65 by 45 μm) in fecal samples. Occasionally, patients present after passing an adult worm—identifiable by its large size and smooth cream-colored surface—in the stool or through the mouth or nose. During the early transpulmonary migratory phase, when eosinophilic pneumonitis occurs, larvae can be found in sputum or gastric aspirates before diagnostic eggs appear in the stool. The eosinophilia that is prominent during this early stage usually decreases to minimal levels in established infection. Adult worms may be visualized, occasionally serendipitously, on contrast studies of the gastrointestinal tract. A plain abdominal

film may reveal masses of worms in gas-filled loops of bowel in patients with intestinal obstruction. Pancreaticobiliary worms can be detected by ultrasound and endoscopic retrograde cholangiopancreatography; the latter method also has been used to extract biliary *Ascaris* worms.

Rx Treatment: **ASCARIASIS**

Ascariasis should always be treated to prevent potentially serious complications. Albendazole (400 mg once), mebendazole (500 mg once), or ivermectin (150–200 µg/kg once) is effective. These medications are contraindicated in pregnancy, however. Pyrantel pamoate (11 mg/kg once; maximum, 1 g) is safe in pregnancy. Mild diarrhea and abdominal pain are uncommon side effects of these agents. Partial intestinal obstruction should be managed with nasogastric suction, IV fluid administration, and instillation of piperazine through the nasogastric tube, but complete obstruction and its severe complications require immediate surgical intervention.

HOOKWORM

Two hookworm species (*A. duodenale* and *N. americanus*) are responsible for human infections. Most infected individuals are asymptomatic. Hookworm disease develops from a combination of factors—a heavy worm burden, a prolonged duration of infection, and an inadequate iron intake—and results in iron-deficiency anemia and, on occasion, hypoproteinemia.

Life Cycle

Adult hookworms, which are ~1 cm long, use buccal teeth (*Ancylostoma*) or cutting plates (*Necator*) to attach to the small-bowel mucosa and suck blood (0.2 mL/d per *Ancylostoma* adult) and interstitial fluid. The adult hookworms produce thousands of eggs daily. The eggs are deposited with feces in soil, where rhabditiform larvae hatch and develop over a 1-week period into infectious filariform larvae. Infective larvae penetrate the skin and reach the lungs by way of the bloodstream. There they invade alveoli and ascend the airways before being swallowed and reaching the small intestine. The prepatent period from skin invasion to appearance of eggs in the feces is ~6–8 weeks, but it may be longer with *A. duodenale*. Larvae of *A. duodenale*, if swallowed, can survive and develop directly in the intestinal mucosa. Adult hookworms may survive over a decade but usually live ~6–8 years for *A. duodenale* and 2–5 years for *N. americanus*.

Epidemiology

A. duodenale is prevalent in southern Europe, North Africa, and northern Asia, and *N. americanus* is the predominant species in the western hemisphere and equatorial Africa. The two species overlap

in many tropical regions, particularly Southeast Asia. In most areas, older children have the highest incidence and greatest intensity of hookworm infection. In rural areas where fields are fertilized with human feces, older working adults also may be heavily affected.

Clinical Features

Most hookworm infections are asymptomatic. Infective larvae may provoke pruritic maculopapular dermatitis (“ground itch”) at the site of skin penetration as well as serpiginous tracks of subcutaneous migration (similar to those of cutaneous larva migrans; Chap. 123) in previously sensitized hosts. Larvae migrating through the lungs occasionally cause mild transient pneumonitis, but this condition develops less frequently in hookworm infection than in ascariasis. In the early intestinal phase, infected persons may develop epigastric pain (often with postprandial accentuation), inflammatory diarrhea, or other abdominal symptoms accompanied by eosinophilia. The major consequence of chronic hookworm infection is iron deficiency. Symptoms are minimal if iron intake is adequate, but marginally nourished individuals develop symptoms of progressive iron-deficiency anemia and hypoproteinemia, including weakness and shortness of breath.

Laboratory Findings

The diagnosis is established by the finding of characteristic 40- by 60-µm oval hookworm eggs in the feces. Stool-concentration procedures may be required to detect light infections. Eggs of the two species are indistinguishable by light microscopy. In a stool sample that is not fresh, the eggs may have hatched to release rhabditiform larvae, which need to be differentiated from those of *S. stercoralis*. Hypochromic microcytic anemia, occasionally with eosinophilia or hypoalbuminemia, is characteristic of hookworm disease.

Rx Treatment: **HOOKWORM INFECTION**

Hookworm infection can be eradicated with several safe and highly effective anthelmintic drugs, including albendazole (400 mg once), mebendazole (500 mg once), and pyrantel pamoate (11 mg/kg for 3 days). Mild iron-deficiency anemia can often be treated with oral iron alone. Severe hookworm disease with protein loss and malabsorption necessitates nutritional support and oral iron replacement along with deworming.

Ancylostoma Caninum* and *Ancylostoma Braziliense

A. caninum, the canine hookworm, has been identified as a cause of human eosinophilic enteritis, especially in northeastern Australia. In this zoonotic infection, adult hookworms attach to the small intestine (where they may be visualized by endoscopy) and elicit abdominal pain and intense local eosinophilia. Treatment with

1142 mebendazole (100 mg twice daily for 3 days) or albendazole (400 mg once) or endoscopic removal is effective. Both of these animal hookworm species can cause cutaneous larva migrans (“creeping eruption”; Chap. 123).

STRONGYLOIDIASIS

S. stercoralis is distinguished by its ability—unusual among helminths—to replicate in the human host. This capacity permits ongoing cycles of autoinfection as infective larvae are internally produced. Strongyloidiasis can thus persist for decades without further exposure of the host to exogenous infective larvae. In immunocompromised hosts, large numbers of invasive *Strongyloides* larvae can disseminate widely and can be fatal.

Life Cycle

In addition to a parasitic cycle of development, *Strongyloides* can undergo a free-living cycle of development in the soil (Fig. 124-1). This adaptability facilitates the parasite’s survival in the absence of mammalian hosts. Rhabditiform larvae passed in feces can transform into infectious filariform larvae either directly or after a free-living

phase of development. Humans acquire strongyloidiasis when filariform larvae in fecally contaminated soil penetrate the skin or mucous membranes. The larvae then travel through the bloodstream to the lungs, where they break into the alveolar spaces, ascend the bronchial tree, are swallowed, and thereby reach the small intestine. There the larvae mature into adult worms that penetrate the mucosa of the proximal small bowel. The minute (2-mm-long) parasitic adult female worms reproduce by parthenogenesis; adult males do not exist. Eggs hatch in the intestinal mucosa, releasing rhabditiform larvae that migrate to the lumen and pass with the feces into soil. Alternatively, rhabditiform larvae in the bowel can develop directly into filariform larvae that penetrate the colonic wall or perianal skin and enter the circulation to repeat the migration that establishes ongoing internal reinfection. This autoinfection cycle allows strongyloidiasis to persist for decades.

Epidemiology

S. stercoralis is spottily distributed in tropical areas and other hot, humid regions and is particularly common in Southeast Asia, sub-Saharan Africa,

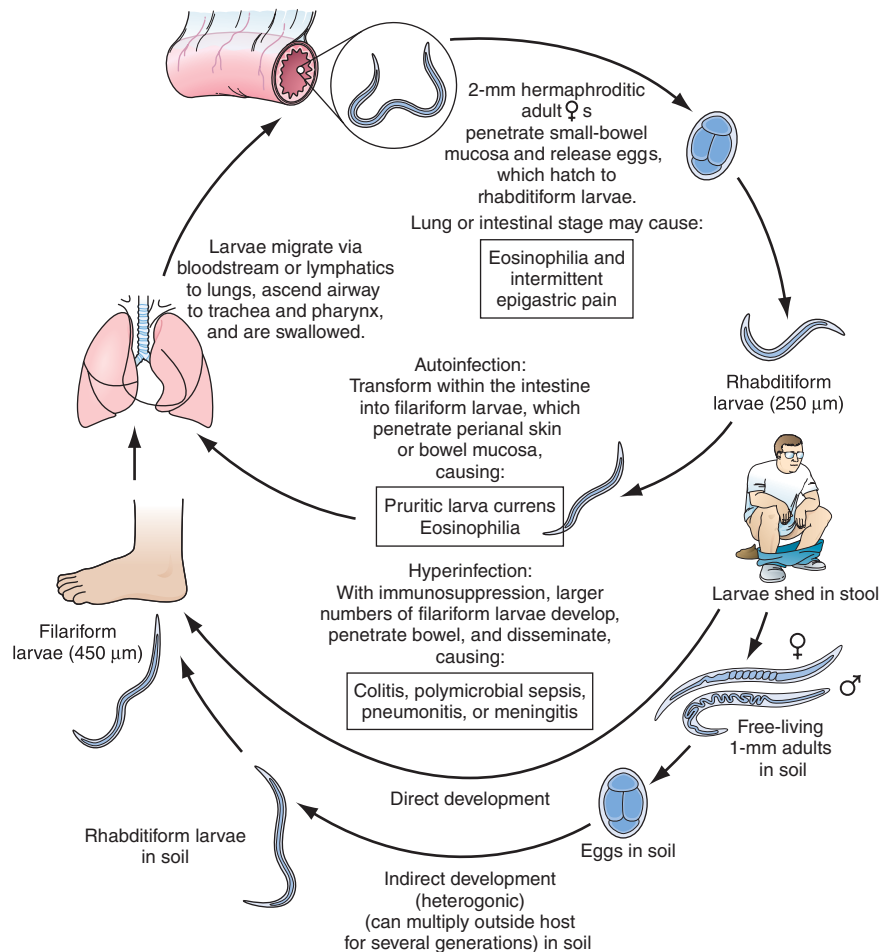

FIGURE 124-1

Life cycle of *Strongyloides stercoralis*. [Adapted from Guerant RL et al (eds): *Tropical Infectious Diseases: Principles,*

Pathogens and Practice, 2d ed, p 1276. © 2006, with permission from Elsevier Science.]

and Brazil. In the United States, the parasite is endemic in parts of the South and is found in immigrants and military veterans who have lived in endemic areas abroad.

Clinical Features

In uncomplicated strongyloidiasis, many patients are asymptomatic or have mild cutaneous and/or abdominal symptoms. Recurrent urticaria, often involving the buttocks and wrists, is the most common cutaneous manifestation. Migrating larvae can elicit a pathognomonic serpiginous eruption, *larva currens* (“running larva”). This pruritic, raised, erythematous lesion advances as rapidly as 10 cm/h along the course of larval migration. Adult parasites burrow into the duodenojejunal mucosa and can cause abdominal (usually midepigastria) pain, which resembles peptic ulcer pain except that it is aggravated by food ingestion. Nausea, diarrhea, gastrointestinal bleeding, mild chronic colitis, and weight loss can occur. Small-bowel obstruction may develop with early, heavy infection. Pulmonary symptoms are rare in uncomplicated strongyloidiasis. Eosinophilia is common, with levels fluctuating over time.

The ongoing autoinfection cycle of strongyloidiasis is normally contained by unknown factors of the host's immune system. Abrogation of host immunity, especially with glucocorticoid therapy and much less commonly with other immunosuppressive medications, leads to hyperinfection, with the generation of large numbers of filariform larvae. Colitis, enteritis, or malabsorption may develop. In disseminated strongyloidiasis, larvae may invade not only gastrointestinal tissues and the lungs but also the central nervous system, peritoneum, liver, and kidneys. Moreover, bacteremia may develop because of the passage of enteric flora through disrupted mucosal barriers. Gram-negative sepsis, pneumonia, or meningitis may complicate or dominate the clinical course. Eosinophilia is often absent in severely infected patients. Disseminated strongyloidiasis, particularly in patients with unsuspected infection who are given glucocorticoids, can be fatal. Strongyloidiasis is a frequent complication of infection with human T-cell lymphotropic virus type I, but disseminated strongyloidiasis is not common among patients infected with HIV.

Diagnosis

In uncomplicated strongyloidiasis, the finding of rhabditiform larvae in feces is diagnostic. Rhabditiform larvae are ~250 µm long, with a short buccal cavity that distinguishes them from hookworm larvae. In uncomplicated infections, few larvae are passed and single stool examinations detect only about one-third of cases. Serial examinations and the use of the agar plate detection method improve the sensitivity of stool diagnosis. In uncomplicated strongyloidiasis (but not in hyperinfection), stool examinations may be repeatedly negative. *Strongyloides* larvae may also be found by sampling of the duodenojejunal contents by aspiration or biopsy. An enzyme-linked immunosorbent assay for serum antibodies to antigens of *Strongyloides* is a sensitive method of

diagnosing uncomplicated infections. Such serologic testing should be performed for patients whose geographic histories indicate potential exposure, especially those who exhibit eosinophilia and/or are candidates for glucocorticoid treatment of other conditions. In disseminated strongyloidiasis, filariform larvae should be sought in stool as well as in samples obtained from sites of potential larval migration, including sputum, bronchoalveolar lavage fluid, or surgical drainage fluid.

R_x Treatment: STRONGYLOIDIASIS

Even in the asymptomatic state, strongyloidiasis must be treated because of the potential for subsequent fatal hyperinfection. Ivermectin (200 µg/kg daily for 2 days) is more effective than albendazole (400 mg daily for 3 days). For disseminated strongyloidiasis, treatment with ivermectin should be extended for at least 5–7 days or until the parasites are eradicated.

TRICHURIASIS

Most infections with the *Trichuris trichiura* are asymptomatic, but heavy infections may cause gastrointestinal symptoms. Like the other soil-transmitted helminths, whipworm is distributed globally in the tropics and subtropics and is most common among poor children from resource-poor regions of the world.

Life Cycle

Adult *Trichuris* worms reside in the colon and cecum, the anterior portions threaded into the superficial mucosa. Thousands of eggs laid daily by adult female worms pass with the feces and mature in the soil. After ingestion, infective eggs hatch in the duodenum, releasing larvae that mature before migrating to the large bowel. The entire cycle takes ~3 months, and adult worms may live for several years.

Clinical Features

Tissue reactions to *Trichuris* are mild. Most infected individuals have no symptoms or eosinophilia. Heavy infections may result in abdominal pain, anorexia, and bloody or mucoid diarrhea resembling inflammatory bowel disease. Rectal prolapse can result from massive infections in children, who often suffer from malnourishment and other diarrheal illnesses. Moderately heavy *Trichuris* burdens also contribute to growth retardation.

Diagnosis and Treatment

The characteristic 50- by 20-µm lemon-shaped *Trichuris* eggs are readily detected on stool examination. Adult worms, which are 3–5 cm long, are occasionally seen on proctoscopy. Mebendazole (500 mg once) or albendazole (400 mg daily for 3 doses) is safe and effective

1144 for treatment. Ivermectin (200 µg/kg daily for 3 doses) is also safe but is not quite as efficacious as the benzimidazoles.

ENTEROBIASIS (PINWORM)

E. vermicularis is more common in temperate countries than in the tropics. In the United States, ~40 million persons are infected with pinworms, with a disproportionate number of cases among children.

Life Cycle and Epidemiology

Enterobius adult worms are ~1 cm long and dwell in the cecum. Gravid female worms migrate nocturnally into the perianal region and release up to 10,000 immature eggs each. The eggs become infective within hours and are transmitted by hand-to-mouth passage. From ingested eggs, larvae hatch and mature into adults. This life cycle takes ~1 month, and adult worms survive for ~2 months. Self-infection results from perianal scratching and transport of infective eggs on the hands or under the nails to the mouth. Because of the ease of person-to-person spread, pinworm infections are common among family members.

Clinical Features

Most pinworm infections are asymptomatic. Perianal pruritus is the cardinal symptom. The itching, which is often worse at night as a result of the nocturnal migration of the female worms, may lead to excoriation and bacterial superinfection. Heavy infections have been claimed to cause abdominal pain and weight loss. On rare occasions, pinworms invade the female genital tract, causing vulvovaginitis and pelvic or peritoneal granulomas. Eosinophilia is uncommon.

Diagnosis

Since pinworm eggs are not released in feces, the diagnosis cannot be made by conventional fecal ova and parasites tests. Instead, eggs are detected by the application of clear cellulose acetate tape to the perianal region in the morning. After the tape is transferred to a slide, microscopic examination will detect pinworm eggs, which are oval, measure 55 by 25 µm, and are flattened along one side.

Treatment: ENTEROBIASIS

Infected children and adults should be treated with mebendazole (100 mg once), albendazole (400 mg once), or pyrantel pamoate (11 mg/kg once; maximum, 1 g), with the same treatment repeated after 2 weeks. Treatment of household members is advocated to eliminate asymptomatic reservoirs of potential reinfection.

TRICHOSTRONGYLIASIS

Trichostrongylus species, which are normally parasites of herbivorous animals, occasionally infect humans, particularly in Asia and Africa. Humans acquire the infection by accidentally ingesting *Trichostrongylus* larvae on contaminated leafy vegetables. The larvae do not migrate in humans but mature directly into adult worms in the small bowel. These worms ingest far less blood than hookworms; most infected persons are asymptomatic, but heavy infections may give rise to mild anemia and eosinophilia. *Trichostrongylus* eggs in stool examinations resemble those of hookworms but are larger (85 by 115 µm). Treatment consists of mebendazole or albendazole (Chap. 113).

ANISAKIASIS

Anisakiasis is a gastrointestinal infection caused by the accidental ingestion in uncooked saltwater fish of nematode larvae belonging to the family Anisakidae. The incidence of anisakiasis in the United States has increased as a result of the growing popularity of raw fish dishes. Most cases occur in Japan, the Netherlands, and Chile, where raw fish—sashimi, pickled green herring, and ceviche, respectively—are national culinary staples. Anisakid nematodes parasitize large sea mammals such as whales, dolphins, and seals. As part of a complex parasitic life cycle involving marine food chains, infectious larvae migrate to the musculature of a variety of fish. Both *Anisakis simplex* and *Pseudoterranova decipiens* have been implicated in human anisakiasis, but an identical gastric syndrome may be caused by the red larvae of eustrongylid parasites of fish-eating birds.

When humans consume infected raw fish, live larvae may be coughed up within 48 h. Alternatively, larvae may immediately penetrate the mucosa of the stomach. Within hours, violent upper abdominal pain accompanied by nausea and occasionally vomiting ensues, mimicking an acute abdomen. The diagnosis can be established by direct visualization on upper endoscopy, outlining of the worm by contrast radiographic studies, or histopathologic examination of extracted tissue. Extraction of the burrowing larvae during endoscopy is curative. In addition, larvae may pass to the small bowel, where they penetrate the mucosa and provoke a vigorous eosinophilic granulomatous response. Symptoms may appear 1–2 weeks after the infective meal, with intermittent abdominal pain, diarrhea, nausea, and fever resembling the manifestations of Crohn's disease. The diagnosis may be suggested by barium studies and confirmed by curative surgical resection of a granuloma in which the worm is embedded. Anisakid eggs are not found in the stool, since the larvae do not mature in humans. Anisakid larvae in saltwater fish are killed by cooking to 60°C, freezing at –20°C for 3 days, or commercial blast freezing, but not usually by salting, marinating, or cold smoking. No medical treatment is available; surgical or endoscopic removal should be undertaken.

CAPILLARIASIS

Intestinal capillariasis is caused by ingestion of raw fish infected with *Capillaria philippinensis*. Subsequent autoinfection can lead to a severe wasting syndrome. The disease occurs in the Philippines and Thailand and, on occasion, elsewhere in Asia. The natural cycle of *C. philippinensis* involves fish from fresh and brackish water. When humans eat infected raw fish, the larvae mature in the intestine into adult worms, which produce invasive larvae that cause intestinal inflammation and villus loss. Capillariasis has an insidious onset with nonspecific abdominal pain and watery diarrhea. If untreated, progressive autoinfection can lead to protein-losing enteropathy and severe malabsorption and ultimately to death from cachexia, cardiac failure, or superinfection. The diagnosis is established by identification of the characteristic peanut-shaped (20- by 40- μ m) eggs on stool examination. Severely ill patients require hospitalization and supportive therapy in addition to prolonged anthelmintic treatment with mebendazole or albendazole (Chap. 113).

ABDOMINAL ANGIOSTRONGYLIASIS

Abdominal angiostrongyliasis is found in Latin America and Africa. The zoonotic parasite *Angiostrongylus costaricensis* causes eosinophilic ileocolitis after the ingestion of contaminated vegetation. *A. costaricensis* normally parasitizes the cotton rat and other rodents, with slugs and snails serving as intermediate hosts. Humans become infected by accidentally ingesting infective larvae in mollusk slime deposited on fruits and vegetables; children are at highest risk. The larvae penetrate the gut wall and migrate to the mesenteric artery, where they develop into adult worms. Eggs deposited in the gut wall provoke an intense eosinophilic granulomatous reaction, and adult worms may cause mesenteric arteritis, thrombosis,

or frank bowel infarction. Symptoms may mimic those of appendicitis, including abdominal pain and tenderness, fever, vomiting, and a palpable mass in the right iliac fossa. Leukocytosis and eosinophilia are prominent. A barium enema may reveal ileocecal-filling defects, but a definitive diagnosis is usually made surgically with partial bowel resection. Pathologic study reveals a thickened bowel wall with eosinophilic granulomas surrounding the *Angiostrongylus* eggs. In nonsurgical cases, the diagnosis rests solely on clinical grounds because larvae and eggs cannot be detected in the stool. Medical therapy for abdominal angiostrongyliasis (mebendazole, thiabendazole; Chap. 113) is of uncertain efficacy. Careful observation and surgical resection for severe symptoms are the mainstays of treatment.

CHAPTER 125

FILARIAL AND RELATED INFECTIONS

Thomas B. Nutman ■ Peter F. Weller

Filarial worms are nematodes that dwell in the subcutaneous tissues and the lymphatics. Eight filarial species infect humans (Table 125-1); of these, four—*Wuchereria bancrofti*, *Brugia malayi*, *Onchocerca volvulus*, and *Loa loa*—are responsible for most serious filarial infections. Filarial parasites, which infect an estimated 170 million persons worldwide, are transmitted by specific species of

mosquitoes or other arthropods and have a complex life cycle including infective larval stages carried by insects and adult worms that reside in either lymphatic or subcutaneous tissues of humans. The offspring of adults are microfilariae, which, depending on their species, are 200–250 μ m long and 5–7 μ m wide, may or may not be enveloped in a loose sheath, and either circulate in the

CHARACTERISTICS OF THE FILARIAE

| ORGANISM | PERIODICITY | DISTRIBUTION | VECTOR | LOCATION OF ADULT | MICROFILARIAL LOCATION | SHEATH |
|-----------------------------|-------------|--|--|--|------------------------|--------|
| <i>Wuchereria bancrofti</i> | Nocturnal | Cosmopolitan areas worldwide, including South America and Africa | <i>Culex</i> (mosquitoes) | Lymphatic tissue | Blood | + |
| | | Mainly India | <i>Anopheles</i> (mosquitoes) | | | |
| | | China, Indonesia | <i>Aedes</i> (mosquitoes) | | | |
| <i>Brugia malayi</i> | Nocturnal | Eastern Pacific | <i>Aedes</i> (mosquitoes) | Lymphatic tissue | Blood | + |
| | | Southeast Asia, Indonesia, India | <i>Mansonia</i> , <i>Anopheles</i> (mosquitoes) | | | |
| | | Indonesia, Southeast Asia | <i>Coquillettidia</i> , <i>Mansonia</i> (mosquitoes) | | | |
| <i>B. timori</i> | Nocturnal | Indonesia | <i>Anopheles</i> (mosquitoes) | Lymphatic tissue | Blood | + |
| <i>Loa loa</i> | Diurnal | West and Central Africa | <i>Chrysops</i> (deerflies) | Subcutaneous tissue | Blood | + |
| <i>Onchocerca volvulus</i> | None | South and Central America, Africa | <i>Simulium</i> (blackflies) | Subcutaneous tissue | Skin, eye | – |
| <i>Mansonella ozzardi</i> | None | South and Central America, Caribbean | <i>Culicoides</i> (midges), <i>Simulium</i> (blackflies) | Undetermined site | Blood | – |
| <i>M. perstans</i> | None | South and Central America, Africa | <i>Culicoides</i> (midges) | Body cavities, mesentery, perirenal tissue | Blood | – |
| <i>M. streptocerca</i> | None | West and Central Africa | <i>Culicoides</i> (midges) | Subcutaneous tissue | Skin | – |

blood or migrate through the skin (Table 125-1). To complete the life cycle, microfilariae are ingested by the arthropod vector and develop over 1–2 weeks into new infective larvae. Adult worms live for many years, whereas microfilariae survive for 3–36 months. The *Rickettsia*-like endosymbiont *Wolbachia* has been found intracellularly in all stages of *Brugia*, *Wuchereria*, *Mansonella*, and *Onchocerca* and is viewed as a possible target for antifilarial chemotherapy.

Usually, infection is established only with repeated, prolonged exposures to infective larvae. Since the clinical manifestations of filarial diseases develop relatively slowly, these infections should be considered to induce chronic diseases with possible long-term debilitating effects. In terms of the nature, severity, and timing of clinical manifestations, patients with filarial infections who are native to endemic areas and undergo lifelong exposure may differ significantly from those who are travelers or who have recently moved to these areas. Characteristically, filarial disease is more acute and intense in newly exposed individuals than in natives of endemic areas.

LYMPHATIC FILARIASIS

Lymphatic filariasis is caused by *W. bancrofti*, *B. malayi*, or *B. timori*. The threadlike adult parasites reside in lymphatic channels or lymph nodes, where they may remain viable for more than two decades.

EPIDEMIOLOGY

W. bancrofti, the most widely distributed human filarial parasite, affects an estimated 115 million people and is found throughout the tropics and subtropics, including Asia and the Pacific Islands, Africa, areas of South America, and the Caribbean basin. Humans are the only definitive host for the parasite. Generally, the subperiodic form is found only in the Pacific Islands; elsewhere, *W. bancrofti* is nocturnally periodic. (Nocturnally periodic forms of microfilariae are scarce in peripheral blood by day and increase at night, whereas subperiodic forms are present in peripheral blood at all times and reach maximal levels in the afternoon.) Natural vectors for *W. bancrofti* are *Culex fatigans*

mosquitoes in urban settings and anopheline or aedeon mosquitoes in rural areas.

Brugian filariasis due to *B. malayi* occurs primarily in China, India, Indonesia, Korea, Japan, Malaysia, and the Philippines. *B. malayi* also has two forms distinguished by the periodicity of microfilaremia. The more common nocturnal form is transmitted in areas of coastal rice fields, while the subperiodic form is found in forests. *B. malayi* naturally infects cats as well as humans. *B. timori* exists only on islands of the Indonesian archipelago.

PATHOLOGY

The principal pathologic changes result from inflammatory damage to the lymphatics, which is typically caused by adult worms and not by microfilariae. Adult worms live in afferent lymphatics or sinuses of lymph nodes and cause lymphatic dilatation and thickening of the vessel walls. The infiltration of plasma cells, eosinophils, and macrophages in and around the infected vessels, along with endothelial and connective tissue proliferation, leads to tortuosity of the lymphatics and damaged or incompetent lymph valves. Lymphedema and chronic-stasis changes with hard or brawny edema develop in the overlying skin. These consequences of filariasis are due both to direct effects of the worms and to the inflammatory response of the host to the parasite. Inflammatory responses are believed to cause the granulomatous and proliferative processes that precede total lymphatic obstruction. It is thought that the lymphatic vessel remains patent as long as the worm remains viable and that the death of the worm leads to enhanced granulomatous reaction and fibrosis. Lymphatic obstruction results, and, despite collateralization of the lymphatics, lymphatic function is compromised.

CLINICAL FEATURES

The most common presentations of the lymphatic filariases are asymptomatic (or subclinical) microfilaremia, hydrocele (Fig. 125-1), acute adenolymphangitis (ADL), and chronic lymphatic disease. In areas where *W. bancrofti* or *B. malayi* is endemic, the overwhelming majority of infected individuals have few overt clinical manifestations of filarial infection despite large numbers of circulating microfilariae in the peripheral blood. Although they may be clinically asymptomatic, virtually all persons with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease that includes microscopic hematuria and/or proteinuria, dilated (and tortuous) lymphatics (visualized by imaging), and—in men—scrotal lymphangiectasia (detectable by ultrasound). In spite of these findings, the majority of individuals appear to remain clinically asymptomatic for years; relatively few progress to either acute or chronic disease.

ADL is characterized by high fever, lymphatic inflammation (lymphangitis and lymphadenitis), and transient local edema. The lymphangitis is retrograde, extending peripherally from the lymph node draining the area where the adult parasites reside. Regional lymph nodes are often enlarged, and the entire lymphatic channel can

FIGURE 125-1

Hydrocele associated with *Wuchereria bancrofti* infection.

become indurated and inflamed. Concomitant local thrombophlebitis can occur as well. In brugian filariasis, a single local abscess may form along the involved lymphatic tract and subsequently rupture to the surface. The lymphadenitis and lymphangitis can involve both the upper and lower extremities in both bancroftian and brugian filariasis, but involvement of the genital lymphatics occurs almost exclusively with *W. bancrofti* infection. This genital involvement can be manifested by funiculitis, epididymitis, and scrotal pain and tenderness. In endemic areas, another type of acute disease—dermatolymphangioadenitis (DLA)—is recognized as a syndrome that includes high fever, chills, myalgias, and headache. Edematous inflammatory plaques clearly demarcated from normal skin are seen. Vesicles, ulcers, and hyperpigmentation may also be noted. There is often a history of trauma, burns, radiation, insect bites, punctiform lesions, or chemical injury. Entry lesions, especially in the interdigital area, are common. DLA is often diagnosed as cellulitis.

If lymphatic damage progresses, transient lymphedema can develop into lymphatic obstruction and the permanent changes associated with elephantiasis (Fig. 125-2). Brawny edema follows early pitting edema, and thickening of the subcutaneous tissues and hyperkeratosis occur. Fissuring of the skin develops, as do hyperplastic changes. Superinfection of these poorly vascularized tissues becomes a problem. In bancroftian filariasis, in which genital involvement is common, hydroceles may develop (Fig. 125-1); in advanced stages, this condition may evolve into scrotal lymphedema and scrotal elephantiasis. Furthermore, if there is obstruction of the retroperitoneal lymphatics, the increased renal lymphatic pressure leads to rupture of the renal lymphatics and the development of

FIGURE 125-2
Elephantiasis of the lower extremity associated with *Wuchereria bancrofti* infection.

chyluria, which is usually intermittent and most prominent in the morning.

The clinical manifestations of filarial infections in travelers or transmigrants who have recently entered an endemic region are distinctive. Given a sufficient number of bites by infected vectors, usually over a 3- to 6-month period, recently exposed patients can develop acute lymphatic or scrotal inflammation with or without urticaria and localized angioedema. Lymphadenitis of epitrochlear, axillary, femoral, or inguinal lymph nodes is often followed by retrogradely evolving lymphangitis. Acute attacks are short-lived and are not usually accompanied by fever. With prolonged exposure to infected mosquitoes, these attacks, if untreated, become more severe and lead to permanent lymphatic inflammation and obstruction.

DIAGNOSIS

A definitive diagnosis can be made only by detection of the parasites and hence can be difficult. Adult worms localized in lymphatic vessels or nodes are largely inaccessible. Microfilariae can be found in blood, in hydrocele fluid, or (occasionally) in other body fluids. Such fluids can be examined microscopically, either directly or—for greater sensitivity—after concentration of the parasites by the passage of fluid through a polycarbonate cylindrical pore filter (pore size, 3 μ m) or by the centrifugation of fluid fixed in 2% formalin (Knott's concentration technique). The timing of blood collection is critical and should be based on the periodicity of the microfilariae in the endemic region involved. Many infected individuals do not have microfilaremia, and definitive diagnosis in such cases can be difficult. Assays

for circulating antigens of *W. bancrofti* permit the diagnosis of microfilaremic and cryptic (amicrofilaremic) infection. Two tests are commercially available: an enzyme-linked immunosorbent assay (ELISA) and a rapid-format immunochromatographic card test. Both assays have sensitivities of 96–100% and specificities approaching 100%. There are currently no tests for circulating antigens in brugian filariasis.

Polymerase chain reaction (PCR)-based assays for DNA of *W. bancrofti* and *B. malayi* in blood have been developed. A number of studies indicate that this diagnostic method is of equivalent or greater sensitivity compared with parasitologic methods, detecting patent infection in almost all infected individuals.

In cases of suspected lymphatic filariasis, examination of the scrotum or the female breast by means of high-frequency ultrasound in conjunction with Doppler techniques may result in the identification of motile adult worms within dilated lymphatics. Worms may be visualized in the lymphatics of the spermatic cord in up to 80% of infected men. Live adult worms have a distinctive pattern of movement within the lymphatic vessels (termed the *filaria dance sign*). Radionuclide lymphoscintigraphic imaging of the limbs reliably demonstrates widespread lymphatic abnormalities in both asymptomatic microfilaremic persons and those with clinical manifestations of lymphatic pathology. While of potential utility in the delineation of anatomic changes associated with infection, lymphoscintigraphy is unlikely to assume primacy in the diagnostic evaluation of individuals with suspected infection; it is principally a research tool, although it has been used more widely for assessment of lymphedema of any cause. Eosinophilia and elevated serum concentrations of IgE and antifilarial antibody support the diagnosis of lymphatic filariasis. There is, however, extensive cross-reactivity between filarial antigens and antigens of other helminths, including the common intestinal roundworms; thus, interpretations of serologic findings can be difficult. In addition, residents of endemic areas can become sensitized to filarial antigens (and thus be serologically positive) through exposure to infected mosquitoes without having patent filarial infections.

The ADL associated with lymphatic filariasis must be distinguished from thrombophlebitis, infection, and trauma. Retrogradely evolving lymphangitis is a characteristic feature that helps distinguish filarial lymphangitis from ascending bacterial lymphangitis. Chronic filarial lymphedema must also be distinguished from the lymphedema of malignancy, postoperative scarring, trauma, chronic edematous states, and congenital lymphatic system abnormalities.

Rx Treatment: LYMPHATIC FILARIASIS

With newer definitions of clinical syndromes in lymphatic filariasis and new tools to assess clinical status (e.g., ultrasound, lymphoscintigraphy, circulating filarial antigen assays, PCR), approaches to treatment based on infection

status can be considered. Diethylcarbamazine (DEC, 6 mg/kg daily for 12 days), which has both macro- and microfilaricidal properties, remains the treatment of choice for the individual with active lymphatic filariasis (microfilaremia, antigen positivity, or adult worms on ultrasound). An alternative treatment is albendazole (400 mg bid for 21 days), although this drug's macrofilaricidal efficacy may be less than that of DEC. An 8-week course of daily doxycycline (targeting the intracellular *Wolbachia* endosymbiont) has significant macrofilaricidal activity, as does a 7-day course of daily DEC/albendazole.

As has already been mentioned, a growing body of evidence indicates that, although they may be asymptomatic, virtually all persons with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease (hematuria, proteinuria, abnormalities on lymphoscintigraphy). Thus, early treatment of asymptomatic persons is recommended to prevent further lymphatic damage. For ADL, supportive treatment (including the administration of antipyretics and analgesics) is recommended, as is antibiotic therapy if secondary bacterial infection is likely. Similarly, because lymphatic disease is associated with the presence of adult worms, treatment with DEC is recommended for microfilaria-negative adult-worm carriers.

In persons with chronic manifestations of lymphatic filariasis, treatment regimens that emphasize hygiene, prevention of secondary bacterial infections, and physiotherapy have gained wide acceptance for morbidity control. These regimens are similar to those recommended for lymphedema of most nonfilarial causes and known by a variety of names, including *complex decongestive physiotherapy* and *complex lymphedema therapy*. Hydroceles (Fig. 125-1) can be drained repeatedly or managed surgically. With chronic manifestations of lymphatic filariasis, drug treatment should be reserved for individuals with evidence of active infection; therapy has been associated with clinical improvement and, in some cases, reversal of lymphedema.

The recommended course of DEC treatment (12 days; total dose, 72 mg/kg) has remained standard for many years. However, data indicate that single-dose DEC treatment with 6 mg/kg may be equally efficacious. The 12-day course provides more rapid short-term microfilarial suppression. Regimens that use combinations of single doses of albendazole and either DEC or ivermectin all have a sustained microfilaricidal effect. As mentioned above, an 8-week course of daily doxycycline (200 mg/d) or a 7-day course of daily DEC/albendazole has both significant macrofilaricidal activity and sustained microfilaricidal activity.

Side effects of DEC treatment include fever, chills, arthralgias, headaches, nausea, and vomiting. Both the development and the severity of these reactions are directly related to the number of microfilariae circulating in the bloodstream. The adverse reactions may represent either an acute hypersensitivity reaction to the antigens being released by dead and dying parasites or an inflammatory reaction induced by lipopolysaccharides from

the intracellular *Wolbachia* endosymbionts freed from their intracellular niche. Ivermectin has a side effect profile similar to that of DEC when used in lymphatic filariasis. In patients infected with *L. loa*, who have high levels of *Loa* microfilaremia, DEC—like ivermectin (see “Loiasis” later in the chapter)—can elicit severe encephalopathic complications. When used in single-dose regimens for the treatment of lymphatic filariasis, albendazole is associated with relatively few side effects.

PREVENTION AND CONTROL

Avoidance of mosquito bites usually is not feasible for residents of endemic areas, but visitors should make use of insect repellent and mosquito nets. Impregnated bed-nets have a salutary effect. DEC can kill developing forms of filarial parasites and is useful as a prophylactic agent in humans.

Community-based intervention is the current approach to elimination of lymphatic filariasis as a public health problem. The underlying tenet of this approach is that mass annual distribution of antimicrofilarial chemotherapy—albendazole with either DEC (for all areas except those where onchocerciasis is endemic) or ivermectin—will profoundly suppress microfilaremia. If the suppression is sustained, then transmission can be interrupted. As an added benefit, these combinations have secondary effects on gastrointestinal helminths. An alternative approach to the control of lymphatic filariasis is the use of salt fortified with DEC. Community use of DEC-fortified salt dramatically reduces microfilarial density with no apparent adverse reactions. Community education and clinical care for persons already suffering from the chronic sequelae of lymphatic filariasis are important components of filariasis control and elimination programs.

TROPICAL PULMONARY EOSINOPHILIA

Tropical pulmonary eosinophilia (TPE) is a distinct syndrome that develops in some individuals infected with lymphatic filarial species. This syndrome affects males and females in a ratio of 4:1, often during the third decade of life. The majority of cases have been reported from India, Pakistan, Sri Lanka, Brazil, Guyana, and Southeast Asia.

CLINICAL FEATURES

The main features include a history of residence in filarial-endemic regions, paroxysmal cough and wheezing (usually nocturnal and probably related to the nocturnal periodicity of microfilariae), weight loss, low-grade fever, adenopathy, and pronounced blood eosinophilia (>3000 eosinophils/ μL). Chest x-rays or CT scans may be normal but generally show increased bronchovascular markings. Diffuse miliary lesions or mottled opacities may be present in the middle and lower lung fields. Tests of pulmonary function show restrictive abnormalities in

most cases and obstructive defects in half. Characteristically, total serum IgE levels (10,000–100,000 ng/mL) and antifilarial antibody titers are markedly elevated.

PATHOLOGY

In TPE, microfilariae and parasite antigens are rapidly cleared from the bloodstream by the lungs. The clinical symptoms result from allergic and inflammatory reactions elicited by the cleared parasites. In some patients, trapping of microfilariae in other reticuloendothelial organs can cause hepatomegaly, splenomegaly, or lymphadenopathy. A prominent, eosinophil-enriched, intraalveolar infiltrate is often reported, and with it comes the release of cytotoxic proinflammatory granular proteins that may mediate some of the pathology seen in TPE. In the absence of successful treatment, interstitial fibrosis can lead to progressive pulmonary damage.

DIFFERENTIAL DIAGNOSIS

TPE must be distinguished from asthma, Löfller's syndrome, allergic bronchopulmonary aspergillosis, allergic granulomatosis with angiitis (Churg-Strauss syndrome), the systemic vasculitides (most notably periarteritis nodosa and Wegener's granulomatosis), chronic eosinophilic pneumonia, and the idiopathic hypereosinophilic syndrome. In addition to a geographic history of filarial exposure, useful features for distinguishing TPE include wheezing that is solely nocturnal, very high levels of antifilarial antibodies, and a rapid initial response to treatment with DEC.

Rx Treatment: **TROPICAL PULMONARY EOSINOPHILIA**

DEC is used at a daily dosage of 4–6 mg/kg for 14 days. Symptoms usually resolve within 3–7 days after the initiation of therapy. Relapse, which occurs in ~12–25% of cases (sometimes after an interval of years), requires retreatment.

ONCHOCERCIASIS

Onchocerciasis (“river blindness”) is caused by the filarial nematode *O. volvulus*, which infects an estimated 13 million individuals. The majority of individuals infected with *O. volvulus* live in the equatorial region of Africa extending from the Atlantic coast to the Red Sea. About 70,000 persons are infected in Guatemala and Mexico, with smaller foci in Venezuela, Colombia, Brazil, Ecuador, Yemen, and Saudi Arabia. Onchocerciasis is the second leading cause of infectious blindness worldwide.

ETIOLOGY AND EPIDEMIOLOGY

Infection in humans begins with the deposition of infective larvae on the skin by the bite of an infected blackfly. The larvae develop into adults, which are typically found in subcutaneous nodules. About 7 months to

3 years after infection, the gravid female releases microfilariae that migrate out of the nodule and throughout the tissues, concentrating in the dermis. Infection is transmitted to other persons when a female fly ingests microfilariae from the host's skin and these microfilariae then develop into infective larvae. Adult *O. volvulus* females and males are ~40–60 cm and ~3–6 cm in length, respectively. The life span of adults can be as long as 18 years, with an average of ~9 years. Because the blackfly vector breeds along free-flowing rivers and streams (particularly in rapids) and generally restricts its flight to an area within several kilometers of these breeding sites, both biting and disease transmission are most intense in these locations.

PATHOLOGY

Onchocerciasis primarily affects the skin, eyes, and lymph nodes. In contrast to the pathology in lymphatic filariasis, the damage in onchocerciasis is elicited by microfilariae and not by adult parasites. In the skin, there are mild but chronic inflammatory changes that can result in loss of elastic fibers, atrophy, and fibrosis. The subcutaneous nodules, or onchocercomata, consist primarily of fibrous tissues surrounding the adult worm, often with a peripheral ring of inflammatory cells. In the eye, neovascularization and corneal scarring lead to corneal opacities and blindness. Inflammation in the anterior and posterior chambers frequently results in anterior uveitis, chorioretinitis, and optic atrophy. Although punctate opacities are due to an inflammatory reaction surrounding dead or dying microfilariae, the pathogenesis of most manifestations of onchocerciasis is still unclear.

CLINICAL FEATURES

Skin

Pruritus and rash are the most frequent manifestations of onchocerciasis. The pruritus can be incapacitating; the rash is typically a papular eruption ([Fig. 125-3](#)) that is generalized rather than localized to a particular region of the body. Long-term infection results in exaggerated and premature wrinkling of the skin, loss of elastic fibers, and epidermal atrophy that can lead to loose, redundant skin and hypo- or hyperpigmentation. Localized eczematoid dermatitis can cause hyperkeratosis, scaling, and pigmentary changes. In an immunologically hyperreactive form of onchodermatitis (commonly termed *sowdah*, from the Yemeni word meaning “black”), the affected skin darkens as a consequence of the profound inflammation that occurs as microfilariae in the skin are cleared.

Onchocercomata

These subcutaneous nodules, which can be palpable and/or visible, contain the adult worm. In African patients, they are common over the coccyx and sacrum, the trochanter of the femur, the lateral anterior crest, and other bony prominences; in patients from South and Central America, nodules tend to

FIGURE 125-3
Papular eruption as a consequence of onchocerciasis.

develop preferentially in the upper part of the body, particularly on the head, neck, and shoulders.

Nodules vary in size and characteristically are firm and not tender. It has been estimated that, for every palpable nodule, there are four deeper nonpalpable ones.

Ocular Tissue

Visual impairment is the most serious complication of onchocerciasis and usually affects only those persons with moderate or heavy infections. Lesions may develop in all parts of the eye. The most common early finding is conjunctivitis with photophobia. Punctate keratitis—acute inflammatory reactions surrounding dying microfilariae and manifested as “snowflake” opacities—is common among younger patients and resolves without apparent complications.

Sclerosing keratitis occurs in 1–5% of infected persons and is the leading cause of onchocercal blindness in Africa. Anterior uveitis and iridocyclitis develop in ~5% of infected persons in Africa. In Latin America, complications of the anterior uveal tract (pupillary deformity) may cause secondary glaucoma. Characteristic chorioretinal lesions develop as a result of atrophy and hyperpigmentation of the retinal pigment epithelium. Constriction of the visual fields and frank optic atrophy may occur.

Lymph Nodes

Mild to moderate lymphadenopathy is common, particularly in the inguinal and femoral areas, where the enlarged nodes may hang down in response to gravity (“hanging groin”), sometimes predisposing to inguinal and femoral hernias.

Systemic Manifestations

Some heavily infected individuals develop cachexia with loss of adipose tissue and muscle mass. Among adults who become blind, there is a three- to fourfold increase in the mortality rate.

DIAGNOSIS

Definitive diagnosis depends on the detection of an adult worm in an excised nodule or, more commonly, of microfilariae in a skin snip. Skin snips are obtained with a corneal-scleral punch, which collects a blood-free skin biopsy sample extending to just below the epidermis, or by lifting of the skin with the tip of a needle and excision of a small (1- to 3-mm) piece with a sterile scalpel blade. The biopsy tissue is incubated in tissue culture medium or in saline on a glass slide or flat-bottomed microtiter plate. After incubation for 2–4 h (or occasionally overnight in light infections), microfilariae emergent from the skin can be seen by low-power microscopy.

Eosinophilia and elevated serum IgE levels are common but, because they occur in many parasitic infections, are not diagnostic in themselves. Assays to detect specific antibodies to *Onchocerca* and PCR to detect onchocercal DNA in skin snips are used in specialized laboratories and are highly sensitive and specific.

The *Mazzotti test* is a provocative technique that can be used in cases where the diagnosis of onchocerciasis is still in doubt (i.e., when skin snips and ocular examination reveal no microfilariae). A small dose of DEC (0.5–1.0 mg/kg) is given orally; the ensuing death of any dermal microfilariae elicits the development or exacerbation of pruritus or dermatitis within hours—an event that strongly suggests onchocerciasis.

Treatment: ONCHOCERCIASIS

The main goals of therapy are to prevent the development of irreversible lesions and to alleviate symptoms. Surgical excision is recommended when nodules are located on the head (because of the proximity of microfilaria-producing adult worms to the eye), but chemotherapy is the mainstay of management. Ivermectin, a semi-synthetic macrocyclic lactone active against microfilariae, is the first-line agent for the treatment of onchocerciasis. It is given orally in a single dose of 150 µg/kg, either yearly or semiannually. Recently, more frequent ivermectin administration (every 3 months) has been suggested to ameliorate pruritus and skin disease. Moreover, quadrennial administration of ivermectin has some macrofilaricidal activity.

After treatment, most individuals have few or no reactions. Pruritus, cutaneous edema, and/or maculopapular rash occurs in ~1–10% of treated individuals.

In areas of Africa co-endemic for *O. volvulus* and *L. loa*, however, ivermectin is contraindicated (as it is for pregnant or breast-feeding women) because of severe posttreatment encephalopathy seen in patients,

especially children, who are heavily microfilaremic for *L. loa* (2000–5000 microfilariae/mL). Although ivermectin treatment results in a marked drop in microfilarial density, its effect can be short-lived (<3 months in some cases). Thus, it is occasionally necessary to give ivermectin more frequently for persistent symptoms. A 6-week course of doxycycline is macrofilaristatic, rendering female adult worms sterile for long periods. Because this agent targets the *Wolbachia* endosymbiont of the filarial parasite, new approaches for definitive treatment (i.e., cure) may become available.

PREVENTION

Vector control has been beneficial in highly endemic areas in which breeding sites are vulnerable to insecticide spraying, but most areas endemic for onchocerciasis are not suited to this type of control. Community-based administration of ivermectin every 6–12 months is being used to interrupt transmission in endemic areas. This measure, in conjunction with vector control, has already helped reduce the prevalence of disease in endemic foci in Africa and Latin America. No drug has proved useful for prophylaxis of *O. volvulus* infection.

LOIASIS

ETIOLOGY AND EPIDEMIOLOGY

Loiasis is caused by *L. loa* (the African eye worm), which is present in the rain forests of West and Central Africa. Adult parasites (females, 50–70 mm long and 0.5 mm wide; males, 25–35 mm long and 0.25 mm wide) live in subcutaneous tissues. Microfilariae circulate in the blood with a diurnal periodicity that peaks between 12:00 noon and 2:00 P.M.

CLINICAL FEATURES

Manifestations of loiasis in natives of endemic areas may differ from those in temporary residents or visitors. Among the indigenous population, loiasis is often an asymptomatic infection with microfilaremia. Infection may be recognized only after subconjunctival migration of an adult worm (Fig. 125-4) or may be manifested by episodic Calabar swellings—evanescent localized areas of angioedema and erythema developing on the extremities and less frequently at other sites. Nephropathy, encephalopathy, and cardiomyopathy are rare. In patients who are not residents of endemic areas, allergic symptoms predominate, episodes of Calabar swelling tend to be more frequent and debilitating, microfilaremia is rare, and eosinophilia and increased levels of antifilarial antibodies are characteristic.

PATHOLOGY

The pathogenesis of the manifestations of loiasis is poorly understood. Calabar swellings are thought to result from a hypersensitivity reaction to adult worm antigens.

FIGURE 125-4

Adult *Loa loa* being surgically removed after its subconjunctival migration.

DIAGNOSIS

Definitive diagnosis of loiasis requires the detection of microfilariae in the peripheral blood or the isolation of the adult worm from the eye (Fig. 125-4) or from a subcutaneous biopsy specimen from a site of swelling developing after treatment. PCR-based assays for the detection of *L. loa* DNA in blood are available in specialized laboratories and are highly sensitive and specific. In practice, the diagnosis must often be based on a characteristic history and clinical presentation, blood eosinophilia, and elevated levels of antifilarial antibodies, particularly in travelers to an endemic region, who are usually amicrofilaremic. Other clinical findings in the latter individuals include hypergammaglobulinemia, elevated levels of serum IgE, and elevated leukocyte and eosinophil counts.

Rx Treatment: LOIASIS

DEC (8–10 mg/kg per day for 21 days) is effective against both the adult and the microfilarial forms of *L. loa*, but multiple courses are frequently necessary before loiasis resolves completely. In cases of heavy microfilaremia, allergic or other inflammatory reactions can take place during treatment, including central nervous system involvement with coma and encephalitis. Heavy infections can be treated initially with apheresis to remove the microfilariae and with glucocorticoids (40–60 mg of prednisone per day) followed by doses of DEC (0.5 mg/kg per day). If antifilarial treatment has no adverse effects, the prednisone dose can be rapidly tapered and the dose of DEC gradually increased to 8–10 mg/kg per day.

Albendazole or ivermectin is effective in reducing microfilarial loads, although neither is approved for this purpose by the U.S. Food and Drug Administration. DEC (300 mg weekly) is an effective prophylactic regimen for loiasis.

STREPTOCERCIASIS

 *Mansonella streptocerca*, found mainly in the tropical forest belt of Africa from Ghana to the Democratic Republic of the Congo, is transmitted by biting midges. The major clinical manifestations involve the skin and include pruritus, papular rashes, and pigmentation changes. Many infected individuals have inguinal adenopathy, although most are asymptomatic. The diagnosis is made by detection of the characteristic microfilariae in skin snips. DEC (6 mg/kg per day in divided doses for 14–21 days) effectively kills both microfilariae and adult worms. As in onchocerciasis, treatment is sometimes accompanied by urticaria, arthralgias, myalgias, headaches, and abdominal discomfort. Ivermectin at a single dose of 150 µg/kg leads to sustained suppression of microfilariae in the skin and is likely to assume primacy in the treatment of streptocerciasis.

MANSONELLA PERSTANS INFECTION

 *Mansonella perstans*, distributed across the center of Africa and in northeastern South America, is transmitted by midges. Adult worms reside in serous cavities—pericardial, pleural, and peritoneal—as well as in the mesentery and the perirenal and retroperitoneal tissues. Microfilariae circulate in the blood without periodicity. The clinical and pathologic features of the infection are poorly defined. Most patients appear to be asymptomatic, but manifestations may include transient angioedema and pruritus of the arms, face, or other parts of the body (analogous to the Calabar swellings of loiasis); fever; headache; arthralgias; and right-upper-quadrant pain. Occasionally, pericarditis and hepatitis occur. The diagnosis is based on the demonstration of microfilariae in blood or serosal effusions. Perstans filariasis is often associated with peripheral-blood eosinophilia and antifilarial antibody elevations. Although DEC (8–10 mg/kg per day for 21 days) is the standard therapeutic agent, there is little evidence that it is effective. Cure is indicated by the disappearance of symptoms and eosinophilia; multiple courses of therapy are usually required. Ivermectin, used in frequent repeated doses, can reduce blood microfilarial levels. Both mebendazole (100 mg bid for 30 days) and albendazole (400 mg bid for 10 days) have occasionally been reported to be effective.

MANSONELLA OZZARDI INFECTION

 The distribution of *Mansonella ozzardi* is restricted to Central and South America and certain Caribbean islands. Adult worms are rarely recovered from humans. Microfilariae circulate in the blood without periodicity. Although this organism has often been considered nonpathogenic, headache, articular pain, fever, pulmonary symptoms, adenopathy, hepatomegaly, pruritus, and eosinophilia have been ascribed to *M. ozzardi* infection. The diagnosis is made by detection of microfilariae in peripheral blood. Ivermectin (a single dose of 6 mg) is effective in treating this infection.

DRACUNCULIASIS (GUINEA WORM INFECTION)

ETIOLOGY AND EPIDEMIOLOGY

 The incidence of dracunculiasis, caused by *Dracunculus medinensis*, has declined dramatically because of global eradication efforts. Current estimates suggest that there are slightly more than 10,000 cases worldwide, the majority in Sudan, Ghana, and Mali. Asia has now been deemed dracunculiasis-free.

Humans acquire *D. medinensis* when they ingest water containing infective larvae derived from *Cyclops*, a crustacean that is the intermediate host. Larvae penetrate the stomach or intestinal wall, mate, and mature. The adult male probably dies; the female worm develops over a year and migrates to subcutaneous tissues, usually in the lower extremity. As the thin female worm, ranging in length from 30 cm to 1 m, approaches the skin, a blister forms that, over days, breaks down and forms an ulcer. When the blister opens, large numbers of motile, rhabditiform larvae can be released into stagnant water; ingestion by *Cyclops* completes the life cycle.

CLINICAL FEATURES

Few or no clinical manifestations of dracunculiasis are evident until just before the blister forms, when there is an onset of fever and generalized allergic symptoms, including periorbital edema, wheezing, and urticaria. The emergence of the worm is associated with local pain and swelling. When the blister ruptures (usually as a result of immersion in water) and the adult worm releases larva-rich fluid, symptoms are relieved. The shallow ulcer surrounding the emerging adult worm heals over weeks to months. Such ulcers, however, can become secondarily infected, the result being cellulitis, local inflammation, abscess formation, or (uncommonly) tetanus. Occasionally, the adult worm does not emerge but becomes encapsulated and calcified.

DIAGNOSIS

The diagnosis is based on the findings developing with the emergence of the adult worm, as described above.

Rx Treatment: DRACUNCULIASIS

Gradual extraction of the worm by winding of a few centimeters on a stick each day remains the common and effective practice. Worms may be excised surgically. The administration of metronidazole (250 mg tid for 10 days) may relieve symptoms but has no proven activity against the worm.

PREVENTION

Prevention, which remains the only real control measure, depends on the provision of safe drinking water.

ZOONOTIC FILARIAL INFECTIONS

Dirofilariae that affect primarily dogs, cats, and raccoons occasionally infect humans incidentally, as do *Brugia* and *Onchocerca* parasites that affect small mammals. Because humans are an abnormal host, the parasites never develop fully. Pulmonary dirofilarial infection caused by the canine heartworm *Dirofilaria immitis* generally presents in humans as a solitary pulmonary nodule. Chest pain, hemoptysis, and cough are uncommon. Infections with *D. repens* (from dogs) or *D. tenuis* (from raccoons) can cause local subcutaneous nodules in humans. Zoonotic *Brugia* infection can produce isolated lymph node enlargement, whereas zoonotic *Onchocerca* can cause subconjunctival masses. Eosinophilia levels and antifilarial antibody titers are not commonly elevated. Excisional biopsy is both diagnostic and curative. These infections usually do not respond to chemotherapy.

CHAPTER 126

SCHISTOSOMIASIS AND OTHER TREMATODE INFECTIONS

Adel A.F. Mahmoud

Trematodes, or flatworms, are a group of morphologically and biologically heterogeneous organisms that belong to the phylum Platyhelminthes. Human infection with trematodes occurs in many geographic areas and can cause considerable morbidity and mortality. For clinical purposes, significant trematode infections of humans may be divided according to tissues invaded by adult flukes: blood, biliary tree, intestines, and lungs ([Table 126-1](#)).

Trematodes share some common morphologic features, including macroscopic size (from 1 cm to several cm); dorsoventral, flattened, bilaterally symmetric bodies (adult worms); and the prominence of two suckers. Except for schistosomes, all human parasitic trematodes are hermaphroditic. Their life cycle involves a definitive host (mammalian/human), in which adult worms initiate

sexual reproduction, and an intermediate host (snails), in which asexual multiplication of larvae occurs. More than one intermediate host may be necessary for some species of trematodes. Human infection is initiated either by direct penetration of intact skin or by ingestion. Upon maturation within humans, adult flukes initiate sexual reproduction and egg production. Helminth ova leave the definitive host in excreta or sputum and, upon reaching suitable environmental conditions, they hatch, releasing free-living miracidia that seek specific snail intermediate hosts. After asexual reproduction, cercariae are released from infected snails. In certain species, these organisms infect humans; in others, they find a second intermediate host to allow encystment into metacercariae—the infective stage.

TABLE 126-1

MAJOR HUMAN TREMATODE INFECTIONS

| TREMATODE | TRANSMISSION | ENDEMIC AREA(S) |
|---------------------------------|---|--|
| Blood Flukes | | |
| <i>Schistosoma mansoni</i> | Skin penetration by cercariae released from snails | Africa, South America, Middle East |
| <i>S. japonicum</i> | Skin penetration by cercariae released from snails | China, Philippines, Indonesia |
| <i>S. intercalatum</i> | Skin penetration by cercariae released from snails | West Africa |
| <i>S. mekongi</i> | Skin penetration by cercariae released from snails | Southeast Asia |
| <i>S. haematobium</i> | Skin penetration by cercariae released from snails | Africa, Middle East |
| Biliary (Hepatic) Flukes | | |
| <i>Clonorchis sinensis</i> | Ingestion of metacercariae in freshwater fish | Far East |
| <i>Opisthorchis viverrini</i> | Ingestion of metacercariae in freshwater fish | Far East, Thailand |
| <i>O. felinus</i> | Ingestion of metacercariae in freshwater fish | Far East, Europe |
| <i>Fasciola hepatica</i> | Ingestion of metacercariae on aquatic plants or in water | Worldwide |
| <i>F. gigantica</i> | Ingestion of metacercariae on aquatic plants or in water | Sporadic, Africa |
| Intestinal Flukes | | |
| <i>Fasciolopsis buski</i> | Ingestion of metacercariae on aquatic plants | Southeast Asia |
| <i>Heterophyes heterophyes</i> | Ingestion of metacercariae in freshwater or brackish-water fish | Far East, North Africa |
| Lung Flukes | | |
| <i>Paragonimus westermani</i> | Ingestion of metacercariae in crayfish or crabs | Global except North America and Europe |

The host-parasite relationship in trematode infections is a product of certain biologic features of these organisms: they are multicellular, undergo several developmental changes within the host, and usually result in chronic infections. In general, the distribution of worm infections in human populations is *overdispersed*; i.e., it follows a negative binomial mathematical relationship in which most infected individuals harbor low worm burdens while a small percentage are heavily infected. It is the heavily infected minority who are particularly prone to disease sequelae and who constitute an epidemiologically significant reservoir of infection in endemic areas. Equally important is an appreciation that worms do not multiply within the definitive host and that they have a relatively long life span, ranging from a few months to a few years. Morbidity and death due to trematode infections reflect a multifactorial process that results from the tipping of a delicate balance between intensity of infection and host reactions, which initiate and modulate immunologic and pathologic outcome. Furthermore, the genetics of the parasite and of the human host contribute to the outcome of infection and disease. Infections with trematodes that migrate through or reside in host tissues are associated with a moderate to high degree of peripheral blood eosinophilia; this association is of significance in protective and immunopathologic sequelae and is a useful clinical indicator of infection.

Approach to the Patient: TREMATODE INFECTION

The approach to individuals with suspected trematode infection begins with a question: Where have you been? Details of geographic history, exposure to freshwater bodies, and indulgence in local eating habits without ensuring safety of food and drink are all essential elements in the history. The workup plan must include a detailed physical examination and tests appropriate for the suspected infection. Diagnosis is based either on detection of the relevant stage of the parasite in excreta, sputum, or (rarely) tissue samples or on sensitive and specific serologic tests. Consultation with physicians familiar with these infections or with the U.S. Centers for Disease Control and Prevention (CDC) is helpful in guiding diagnosis and selecting therapy.

BLOOD FLUKES: SCHISTOSOMIASIS

Human schistosomiasis is caused by five species of the parasitic trematode genus *Schistosoma*: the intestinal species *S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum* and the urinary species *S. haematobium*. Infection may cause considerable morbidity in the intestines, liver,

1156 and urinary tract, and a proportion of affected individuals die. Other schistosomes (e.g., avian species) may invade human skin but then die in subcutaneous tissue, producing only self-limiting cutaneous manifestations.

ETIOLOGY

Human infection is initiated by penetration of intact skin with infective cercariae. These organisms, which are released from infected snails in freshwater bodies, measure ~2 mm in length and possess an anterior and a ventral sucker that attach to the skin and facilitate penetration. Once in subcutaneous tissue, cercariae transform into schistosomula, with morphologic, membrane, and immunologic changes. The cercarial outer membrane changes from a trilaminar to a heptalaminar structure that is then maintained throughout the organism's life span in humans. This transformation is thought to be the

schistosome's main adaptive mechanism for survival in humans. Schistosomula begin their migration within 2–4 days via venous or lymphatic vessels, reaching the lungs and finally the liver parenchyma. Sexually mature worms descend into the venous system at specific anatomic locations: intestinal veins (*S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*) and vesical veins (*S. haematobium*). After mating, adult gravid females travel against venous blood flow to small tributaries, where they deposit their ova intravascularly. Schistosome ova (Fig. 126-1) have specific morphologic features that vary with the species. Aided by enzymatic secretions through minipores in eggshells, ova move through the venous wall, traversing host tissues to reach the lumen of the intestinal or urinary tract, and are voided with stools or urine. Approximately 50% of ova are retained in host tissues locally (intestines or urinary tract) or are carried by venous blood flow to the liver and other organs. Schistosome ova that reach freshwater

FIGURE 126-1

Morphology of schistosome eggs, the diagnostic stage of the parasite's life cycle. **A.** *S. haematobium* egg found in urine sample. Egg is large (~140 μ m long), with a terminal spine. **B.** *S. mansoni* egg found in feces. Egg is large (~150 μ m long), with a thin shell and lateral spine. **C.** *S. japonicum* egg found in feces. Egg is smaller than that of *S. mansoni* (~90 μ m long), with a small spine or hooklike structure. **D.** *S.*

mekongi egg found in feces. Egg is similar to that of *S. japonicum* but smaller (~65 μ m long). **E.** *S. intercalatum* egg found in feces. Egg is larger than that of *S. haematobium* (~190 μ m long), with a longer, sharply pointed spine. (From LR Ash, TC Orihel: *Atlas of Human Parasitology*, 3d ed. Chicago, ASCP Press, 1990; with permission.)

bodies hatch, releasing free-living miracidia that seek the snail intermediate host and undergo several asexual multiplication cycles. Finally, infective cercariae are shed from snails.

Adult schistosomes are ~1–2 cm long. Males are slightly shorter than females, with flattened bodies and anteriorly curved edges forming the gynecophoral canal, in which mature adult females are usually held. Females are longer, slender, and rounded in cross-section. The precise nature of biochemical and reproductive exchanges between the two sexes is unknown, as are the regulatory mechanisms for pairing. Adult schistosomes parasitize specific sites in the host venous system. What guides adult intestinal schistosomes to branches of the superior or inferior mesenteric veins or adult *S. haematobium* worms to the vesical plexus is unknown. In addition, adult worms inhibit the coagulation cascade and evade the effector arms of the host immune responses by still-undetermined mechanisms. The genome of schistosomes is relatively large (~270 Mb) and is arrayed on seven pairs of autosomes and one pair of sex chromosomes. For *S. mansoni*, a total of ~14,000 genes have been estimated; some are species-conserved. The complete sequence of the schistosome genome should be available soon.

EPIDEMIOLOGY

The global distribution of schistosome infection in human populations (Fig. 126-2) is dependent on both parasite and host factors. Information on prevalence and global distribution is inexact. The five

Schistosoma species are estimated to infect 200–300 million individuals in South America, the Caribbean, Africa, the Middle East, and Southeast Asia. The total population living under conditions favoring transmission approximates double or triple that number—a fact reflecting the public health significance of schistosomiasis.

In endemic areas, the rate of yearly onset of new infection, or incidence, is generally low. Prevalence, on the other hand, starts to be appreciable by the age of 3–4 years and builds to a maximum that varies by endemic region (up to 100%) in the 15- to 20-year age group. Prevalence then stabilizes or decreases slightly in older age groups (>40 years). Intensity of infection (as measured by fecal or urinary egg counts, which correlate with adult worm burdens in most circumstances) follows the increase in prevalence up to the age of 15–20 years and then declines markedly in older age groups. This decline may reflect acquisition of resistance or may be due to changes in water contact patterns, since older people have less exposure. Furthermore, the overdispersed distribution of schistosomes in human populations may be due to the heterogeneity of worm populations, with some more invasive than others; alternatively, it may be due to the demonstrated differences in genetic susceptibility of host populations.

Disease due to schistosome infection is the outcome of parasitologic, host, and additional infectious, nutritional, and environmental factors. Most disease syndromes relate to the presence of one or more of the parasite stages in humans. Disease manifestations in the populations of endemic areas correlate, in general, with the intensity and

FIGURE 126-2

Global distribution of schistosomiasis. **A.** *S. mansoni* infection (dark blue) is endemic in Africa, the Middle East, South America, and a few Caribbean countries. *S. intercalatum* infection (green) is endemic in sporadic foci in West and Central Africa. **B.** *S. haematobium* infection (purple) is

endemic in Africa and the Middle East. The major endemic countries for *S. japonicum* infection (green) are China, the Philippines, and Indonesia. *S. mekongi* infection (red) is endemic in sporadic foci in Southeast Asia.

duration of infection as well as with the age and genetic susceptibility of the host. Overall, disease manifestations are clinically relevant in only a small proportion of persons infected with any of the intestinal schistosomes. In contrast, urinary schistosomiasis manifests clinically in most infected individuals. Recent estimates of total morbidity due to chronic schistosomiasis indicate a significantly greater burden than was previously appreciated.

Patients with both HIV infection and schistosomiasis excrete far fewer eggs in their stools than those infected with *S. mansoni* alone; the mechanism underlying this difference is unknown. Treatment with praziquantel may result in reduced HIV replication and increased CD4+ T lymphocyte counts.

PATHOGENESIS AND IMMUNITY

Cercarial invasion is associated with dermatitis arising from dermal and subdermal inflammatory responses, both humoral and cell-mediated. As the parasites approach sexual maturity and with the commencement of oviposition, acute schistosomiasis or Katayama fever (a serum sickness-like illness; see “Clinical Features” next in the chapter) may occur. The associated antigen excess results in formation of soluble immune complexes, which may be deposited in several tissues, initiating multiple pathologic events. In chronic schistosomiasis, most disease manifestations are due to eggs retained in host tissues. The granulomatous response around these ova is cell-mediated and is regulated both positively and negatively by a cascade of cytokine, cellular, and humoral responses. Granuloma formation begins with recruitment of a host of inflammatory cells in response to antigens secreted by the living organism within the ova. Cells recruited initially include phagocytes, antigen-specific T cells, and eosinophils. Fibroblasts, giant cells, and B lymphocytes predominate later. These lesions reach a size many times that of parasite eggs, thus inducing organomegaly and obstruction. Immunomodulation or downregulation of host responses to schistosome eggs plays a significant role in limiting the extent of the granulomatous lesions—and consequently disease—in chronically infected experimental animals or humans. The underlying mechanisms involve another cascade of regulatory cytokines and idiotype antibodies. Subsequent to the granulomatous response, fibrosis sets in, resulting in more permanent disease sequelae. Because schistosomiasis is also a chronic infection, the accumulation of antigen-antibody complexes results in deposits in renal glomeruli and may cause significant kidney disease.

The better-studied pathologic sequelae in schistosomiasis are those observed in liver disease. Ova that are carried by portal blood embolize to the liver. Because of their size (~150 × 60 μm in the case of *S. mansoni*), they lodge at presinusoidal sites, where granulomas are formed. These granulomas contribute to the hepatomegaly observed in infected individuals. Schistosomal liver enlargement is also associated with certain class I and class II human leukocyte antigen (HLA) haplotypes and markers; its genetic basis appears to be multigenic. Presinusoidal

portal blockage causes several hemodynamic changes, including portal hypertension and associated development of portosystemic collaterals at the esophagogastric junction and other sites. Esophageal varices are most likely to break and cause repeated episodes of hematemesis. Because changes in hepatic portal blood flow occur slowly, compensatory arterialization of the blood flow through the liver is established. While this compensatory mechanism may be associated with certain metabolic side effects, retention of hepatocyte perfusion permits maintenance of normal liver function for several years.

The second most significant pathologic change in the liver relates to fibrosis. It is characteristically periportal (Symmers' clay pipe-stem fibrosis) but may be diffuse. Fibrosis, when diffuse, may be seen in areas of egg deposition and granuloma formation but is also seen in distant locations such as portal tracts. Schistosomiasis results in pure fibrotic lesions in the liver; cirrhosis occurs when other nutritional factors or infectious agents (e.g., hepatitis B or C virus) are involved. In recent years, it has been recognized that deposition of fibrotic tissue in the extracellular matrix results from the interaction of T lymphocytes with cells of the fibroblast series; several cytokines, such as interleukin (IL) 2, IL-4, IL-1, and transforming growth factor β (TGF-β), are known to stimulate fibrogenesis. The process may be dependent on the genetic constitution of the host. Furthermore, regulatory cytokines that can suppress fibrogenesis, such as interferon γ (IFN-γ) or IL-12, may play a role in modulating the response.

While the above description focuses on granuloma formation and fibrosis of the liver, similar processes occur in urinary schistosomiasis. Granuloma formation at the lower end of the ureters obstructs urinary flow, with subsequent development of hydroureter and hydronephrosis. Similar lesions in the urinary bladder cause the protrusion of papillomatous structures into its cavity; these may ulcerate and/or bleed. The chronic stage of infection is associated with scarring and deposition of calcium in bladder wall.

Studies on immunity to schistosomiasis, whether innate or adaptive, have expanded our knowledge of the components of these responses and target antigens. The critical question, however, is whether humans acquire immunity to schistosomes. Epidemiologic data suggest the onset of acquired immunity during the course of infection in young adults. Curative treatment of infection divides populations in endemic areas into those who acquire reinfection rapidly (susceptible) and those who follow a protracted course (resistant). This difference may be explained by differences in transmission, immunologic response, or genetic susceptibility. The mechanism of acquired immunity involves antibodies, complement, and several effector cells, particularly eosinophils. Furthermore, the intensity of schistosome infection has been correlated with a region in chromosome 5. In several studies, a few protective schistosome antigens have been identified as vaccine candidates, but none has been evaluated in human populations to date.

CLINICAL FEATURES

In general, disease manifestations of schistosomiasis occur in three stages, which vary not only by species but also by intensity of infection and other host factors, such as age and genetics. During the phase of cercarial invasion, a form of dermatitis may be observed. This so-called swimmers' itch occurs most often with *S. mansoni* and *S. japonicum* infections, manifesting 2 or 3 days after invasion as an itchy maculopapular rash on the affected areas of the skin. The condition is particularly severe when humans are exposed to avian schistosomes. This form of cercarial dermatitis is also seen around freshwater lakes in the northern United States, particularly in the spring. Cercarial dermatitis is a self-limiting clinical entity. During worm maturation and at the beginning of oviposition (i.e., 4–8 weeks after skin invasion), acute schistosomiasis or Katayama fever—a serum sickness–like syndrome with fever, generalized lymphadenopathy, and hepatosplenomegaly—may develop. Individuals with acute schistosomiasis show a high degree of peripheral blood eosinophilia. Parasite-specific antibodies may be detected before schistosome eggs are identified in excreta. Acute schistosomiasis has become an important clinical entity worldwide because of increased travel to endemic areas. Travelers are exposed to parasites while swimming or wading in freshwater bodies and upon their return present with the acute manifestations. The course of acute schistosomiasis is generally benign, but deaths are occasionally reported in association with heavy exposure to schistosomes.

The main clinical manifestations of chronic schistosomiasis are species-dependent. Intestinal species (*S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*) cause intestinal and hepatosplenic disease as well as several manifestations associated with portal hypertension. During the intestinal phase, which may begin a few months after infection and may last for years, symptomatic patients characteristically have colicky abdominal pain, bloody diarrhea, and anemia. Patients may also report fatigue and an inability to perform daily routine functions and may show evidence of growth retardation. It has been demonstrated that schistosomiasis morbidity is generally underappreciated. The severity of intestinal schistosomiasis is often related to the intensity of the worm burden. The disease runs a chronic course and may result in colonic polyposis, which has been reported from some endemic areas, such as Egypt.

The hepatosplenic phase of disease manifests early (during the first year of infection, particularly in children) with liver enlargement due to parasite-induced granulomatous lesions. Hepatomegaly is seen in ~15–20% of infected individuals; it correlates roughly with intensity of infection, occurs more often in children, and may be related to specific HLA haplotypes. In subsequent phases of infection, presinusoidal blockage of blood flow leads to portal hypertension and splenomegaly. Moreover, portal hypertension may lead to varices at the lower end of the esophagus and at other sites. Patients with schistosomal liver disease may have right-upper-quadrant “dragging” pain during the hepatomegaly phase, and this pain may move to the left upper quadrant as splenomegaly pro-

gresses. Bleeding from esophageal varices may, however, be the first clinical manifestation of this phase. Patients may experience repeated bleeding but seem to tolerate its impact, since an adequate total hepatic blood flow permits normal liver function for a considerable duration. In late-stage disease, typical fibrotic changes occur along with liver function deterioration and the onset of ascites, hypoalbuminemia, and defects in coagulation. Intercurrent viral infections of the liver (especially hepatitis B and C) or nutritional deficiencies may well accelerate or exacerbate the deterioration of hepatic function.

The extent and severity of intestinal and hepatic disease in schistosomiasis *mansoni* and *japonica* have been well described. While it was originally thought that *S. japonicum* might induce more severe disease manifestations because the adult worms can produce 10 times more eggs than *S. mansoni*, subsequent field studies have not supported this claim. Clinical observations of individuals infected with *S. mekongi* or *S. intercalatum* have been less detailed, partly because of the limited geographic distribution of these organisms.

The clinical manifestations of *S. haematobium* infection occur relatively early and involve a high percentage of infected individuals. Up to 80% of children infected with *S. haematobium* have dysuria, frequency, and hematuria, which may be terminal. Urine examination reveals blood and albumin as well as an unusually high frequency of bacterial urinary tract infection and urinary sediment cellular metaplasia. These manifestations correlate with intensity of infection, the presence of urinary bladder granulomas, and subsequent ulceration. Along with local effects of granuloma formation in the urinary bladder, obstruction of the lower end of the ureters results in hydronephrosis, which may be seen in 25–50% of infected children. As infection progresses, bladder granulomas undergo fibrosis, which results in typical sandy patches visible on cystoscopy. In many endemic areas, an association between squamous cell carcinoma of the bladder and *S. haematobium* infection has been observed. Such malignancy is detected in a younger age group than is transitional cell carcinoma. In fact, *S. haematobium* has now been classified as a human carcinogen.

Significant disease may occur in other organs during chronic schistosomiasis. Most important are the lungs and central nervous system (CNS); other locations, such as the skin and the genital organs, are far less frequently affected. In pulmonary schistosomiasis, embolized eggs lodge in small arterioles, producing acute necrotizing arteriolitis and granuloma formation. During *S. mansoni* and *S. japonicum* infection, schistosome eggs reach the lungs after the development of portosystemic collateral circulation; in *S. haematobium* infection, ova may reach the lungs directly via connections between the vesical and systemic circulation. Subsequent fibrous tissue deposition leads to endarteritis obliterans, pulmonary hypertension, and cor pulmonale. The most common symptoms are cough, fever, and dyspnea. Cor pulmonale may be diagnosed radiologically on the basis of prominent right side of the heart and dilation of the pulmonary artery. Frank evidence of right-sided heart failure may be seen in late cases.

CNS schistosomiasis is important but less common than pulmonary schistosomiasis. It characteristically occurs as cerebral disease due to *S. japonicum* infection. Migratory worms deposit eggs in the brain and induce a granulomatous response. The frequency of this manifestation among infected individuals in some endemic areas (e.g., the Philippines) is calculated at 2–4%. Jacksonian epilepsy due to *S. japonicum* infection is the second most common cause of epilepsy in these areas. *S. mansoni* and *S. haematobium* infections have been associated with transverse myelitis. This syndrome is thought to be due to eggs traveling to the venous plexus around the spinal cord. In schistosomiasis *mansoni*, transverse myelitis is usually seen in the chronic stage after the development of portal hypertension and portosystemic shunts, which allow ova to travel to the spinal cord veins. This proposed sequence of events has been challenged because of a few reports of transverse myelitis occurring early in the course of *S. mansoni* infection. More information is needed to confirm these observations. During schistosomiasis haematobia, ova may travel through communication between vesical and systemic veins, resulting in spinal cord disease that may be detected at any stage of infection. Pathologic study of lesions in schistosomal transverse myelitis may reveal eggs along with necrotic or granulomatous lesions. Patients usually present with acute or rapidly progressing lower-leg weakness accompanied by sphincter dysfunction.

DIAGNOSIS

Physicians in areas not endemic for schistosomiasis face considerable diagnostic challenges. In the most common clinical presentation, a traveler returns with symptoms and signs of acute syndromes of schistosomiasis—namely, cercarial dermatitis or Katayama fever. Central to correct diagnosis is a thorough inquiry into travel history and exposure to freshwater bodies, whether slow or fast running. Differential diagnosis of fever in returned travelers includes a spectrum of infections whose etiologies are viral (e.g., Dengue fever), bacterial (e.g., enteric fever, leptospirosis), rickettsial, or protozoal (e.g., malaria). In cases of Katayama fever, prompt diagnosis is essential and is based on clinical presentation, high-level peripheral blood eosinophilia, and a positive serologic assay for schistosomal antibodies. Two tests are available at the CDC: the Falcon assay screening test/enzyme-linked immunosorbent assay (FAST-ELISA) and the confirmatory enzyme-linked immunoelectrotransfer blot (EITB). Both tests are highly sensitive and ~96% specific. In some instances, examination of stool or urine for ova may yield positive results.

Individuals with established infection are diagnosed by a combination of geographic history, characteristic clinical presentation, and presence of schistosome ova in excreta. The diagnosis may also be established with the serologic assays mentioned above or with those that detect circulating schistosome antigens. These assays can be applied either to blood or to other body fluids (e.g., cerebrospinal fluid). For suspected schistosome infection, stool examination by the Kato thick smear or any other concentration method generally identifies all but the most lightly infected individuals. For *S. haematobium*, urine may be

examined by microscopy of sediment or by filtration of a known volume through Nuclepore filters. Kato thick smear and Nuclepore filtration provide quantitative data on the intensity of infection, which is of value in assessing the degree of tissue damage and in monitoring the effect of chemotherapy. Schistosome infection may also be diagnosed by examination of tissue samples, typically rectal biopsies; other biopsy procedures (e.g., liver biopsy) are not needed, except in rare circumstances.

Differential diagnosis of schistosomal hepatomegaly must include viral hepatitis of all etiologies, miliary tuberculosis, malaria, visceral leishmaniasis, ethanol abuse, and causes of hepatic and portal vein obstruction. Differential diagnosis of hematuria in *S. haematobium* infection includes bacterial cystitis, tuberculosis, urinary stones, and malignancy.

Rx Treatment: SCHISTOSOMIASIS

Treatment of schistosomiasis depends on stage of infection and clinical presentation. Other than topical dermatologic applications for relief of itching, no specific treatment is indicated for cercarial dermatitis caused by avian schistosomes. Therapy for acute schistosomiasis or Katayama fever needs to be adjusted appropriately for each case. While antischistosomal chemotherapy may be used, it does not have a significant impact on maturing worms. In severe acute schistosomiasis, management in an acute-care setting is necessary, with supportive measures and consideration of glucocorticoid treatment. Once the acute critical phase is over, specific chemotherapy is indicated for parasite elimination. For all individuals with established infection, treatment to eradicate the parasite should be administered. The drug of choice is praziquantel, which—depending on the infecting species ([Table 126-2](#))—is administered PO as a total of 40 or 60 mg/kg in two or three doses over a single day. Praziquantel treatment results in parasitologic cure in ~85% of cases and reduces egg counts by >90%. Few side effects have been encountered, and those that do develop usually do not interfere with completion of treatment. Dependence on a single chemotherapeutic agent has raised the possibility of development of resistance in schistosomes; to date, such resistance does not seem to be clinically significant. The effect of antischistosomal treatment on disease manifestations varies by stage. Early hepatomegaly and bladder lesions are known to resolve after chemotherapy, but the late established manifestations, such as fibrosis, do not recede. Additional management modalities are needed for individuals with other manifestations, such as hepatocellular failure or recurrent hematemesis. The use of these interventions is guided by general medical and surgical principles.

PREVENTION AND CONTROL

Transmission of schistosomiasis is dependent on human behavior. Since the geographic distribution of infections in endemic regions of the world

TABLE 126-2**DRUG THERAPY FOR HUMAN TREMATODE INFECTIONS**

| INFECTION | DRUG OF CHOICE | ADULT DOSE AND DURATION |
|--|-----------------|---|
| Blood Flukes | | |
| <i>S. mansoni</i> , <i>S. intercalatum</i> , <i>S. haematobium</i> | Praziquantel | 20 mg/kg, 2 doses in 1 day |
| <i>S. japonicum</i> , <i>S. mekongi</i> | Praziquantel | 20 mg/kg, 3 doses in 1 day |
| Biliary (Hepatic) Flukes | | |
| <i>C. sinensis</i> , <i>O. viverrini</i> , <i>O. felinus</i> | Praziquantel | 25 mg/kg, 3 doses in 1 day |
| <i>F. hepatica</i> , <i>F. gigantica</i> | Triclabendazole | 10 mg/kg once |
| Intestinal Flukes | | |
| <i>F. buski</i> , <i>H. heterophyes</i> | Praziquantel | 25 mg/kg, 3 doses in 1 day |
| Lung Flukes | | |
| <i>P. westermani</i> | Praziquantel | 25 mg/kg, 3 doses per day for 2 days |

is not clearly demarcated, it is prudent for travelers to avoid contact with all freshwater bodies, irrespective of the speed of water flow or unsubstantiated claims of safety. Some topical agents, when applied to skin, may inhibit cercarial penetration, but none is currently available. If exposure occurs, a follow-up visit with a health care provider is strongly recommended. Prevention of infection in inhabitants of endemic areas is a significant challenge. Residents of these regions use freshwater bodies for sanitary, domestic, recreational, and agricultural purposes. Several control measures have been used, including application of molluscicides, provision of sanitary water and sewage disposal, chemotherapy, and health education. Current recommendations to countries endemic for schistosomiasis emphasize the use of multiple approaches. With the advent of an oral, safe, and effective antischistosomal agent, chemotherapy has been most successful in reducing intensity of infection and reversing disease. The duration of this positive impact depends on transmission dynamics of the parasite in any specific endemic region. The ultimate goal of research on prevention and control is development of a vaccine. Although there are a few promising leads, this goal is probably not within reach during the next decade or so.

LIVER (BILIARY) FLUKES

Several species of biliary fluke infecting humans are particularly common in Southeast Asia and Russia. Other species are transmitted in Europe, Africa, and the Americas. On the basis of their migratory

pathway in humans, these infections may be divided into the *Clonorchis* and *Fasciola* groups (Table 126-1).

CLONORCHIASIS AND OPISTHORCHIASIS

Infection with *Clonorchis sinensis*, the Chinese or oriental fluke, is endemic among fish-eating mammals in Southeast Asia. Humans are an incidental host; the prevalence of human infection is highest in China, Vietnam, and Korea. Infection with *Opisthorchis viverrini* and *O. felinus* is zoonotic in cats and dogs. Transmission to humans occurs occasionally, particularly in Thailand (*O. viverrini*) and in Southeast Asia and eastern Europe (*O. felinus*). Data on the exact geographic distribution of these infectious agents in human populations are rudimentary.

Infection with any of these three species is established by ingestion of raw or inadequately cooked freshwater fish harboring metacercariae. These organisms excyst in the duodenum, releasing larvae that travel through the ampulla of Vater and mature into adult worms in bile canaliculi. Mature flukes are flat and elongated, measuring 1–2 cm in length. The hermaphroditic worms reproduce by releasing small operculated eggs, which pass with bile into the intestines and are voided with stools. The life cycle is completed in the environment in specific freshwater snails (the first intermediate host) and encystment of metacercariae in freshwater fish.

Except for late sequelae, the exact clinical syndromes caused by clonorchiasis and opisthorchiasis are not well defined. Since most infected individuals harbor a low worm burden, many are asymptomatic. Moderate to heavy infection may be associated with vague right-upper-quadrant pain. In contrast, chronic or repeated infection is associated with manifestations such as cholangitis, cholangiohepatitis, and biliary obstruction. Cholangiocarcinoma is epidemiologically related to *C. sinensis* infection in China and to *O. viverrini* infection in northeastern Thailand. This association has resulted in classification of these infectious agents as human carcinogens.

FASCIOLIASIS

Infections with *Fasciola hepatica* and *F. gigantica* are worldwide zoonoses that are particularly endemic in sheep-raising countries. Human cases have been reported in South America, Europe, Africa, Australia, and the Far East. Recent estimates indicate a worldwide prevalence of 17 million cases. High endemicity has been reported in certain areas of Peru and Bolivia. In most endemic areas the predominant species is *F. hepatica*, but in Asia and Africa a varying degree of overlap with *F. gigantica* has been observed.

Humans acquire fascioliasis by ingestion of metacercariae attached to certain aquatic plants, such as watercress. Infection may also be acquired by consumption of contaminated water or ingestion of food items washed with such water. Acquisition of human infection through consumption of freshly prepared raw liver containing immature flukes has been reported. Infection is initiated when metacercariae excyst, penetrate the gut wall, and travel through the peritoneal cavity to invade the liver capsule. Adult worms finally reach bile ducts,

where they produce large operculated eggs, which are voided in bile through the gastrointestinal tract to the outside environment. The flukes' life cycle is completed in specific snails (the first intermediate host) and encystment on aquatic plants.

Clinical features of fascioliasis relate to the stage and intensity of infection. Acute disease develops during parasite migration (1–2 weeks after infection) and includes fever, right-upper-quadrant pain, hepatomegaly, and eosinophilia. CT of the liver may show migratory tracks. Symptoms and signs usually subside as the parasites reach their final habitat. In individuals with chronic infection, bile duct obstruction and biliary cirrhosis are infrequently demonstrated. No relation to hepatic malignancy has been ascribed to fascioliasis.

DIAGNOSIS

Diagnosis of infection with any of the biliary flukes depends on a high degree of suspicion, elicitation of an appropriate geographic history, and stool examination for characteristically shaped parasite ova. Additional evidence may be obtained by documenting peripheral blood eosinophilia or imaging the liver. Serologic testing is helpful, particularly in lightly infected individuals.

Treatment: BILIARY FLUKES

Drug therapy (praziquantel or triclabendazole) is summarized in Table 126-2. Patients with anatomic lesions in the biliary tract or malignancy are managed according to general medical guidelines.

INTESTINAL FLUKES

Two species of intestinal flukes cause human infection in defined geographic areas worldwide (Table 126-1). The large *Fasciolopsis buski* (adults measure 2 × 7 cm) is endemic in Southeast Asia, while the smaller *Heterophyes heterophyes* is found in the Nile Delta of Egypt and in the Far East. Infection is initiated by ingestion of metacercariae attached to aquatic plants (*F. buski*) or encysted in freshwater or brackish-water fish (*H. heterophyes*). Flukes mature in human intestines, and eggs are passed with stools. Most individuals infected with intestinal flukes are asymptomatic. In heavy *F. buski* infection, diarrhea, abdominal pain, and malabsorption may be encountered. Heavy infection with *H. heterophyes* may be associated with abdominal pain and mucous diarrhea. Diagnosis is established by detection of characteristically shaped ova in stool samples. The drug of choice for treatment is praziquantel (Table 126-2).

LUNG FLUKES

Infection with the lung fluke *Paragonimus westermani* (Table 126-1) and related species (e.g., *P. africanus*) is endemic in many parts of the

world, excluding North America and Europe. Endemicity is particularly noticeable in West Africa, Central and South America, and Asia. In nature, the reservoir hosts of *P. westermani* are wild and domestic felines. In Africa, *P. africanus* has been found in other species, such as dogs. Adult lung flukes, which are 7–12 mm in length, are found encapsulated in the lungs of infected persons. In rare circumstances, flukes are found encysted in the CNS (cerebral paragonimiasis) or abdominal cavity. Humans acquire lung fluke infection by ingesting infective metacercariae encysted in the muscles and viscera of crayfish and freshwater crabs. In endemic areas, these crustaceans are consumed either raw or pickled. Once the organisms reach the duodenum, they excyst, penetrate the gut wall, and travel through the peritoneal cavity, diaphragm, and pleural space to reach the lungs. Mature flukes are found in the bronchioles surrounded by cystic lesions. Parasite eggs are either expectorated with sputum or swallowed and passed to the outside environment with feces. The life cycle is completed in snails and freshwater crustacea.

When maturing flukes lodge in lung tissues, they cause hemorrhage and necrosis, resulting in cyst formation. The adjacent lung parenchyma shows evidence of inflammatory infiltration, predominantly by eosinophils. Cysts usually measure 1–2 cm in diameter and may contain one or two worms each. With the onset of oviposition, cysts usually rupture in adjacent bronchioles—an event allowing ova to exit the human host. Older cysts develop thickened walls, which may undergo calcification. During the active phase of paragonimiasis, lung tissues surrounding parasite cysts may contain evidence of pneumonia, bronchitis, bronchiectasis, and fibrosis.

Pulmonary paragonimiasis is particularly symptomatic in persons with moderate to heavy infection. Productive cough with brownish sputum or frank hemoptysis associated with peripheral blood eosinophilia is usually the presenting feature. Chest examination may reveal signs of pleurisy. In chronic cases, bronchitis or bronchiectasis may predominate, but these conditions rarely proceed to lung abscess. Imaging of the lungs demonstrates characteristic features, including patchy densities, cavities, pleural effusion, and ring shadows. Cerebral paragonimiasis presents as either space-occupying lesions or epilepsy.

DIAGNOSIS

Pulmonary paragonimiasis is diagnosed by detection of parasite ova in sputum and/or stools. Serology is of considerable help in egg-negative cases and in cerebral paragonimiasis.

Treatment: LUNG FLUKES

The drug of choice for treatment is praziquantel (Table 126-2). Other medical or surgical management may be needed for pulmonary or cerebral lesions.

CONTROL AND PREVENTION OF TISSUE FLUKES

For residents of nonendemic areas who are visiting an endemic region, the only effective preventive measure is to avoid ingestion of local plants, fish, or crustaceans; if their ingestion is necessary, these items should be washed or cooked thoroughly. Instruction on water and food preparation and consumption should be included in physicians' advice to travelers (Chap. 4). Interruption of transmission among residents of endemic areas depends on avoiding ingestion of infective stages and disposing of feces and sputum appropriately to prevent hatching of eggs in the environment. These two approaches rely greatly on socioeconomic development and health education. In countries where economic progress has resulted in financial and social improvements, transmission has decreased. The third approach to control in endemic communities entails selective use of chemotherapy for individuals posing the highest risk of transmission—i.e., those with heavy infections. The availability of praziquantel—a broad-spectrum, safe, and effective anthelmintic agent—provides a means for reducing the reservoirs of infection in human populations. However, the existence of most of these helminths as zoonoses in several animal species complicates control efforts.

CHAPTER 127

CESTODES

A. Clinton White, Jr. ■ Peter F. Weller

Cestodes, or tapeworms, are segmented worms. The adults reside in the gastrointestinal tract, but the larvae can be found in almost any organ. Human tapeworm infections can be divided into two major clinical groups. In one group, humans are the definitive hosts, with the adult tapeworms living in the gastrointestinal tract (*Taenia saginata*, *Diphyllobothrium*, *Hymenolepis*, and *Dipylidium caninum*). In the other, humans are intermediate hosts, with larval-stage parasites present in the tissues; diseases in this category include echinococcosis, sparganosis, and

coenurosis. For *Taenia solium*, the human may be either the definitive or the intermediate host.

The ribbon-shaped tapeworm attaches to the intestinal mucosa by means of sucking cups or hooks located on the scolex. Behind the scolex is a short, narrow neck from which proglottids (segments) form. As each proglottid matures, it is displaced further back from the neck by the formation of new, less mature segments. The progressively elongating chain of attached proglottids, called the *strobila*, constitutes the bulk of the tapeworm.

The length varies among species. In some, the tapeworm may consist of more than 1000 proglottids and may be several meters long. The mature proglottids are hermaphroditic and produce eggs, which are subsequently released. Since eggs of the different *Taenia* species are morphologically identical, differences in the morphology of the scolex or proglottids provide the basis for diagnostic identification to the species level.

Most human tapeworms require at least one intermediate host for complete larval development. After ingestion of the eggs or proglottids by an intermediate host, the larval oncospheres are activated, escape the egg, and penetrate the intestinal mucosa. The oncosphere migrates to tissues and develops into an encysted form known as a *cysticercus* (single scolex), a *coenurus* (multiple scolices), or a *hydatid* (cyst with daughter cysts, each containing several protoscolices). Ingestion by the definitive host of tissues containing a cyst enables a scolex to develop into a tapeworm.

TAENIASIS SAGINATA

The beef tapeworm *T. saginata* occurs in all countries where raw or undercooked beef is eaten. It is most prevalent in sub-Saharan African and Middle Eastern countries. *T. saginata asiatica* is a variant of *T. saginata* that is found in Asia and for which pigs are the intermediate host.

Etiology and Pathogenesis

Humans are the only definitive host for the adult stage of *T. saginata*. This tapeworm, which can reach 8 m in length, inhabits the upper jejunum and has a scolex with four prominent suckers and 1000–2000 proglottids. Each gravid segment has 15–30 uterine branches (in contrast to 8–12 for *T. solium*). The eggs are indistinguishable from those of *T. solium*; they measure 30–40 μm , contain the oncosphere, and have a thick brown striated shell. Eggs deposited on vegetation can live for months or years until they are ingested by cattle or other herbivores. The embryo released after ingestion invades the intestinal wall and is carried to striated muscle, where it transforms into a cysticercus. When ingested in raw or undercooked beef, this form can infect humans. After the cysticercus is ingested, it takes ~2 months for the mature adult worm to develop.

Clinical Manifestations

Patients become aware of the infection most commonly by noting passage of proglottids in their feces. The proglottids are often motile, and patients may experience perianal discomfort when proglottids are discharged. Mild abdominal pain or discomfort, nausea, change in appetite, weakness, and weight loss can occur with *T. saginata* infection.

Diagnosis

The diagnosis is made by the detection of eggs or proglottids in the stool. Eggs may also be present in the perianal area; thus, if proglottids or eggs are not found in the stool, the perianal region should be examined with

use of a cellophane-tape swab (as in pinworm infection; Chap. 124). Distinguishing *T. saginata* from *T. solium* requires examination of mature proglottids or the scolex. Serologic tests are not helpful diagnostically. Eosinophilia and elevated levels of serum IgE may be detected.

Treatment:

TAENIASIS SAGINATA

A single dose of praziquantel (10 mg/kg) is highly effective.

Prevention

The major method of preventing infection is the adequate cooking of beef; exposure to temperatures as low as 56°C for 5 min will destroy cysticerci. Refrigeration or salting for long periods or freezing at –10°C for 9 days also kills cysticerci in beef. General preventive measures include inspection of beef and proper disposal of human feces.

TAENIASIS SOLIUM AND CYSTICERCOSIS

The pork tapeworm *T. solium* can cause two distinct forms of infection in humans: adult tapeworms in the intestine or larval forms in the tissues (cysticercosis). Humans are the only definitive hosts for *T. solium*; pigs are the usual intermediate hosts, although other animals may harbor the larval forms.

T. solium exists worldwide but is most prevalent in Latin America, sub-Saharan Africa, China, southern and Southeast Asia, and eastern Europe. Cysticercosis occurs in industrialized nations largely as a result of the immigration of infected persons from endemic areas.

Etiology and Pathogenesis

The adult tapeworm generally resides in the upper jejunum. The scolex attaches by both sucking disks and two rows of hooklets. Often only one adult worm is present, but that worm may live for years. The tapeworm, usually ~3 m in length, may have as many as 1000 proglottids, each of which produces up to 50,000 eggs. Groups of 3–5 proglottids are generally released and excreted into the feces, and the eggs in these proglottids are infective for both humans and animals. The eggs may survive in the environment for several months. After ingestion of eggs by the pig intermediate host, the larvae are activated, escape the egg, penetrate the intestinal wall, and are carried to many tissues, with a predilection for striated muscle of the neck, tongue, and trunk. Within 60–90 days, the encysted larval stage develops. These cysticerci can survive for months to years. By ingesting undercooked pork containing cysticerci, humans acquire infections that lead to intestinal tapeworms. Infections that cause human cysticercosis follow the ingestion of *T. solium* eggs, usually from close contact with a tapeworm carrier. Autoinfection may

FIGURE 127-1

Neurocysticercosis is caused by *Taenia solium*. Neurologic infection can be classified on the basis of the location and viability of the parasites. When the parasites are in the ventricles, they often cause obstructive hydrocephalus. **A.** MRI showing a cysticercus in the lateral ventricle, with resultant hydrocephalus. The arrow points to the scolex within the cystic parasite. **B.** CT showing a parenchymal cysticercus,

with enhancement of the cyst wall and an internal scolex (arrow). **C.** Multiple cysticerci, including calcified lesions from prior infection (arrowheads), viable cysticerci in the basilar cisterns (white arrow), and a large degenerating cysticercus in the Sylvian fissure (black arrow). (Modified with permission from JC Bandres et al: *Clin Infect Dis* 15:799, 1992. © The University of Chicago Press.)

occur if an individual with an egg-producing tapeworm ingests eggs derived from his or her own feces.

Clinical Manifestations

Intestinal infections with *T. solium* may be asymptomatic. Fecal passage of proglottids may be noted by patients. Other symptoms are infrequent.

In cysticercosis, the clinical manifestations are variable. Cysticerci can be found anywhere in the body but are most commonly detected in the brain, cerebrospinal fluid (CSF), skeletal muscle, subcutaneous tissue, or eye. The clinical presentation of cysticercosis depends on the number and location of cysticerci as well as the extent of associated inflammatory responses or scarring. Neurologic manifestations are the most common (Fig. 127-1). Seizures are associated with inflammation surrounding cysticerci in the brain parenchyma. These seizures may be generalized, focal, or Jacksonian. Hydrocephalus results from obstruction of CSF flow by cysticerci and accompanying inflammation or by CSF outflow obstruction from arachnoiditis. Signs of increased intracranial pressure, including headache, nausea, vomiting, changes in vision, dizziness, ataxia, or confusion, are often evident. Patients with hydrocephalus may develop papilledema or display altered mental status. When cysticerci develop at the base of the brain or in the subarachnoid space, they may cause chronic meningitis or arachnoiditis, communicating hydrocephalus, or strokes.

Diagnosis

The diagnosis of intestinal *T. solium* infection is made by the detection of eggs or proglottids, as described for *T. saginata*. In cysticercosis, diagnosis can be difficult. A consensus conference has delineated absolute, major, minor, and epidemiologic criteria for diagnosis (Table 127-1). Diagnostic certainty is possible only with definite

demonstration of the parasite (absolute criteria). This task can be accomplished by histologic observation of the parasite in excised tissue, by fundoscopic visualization of the parasite in the eye (in the anterior chamber, vitreous, or subretinal spaces), or by neuroimaging studies demonstrating cystic lesions containing a characteristic scolex. In most cases, diagnostic certainty is not possible. Instead, a clinical diagnosis is made on the basis of a combination of clinical presentation, radiographic studies, serologic tests, and exposure history.

Neuroimaging findings suggestive of neurocysticercosis constitute the primary major diagnostic criterion. These findings include cystic lesions with or without enhancement (e.g., ring enhancement), one or more nodular calcifications (which may also have associated enhancement), or focal enhancing lesions. Cysticerci in the brain parenchyma are usually 5–20 mm in diameter and rounded. Cystic lesions in the subarachnoid space or fissures may enlarge up to 6 cm in diameter and may be lobulated. For cysticerci within the subarachnoid space or ventricles, the walls may be very thin and the cyst fluid is often isodense with CSF. Thus, obstructive hydrocephalus or enhancement of the basilar meninges may be the only finding on CT in extraparenchymal neurocysticercosis. Cysticerci in the ventricles or subarachnoid space are usually visible to an experienced neuroradiologist on MRI or on CT with intraventricular contrast injection. CT is more sensitive than MRI in identifying calcified lesions, whereas MRI is better for identifying cystic lesions and enhancement.

The second major diagnostic criterion is detection of specific antibodies to cysticerci. While most tests employing unfractionated antigen have high rates of false-positive and false-negative results, this problem can be overcome by using the more specific immunoblot assay. An immunoblot assay using lentil-lectin purified glycoproteins has >99% specificity and is highly sensitive. However,

DIAGNOSTIC CRITERIA FOR HUMAN CYSTICERCOSIS^a

- 1. Absolute criteria
 - a. Demonstration of cysticerci by histologic or microscopic examination of biopsy material
 - b. Visualization of the parasite in the eye by funduscopy
 - c. Neuroradiologic demonstration of cystic lesions containing a characteristic scolex
- 2. Major criteria
 - a. Neuroradiologic lesions suggestive of neurocysticercosis
 - b. Demonstration of antibodies to cysticerci in serum by enzyme-linked immunoelectrotransfer blot
 - c. Resolution of intracranial cystic lesions spontaneously or after therapy with albendazole or praziquantel alone
- 3. Minor criteria
 - a. Lesions compatible with neurocysticercosis detected by neuroimaging studies
 - b. Clinical manifestations suggestive of neurocysticercosis
 - c. Demonstration of antibodies to cysticerci or cysticercal antigen in cerebrospinal fluid by ELISA
 - d. Evidence of cysticercosis outside the central nervous system (e.g., cigar-shaped soft tissue calcifications)
- 4. Epidemiologic criteria
 - a. Residence in a cysticercosis-endemic area
 - b. Frequent travel to a cysticercosis-endemic area
 - c. Household contact with an individual infected with *Taenia solium*

^aDiagnosis is confirmed by either one absolute criterion or a combination of two major criteria, one minor criterion, and one epidemiologic criterion. A probable diagnosis is supported by the fulfillment of (1) one major criterion plus two minor criteria; (2) one major criterion plus one minor criterion and one epidemiologic criterion; or (3) three minor criteria plus one epidemiologic criterion.

Note: ELISA, enzyme-linked immunosorbent assay.
Source: Modified from Del Brutto et al.

patients with single intracranial lesions or with calcifications may be seronegative. With this assay, serum samples provide greater diagnostic sensitivity than CSF. All of the diagnostic antigens have been cloned, and enzyme-linked immunosorbent assays (ELISAs) using recombinant antigens are being developed. Antigen detection assays employing monoclonal antibodies to detect parasite antigen in the blood or spinal fluid may also facilitate diagnosis. However, these assays are not widely available.

Studies have demonstrated that clinical criteria can aid in the diagnosis in selected cases. In patients from endemic areas who had single enhancing lesions presenting with seizures, a normal physical examination, and no evidence of systemic disease (e.g., no fever, adenopathy, or abnormal chest radiograph), the constellation of rounded CT lesions 5–20 mm in diameter with no midline shift was almost always caused by neurocysticercosis. Finally, spontaneous resolution or resolution after therapy with albendazole alone is consistent with neurocysticercosis.

Minor diagnostic criteria include neuroimaging findings consistent with but less characteristic of cysticercosis, clinical manifestations suggestive of neurocysticercosis (e.g., seizures, hydrocephalus, or altered mental status), evidence of cysticercosis outside the central nervous system (CNS; e.g., cigar-shaped soft tissue calcifications), or detection of antibody in CSF by ELISA. Epidemiologic criteria include exposure to a tapeworm carrier or household member infected with *T. solium*, current or prior residence in an endemic area, and frequent travel to an endemic area.

Diagnosis is confirmed in patients with either one absolute criterion or a combination of two major criteria, one minor criterion, and one epidemiologic criterion (Table 127-1). A probable diagnosis is supported by the fulfillment of (1) one major criterion plus two minor criteria; (2) one major criterion plus one minor criterion and one epidemiologic criterion; or (3) three minor criteria plus one epidemiologic criterion. While the CSF is usually abnormal in neurocysticercosis, CSF abnormalities are not pathognomonic. Patients may have CSF pleocytosis with a predominance of lymphocytes, neutrophils, or eosinophils. The protein level in CSF may be elevated; the glucose concentration is usually normal but may be depressed.

Treatment:

Rx TAENIASIS SOLIUM AND CYSTICERCOSIS

Intestinal *T. solium* infection is treated with a single dose of praziquantel (10 mg/kg). However, praziquantel occasionally evokes an inflammatory response in the CNS if concomitant cryptic cysticercosis is present. Niclosamide (2 g) is also effective but is not widely available.

The initial management of neurocysticercosis should focus on symptom-based treatment of seizures or hydrocephalus. Seizures can usually be controlled with antiepileptic treatment. If parenchymal lesions resolve without development of calcifications and patients remain free of seizures, antiepileptic therapy can usually be discontinued after 1–2 years. Placebo-controlled trials are beginning to clarify the clinical advantage of antiparasitic drugs for parenchymal neurocysticercosis. Trends toward faster resolution of neuroradiologic abnormalities have been observed in most studies. The clinical benefits are less dramatic and consist mainly of shortening the period during which recurrent seizures occur and decreasing the number of patients who have many recurrent seizures. For the treatment of patients with brain parenchymal cysticerci, most authorities favor antiparasitic drugs, including praziquantel (50–60 mg/kg daily in three divided doses for 15–30 days) or albendazole (15 mg/kg per day for 8–28 days). Both agents may exacerbate the inflammatory response around the dying parasite, thereby exacerbating seizures or hydrocephalus as well. Thus, patients receiving these drugs should be carefully monitored, and high-dose glucocorticoids should be used during treatment. Since glucocorticoids induce first-pass metabolism of praziquantel

and may decrease its antiparasitic effect, cimetidine should be coadministered to inhibit praziquantel metabolism.

For patients with hydrocephalus, the emergent reduction of intracranial pressure is the mainstay of therapy. In the case of obstructive hydrocephalus, the preferred approach is removal of the cysticercus via endoscopic surgery. However, this intervention is not always possible. An alternative approach is initially to perform a diverting procedure, such as ventriculoperitoneal shunting. Historically, shunts have usually failed, but low failure rates have been attained with administration of antiparasitic drugs and glucocorticoids. Open craniotomy to remove cysticerci is now required only infrequently. For patients with subarachnoid cysts or giant cysticerci, glucocorticoids are needed to reduce arachnoiditis and accompanying vasculitis. Most authorities recommend prolonged courses of antiparasitic drugs and shunting when hydrocephalus is present. In patients with diffuse cerebral edema and elevated intracranial pressure due to multiple inflamed lesions, glucocorticoids are the mainstay of therapy, and antiparasitic drugs should be avoided. For ocular and spinal medullary lesions, drug-induced inflammation may cause irreversible damage. Most patients should be managed surgically, although case reports have described cures with medical therapy.

Prevention

Measures for the prevention of intestinal *T. solium* infection consist of the application to pork of precautions similar to those described above for beef with regard to *T. saginata* infection. The prevention of cysticercosis involves minimizing the opportunities for ingestion of fecally derived eggs by means of good personal hygiene, effective fecal disposal, and treatment and prevention of human intestinal infections. Mass chemotherapy has been administered to human and porcine populations in efforts at disease eradication.

ECHINOCOCCOSIS

Echinococcosis is an infection caused in humans by the larval stage of the *Echinococcus granulosus* complex, *E. multilocularis*, or *E. vogeli*. *E. granulosus* complex parasites, which produce unilocular cystic lesions, are prevalent in areas where livestock is raised in association with dogs.

These parasites are found on all continents, with areas of high prevalence in China, central Asia, the Middle East, the Mediterranean region, eastern Africa, and parts of South America. Molecular evidence suggests that *E. granulosus* strains may actually belong to more than one species; specifically, strains from sheep, cattle, pigs, horses, and camels probably represent separate species. *E. multilocularis*, which causes multilocular alveolar lesions that are locally invasive, is found in Alpine, sub-Arctic, or Arctic regions, including Canada, the United States, and central and northern Europe; China; and central Asia.

E. vogeli causes polycystic hydatid disease and is found only in Central and South America.

Like other cestodes, echinococcal species have both intermediate and definitive hosts. The definitive hosts are canines that pass eggs in their feces. After the ingestion of eggs, cysts develop in the intermediate hosts—sheep, cattle, humans, goats, camels, and horses for the *E. granulosus* complex and mice and other rodents for *E. multilocularis*. When a dog (*E. granulosus*) or fox (*E. multilocularis*) ingests infected meat containing cysts, the life cycle is completed.

Etiology

The small (5-mm-long) adult *E. granulosus* worm, which lives for 5–20 months in the jejunum of dogs, has only three proglottids: one immature, one mature, and one gravid. The gravid segment splits to release eggs that are morphologically similar to *Taenia* eggs and are extremely hardy. After humans ingest the eggs, embryos escape from the eggs, penetrate the intestinal mucosa, enter the portal circulation, and are carried to various organs, most commonly the liver and lungs. Larvae develop into fluid-filled unilocular hydatid cysts that consist of an external membrane and an inner germinal layer. Daughter cysts develop from the inner aspect of the germinal layer, as do germinating cystic structures called *brood capsules*. New larvae, called *protoscolices*, develop in large numbers within the brood capsule. The cysts expand slowly over a period of years.

The life cycle of *E. multilocularis* is similar except that wild canines, such as foxes, serve as the definitive hosts and small rodents serve as the intermediate hosts. The larval form of *E. multilocularis*, however, is quite different in that it remains in the proliferative phase, the parasite is always multilocular, and vesicles without brood capsule or protoscolices progressively invade the host tissue by peripheral extension of processes from the germinal layer.

Clinical Manifestations

Slowly enlarging echinococcal cysts generally remain asymptomatic until their expanding size or their space-occupying effect in an involved organ elicits symptoms. The liver and the lungs are the most common sites of these cysts. The liver is involved in about two-thirds of *E. granulosus* infections and in nearly all *E. multilocularis* infections. Since a period of years elapses before cysts enlarge sufficiently to cause symptoms, they may be discovered incidentally on a routine x-ray or ultrasound study.

Patients with hepatic echinococcosis who are symptomatic most often present with abdominal pain or a palpable mass in the right upper quadrant. Compression of a bile duct or leakage of cyst fluid into the biliary tree may mimic recurrent cholelithiasis, and biliary obstruction can result in jaundice. Rupture of or episodic leakage from a hydatid cyst may produce fever, pruritus, urticaria, eosinophilia, or anaphylaxis. Pulmonary hydatid cysts may rupture into the bronchial tree or peritoneal cavity and produce cough, dyspnea, chest pain, or hemoptysis. Rupture of hydatid cysts, which can occur spontaneously

or at surgery, may lead to multifocal dissemination of protoscolices, which can form additional cysts. Other presentations are due to the involvement of bone (invasion of the medullary cavity with slow bone erosion producing pathologic fractures), the CNS (space-occupying lesions), the heart (conduction defects, pericarditis), and the pelvis (pelvic mass).

The larval forms of *E. multilocularis* characteristically present as a slowly growing hepatic tumor, with progressive destruction of the liver and extension into vital structures. Patients commonly report upper quadrant and epigastric pain. Liver enlargement and obstructive jaundice may be apparent. The lesions may infiltrate adjoining organs (e.g., diaphragm, kidneys, or lungs) or may metastasize to the spleen, lungs, or brain.

Diagnosis

Radiographic and related imaging studies are important in detecting and evaluating echinococcal cysts. Plain films will define pulmonary cysts of *E. granulosus*—usually as rounded masses of uniform density—but may miss cysts in other organs unless there is cyst wall calcification (as occurs in the liver). MRI, CT, and ultrasound reveal well-defined cysts with thick or thin walls. When older cysts contain a layer of hydatid sand that is rich in accumulated protoscolices, these imaging methods may detect this fluid layer of different density. However, the most pathognomonic finding, if demonstrable, is that of daughter cysts within the larger cyst. This finding, like eggshell or mural calcification on CT, is indicative of

E. granulosus infection and helps to distinguish the cyst from carcinomas, bacterial or amebic liver abscesses, or hemangiomas. In contrast, ultrasound or CT of alveolar hydatid cysts reveals indistinct solid masses with central necrosis and plaquelike calcifications.

A specific diagnosis of *E. granulosus* infection can be made by the examination of aspirated fluids for protoscolices or hooklets, but diagnostic aspiration is not usually recommended because of the risk of fluid leakage resulting in either dissemination of infection or anaphylactic reactions. Serodiagnostic assays can be useful, although a negative test does not exclude the diagnosis of echinococcosis. Cysts in the liver elicit positive antibody responses in ~90% of cases, whereas up to 50% of individuals with cysts in the lungs are seronegative. Detection of antibody to specific echinococcal antigens by immunoblotting has the highest degree of specificity.

Rx Treatment: ECHINOCOCCOSIS

Therapy for cystic echinococcosis is based on considerations of the size, location, and manifestations of cysts and the overall health of the patient. Surgery has traditionally been the principal definitive method of treatment. Currently, ultrasound staging is recommended for *E. granulosus* infections (Fig. 127-2). For CE1 lesions, uncomplicated CE3 lesions, and some CE2 lesions, PAIR (percutaneous aspiration, infusion of scolicedal agents,

FIGURE 127-2

Management of cystic hydatid disease caused by *Echinococcus granulosus* should be based on viability of the parasite, which can be estimated from radiographic appearance. The ultrasound appearance includes lesions classified as active, transitional, and inactive. Active cysts include types CL (with a cystic lesion and no visible cyst wall), CE1 [with a visible cyst wall and internal echoes (snowflake sign)], and CE2 (with a

visible cyst wall and internal septation). Transitional cysts (CE3) may have detached laminar membranes or may be partially collapsed. Inactive cysts include types CE4 (a nonhomogeneous mass) and CE5 (a cyst with a thick calcified wall). [Adapted from RL Guerrant et al (eds): *Tropical Infectious Diseases: Principles, Pathogens and Practice*, 2d ed, p 1312. © 2005, with permission from Elsevier Science.]

and reaspiration) is now recommended instead of surgery. PAIR is contraindicated for superficially located cysts (because of the risk of rupture), for cysts with multiple thick internal septal divisions (honeycombing pattern), and for cysts communicating with the biliary tree. For prophylaxis of secondary peritoneal echinococcosis due to inadvertent spillage of fluid during PAIR, the administration of albendazole (15 mg/kg daily in two divided doses) should be initiated at least 4 days before the procedure and continued for at least 4 weeks afterward. Ultrasound- or CT-guided aspiration allows confirmation of the diagnosis by demonstration of protoscolices in the aspirate. After aspiration, contrast material should be injected to detect occult communications with the biliary tract. Alternatively, the fluid should be checked for bile staining by dipstick. If no bile is found and no communication visualized, the contrast material is reaspirated, with subsequent infusion of scolicalid agents (usually 95% ethanol; alternatively, hypertonic saline). Daughter cysts within the primary cyst may need to be punctured separately. In experienced hands, this approach yields rates of cure and relapse equivalent to those following surgery, with less perioperative morbidity and shorter hospitalization.

Surgery remains the treatment of choice for complicated *E. granulosus* cysts (e.g., those communicating with the biliary tract) or for areas where PAIR is not possible. For *E. granulosus*, the preferred surgical approach is pericystectomy, in which the entire cyst and the surrounding fibrous tissue are removed. The risks posed by leakage of fluid during surgery or PAIR include anaphylaxis and dissemination of infectious protoscolices. The latter complication has been minimized by careful attention to the prevention of spillage of the cyst and by soaking of the drapes with hypertonic saline. Infusion of scolicalid agents is no longer recommended because of problems with hypernatremia, intoxication, or sclerosing cholangitis. Albendazole, which is active against *Echinococcus*, should be administered adjunctively, beginning several days before resection and continuing for several weeks for *E. granulosus*. Praziquantel (50 mg/kg daily for 2 weeks) may hasten the death of the protoscolices. Medical therapy with albendazole alone for 12 weeks to 6 months results in cure in ~30% of cases and in improvement in another 50%. In many instances of treatment failure, *E. granulosus* infections are subsequently treated successfully with PAIR or additional courses of medical therapy. Response to treatment is best assessed by serial imaging studies, with attention to cyst size and consistency. Some cysts may not demonstrate complete radiologic resolution even though no viable protoscolices are present. Some of these cysts with partial radiologic resolution (e.g., CE4) can be managed with observation only.

Surgical resection remains the treatment of choice for *E. multilocularis* infection. Complete removal of the parasite continues to offer the best chance for cure. Ongoing therapy with albendazole for at least 2 years after presumptively curative surgery is recommended. Most cases are diagnosed at a stage at which complete

resection is not possible; in these cases, albendazole treatment should be continued indefinitely, with careful monitoring. In some cases, liver transplantation has been used because of the size of the necessary liver resection. However, continuous immunosuppression favors the proliferation of *E. multilocularis* larvae and reinfection of the transplant. Thus, indefinite treatment with albendazole is required.

Prevention

In endemic areas, echinococcosis can be prevented by administering praziquantel to infected dogs, by denying dogs access to infected animals, or by vaccinating sheep. Limitation of the number of stray dogs is helpful in reducing the prevalence of infection among humans.

HYMENOLEPIASIS NANA

Infection with *Hymenolepis nana*, the dwarf tapeworm, is the most common of all the cestode infections. *H. nana* is endemic in both temperate and tropical regions of the world. Infection is spread by fecal/oral contamination and is common among institutionalized children.

Etiology and Pathogenesis

H. nana is the only cestode of humans that does not require an intermediate host. Both the larval and adult phases of the life cycle take place in the human. The adult—the smallest tapeworm parasitizing humans—is ~2 cm long and dwells in the proximal ileum. Proglottids, which are quite small and are rarely seen in the stool, release spherical eggs 30–44 µm in diameter, each of which contains an oncosphere with six hooklets. The eggs are immediately infective and are unable to survive for >10 days in the external environment. *H. nana* can also be acquired by the ingestion of infected insects (especially larval meal-worms and larval fleas). When the egg is ingested by a new host, the oncosphere is freed and penetrates the intestinal villi, becoming a cysticercoid larva. Larvae migrate back into the intestinal lumen, attach to the mucosa, and mature into adult worms over 10–12 days. Eggs may also hatch before passing into the stool, causing internal autoinfection with increasing numbers of intestinal worms. Although the life span of adult *H. nana* worms is only ~4–10 weeks, the autoinfection cycle perpetuates the infection.

Clinical Manifestations

H. nana infection, even with many intestinal worms, is usually asymptomatic. When infection is intense, anorexia, abdominal pain, and diarrhea develop.

Diagnosis

Infection is diagnosed by the finding of eggs in the stool.

R_x Treatment: **HYMENOLEPIASIS NANA**

Praziquantel (25 mg/kg once) is the treatment of choice, since it acts against both the adult worms and the cysticercoids in the intestinal villi. Nitazoxanide (500 mg bid for 3 days) may be used as an alternative.

Prevention

Good personal hygiene and improved sanitation can eradicate the disease. Epidemics have been controlled by mass chemotherapy coupled with improved hygiene.

HYMENOLEPIASIS DIMINUTA

Hymenolepis diminuta, a cestode of rodents, occasionally infects small children, who ingest the larvae in uncooked cereal foods contaminated by fleas and other insects in which larvae develop. Infection is usually asymptomatic and is diagnosed by the detection of eggs in the stool. Treatment with praziquantel results in cure in most cases.

DIPHYLLOBOOTHRIASIS

Diphyllobothrium latum and other *Diphyllobothrium* species are found in the lakes, rivers, and deltas of the northern hemisphere, Central Africa, and Chile.

Etiology and Pathogenesis

The adult worm—the longest tapeworm (up to 25 m)—attaches to the ileal and occasionally to the jejunal mucosa by its suckers, which are located on its elongated scolex. The adult worm has 3000–4000 proglottids, which release ~1 million eggs daily into the feces. If an egg reaches water, it hatches and releases a free-swimming embryo that can be eaten by small freshwater crustaceans (*Cyclops* or *Diaptomus* species). After an infected crustacean containing a developed procercoid is swallowed by a fish, the larva migrates into the fish's flesh and grows into a plerocercoid, or sparganum larva. Humans acquire the infection by ingesting infected raw or smoked fish. Within 3–5 weeks, the tapeworm matures into an adult in the human intestine.

Clinical Manifestations

Most *D. latum* infections are asymptomatic, although manifestations may include transient abdominal discomfort, diarrhea, vomiting, weakness, and weight loss. Occasionally, infection can cause acute abdominal pain and intestinal obstruction; in rare cases, cholangitis or cholecystitis may be produced by migrating proglottids. Because the tapeworm absorbs large quantities of vitamin B₁₂ and interferes with ileal B₁₂ absorption, vitamin B₁₂ deficiency can develop. Up to 2% of infected patients, especially the elderly, have megaloblastic anemia resembling pernicious anemia and may exhibit neurologic sequelae of B₁₂ deficiency.

Diagnosis

The diagnosis is made readily by the detection of the characteristic eggs in the stool. The eggs possess a single shell with an operculum at one end and a knob at the other. Mild to moderate eosinophilia may be detected.

R_x Treatment: **DIPHYLLOBOOTHRIASIS**

Praziquantel (5–10 mg/kg once) is highly effective. Parenteral vitamin B₁₂ should be given if B₁₂ deficiency is manifest.

Prevention

Infection can be prevented by heating fish to 54°C for 5 min or by freezing it at –18°C for 24 h. Placing fish in brine with a high salt concentration for long periods kills the eggs.

DIPYLIDIASIS

Dipylidium caninum, a common tapeworm of dogs and cats, may accidentally infect humans. Dogs, cats, and occasionally humans become infected by ingesting fleas harboring cysticercoids. Children are more likely to become infected than adults. Most infections are asymptomatic, but abdominal pain, diarrhea, anal pruritus, urticaria, eosinophilia, or passage of segments in the stool may occur. The diagnosis is made by the detection of proglottids or ova in the stool. As in *D. latum* infection, therapy consists of praziquantel. Prevention requires anthelmintic treatment and flea control for pet dogs or cats.

SPARGANOSIS

Humans can be infected by the sparganum, or plerocercoid larva, of a diphyllobothrid tapeworm of the genus *Spirometra*. Infection can be acquired by the consumption of water containing infected *Cyclops*; by the ingestion of infected snakes, birds, or mammals; or by the application of infected flesh as poultices. The worm migrates slowly in tissues, and infection commonly presents as a subcutaneous swelling. Periorbital tissues can be involved, and ocular sparganosis may destroy the eye. Surgical excision is used to treat localized sparganosis.

COENUROSIS

This rare infection of humans by the larval stage (coenurus) of the dog tapeworm *Taenia multiceps* or *T. serialis* results in a space-occupying cystic lesion. As in cysticercosis, involvement of the CNS and subcutaneous tissue is most common. Both definitive diagnosis and treatment require surgical excision of the lesion. Chemotherapeutic agents generally are not effective.

APPENDIX

LABORATORY VALUES OF CLINICAL IMPORTANCE

Alexander Kratz ■ Michael A. Pesce ■ Daniel J. Fink[†]

INTRODUCTORY COMMENTS

The following are tables of reference values for laboratory tests, special analytes, and special function tests. A variety of factors can influence reference values. Such variables include the population studied, the duration and means of specimen transport, laboratory methods and instrumentation, and even the type of container used for the collection of the specimen. The reference or “normal” ranges given in this Appendix may therefore not be appropriate for all laboratories, and these values should only be used as general guidelines. Whenever possible, reference values provided by the laboratory performing the testing should be utilized in the interpretation of laboratory data. Values supplied in this Appendix reflect typical reference ranges in adults. Pediatric reference ranges may vary significantly from adult values.

In preparing the Appendix, the authors have taken into account the fact that the system of international units (SI, système international d’unités) is used in most countries and in some medical journals. However, clinical laboratories may continue to report values in “conventional” units. Therefore, both systems are provided in the Appendix. The dual system is also used in the text except for (1) those instances in which the numbers remain the same but only the terminology is changed (mmol/L for meq/L or IU/L for mIU/mL), when only the SI units are given; and (2) most pressure measurements (e.g., blood and cerebrospinal fluid pressures), when the conventional units (mmHg, mmH₂O) are used. In all other instances in the text the SI unit is followed by the traditional unit in parentheses.

[†]Deceased.

TABLE A-1

HEMATOLOGY AND COAGULATION

| ANALYTE | SPECIMEN ^a | SI UNITS | CONVENTIONAL UNITS |
|--|-----------------------|---|---|
| Activated clotting time | WB | 70–180 s | 70–180 s |

TABLE A-5

CLASSIFICATION OF LDL, TOTAL, AND HDL CHOLESTEROL

| LDL Cholesterol, mg/dL (mmol/L) | |
|-----------------------------------|--|
| <70 (<1.81) | Therapeutic option for very high risk patients |
| <100 (<2.59) | Optimal |
| 100–129 (2.59–3.34) | Near optimal/above optimal |
| 130–159 (3.36–4.11) | Borderline high |
| 160–189 (4.14–4.89) | High |
| ≥190 (≥4.91) | Very high |
| Total Cholesterol, mg/dL (mmol/L) | |
| <200 (<5.17) | Desirable |
| 200–239 (5.17–6.18) | Borderline high |
| ≥240 (≥6.21) | High |
| HDL Cholesterol, mg/dL (mmol/L) | |
| <40 (<1.03) | Low |
| ≥60 (≥1.55) | High |

Note: LDL, low-density lipoprotein; HDL, high-density lipoprotein

| IgG | 0.009–0.057 g/L | 0.9–5.7 mg/dL |
| IgG index ^b | 0.29–0.59 | |

(Continued)

TABLE A-6 (CONTINUED)

| CEREBROSPINAL FLUID (CSF) ^a | | |
|--|--|---|
| CONSTITUENT | REFERENCE RANGE | |
| | SI UNITS | CONVENTIONAL UNITS |
| Total protein (<i>Continued</i>) | | |
| Oligoclonal bands | <2 bands not present in matched serum sample | |
| Ammonia | 15–47 µmol/L | 25–80 µg/dL |
| Creatinine | 44–168 µmol/L | 0.5–1.9 mg/dL |
| Myelin basic protein | <4 µg/L | |
| CSF pressure | | 50–180 mmH ₂ O |
| CSF volume (adult) | ~150 mL | |
| Red blood cells | 0 | 0 |
| Leukocytes | | |
| Total | 0–5 mononuclear cells per µL | 0–5 mononuclear cells per mm ³ |
| Differential | | |
| Lymphocytes | 60–70% | |
| Monocytes | 30–50% | |
| Neutrophils | None | |

^aSince cerebrospinal fluid concentrations are equilibrium values, measurements of the same parameters in blood plasma obtained at the same time are recommended. However, there is a time lag in attainment of equilibrium, and cerebrospinal levels of plasma constituents that can fluctuate rapidly (such as plasma glucose) may not achieve stable values until after a significant lag phase.

^bIgG index = CSF IgG(mg/dL) × serum albumin(g/dL)/Serum IgG(g/dL) × CSF albumin(mg/dL).

TABLE A-7

| URINE ANALYSIS | | |
|--|------------------------|---------------------|

TABLE A-12

GASTROINTESTINAL TESTS

| TEST | RESULTS | |
|---|---|---|
| | SI UNITS | CONVENTIONAL UNITS |
| Absorption tests | | |
| D-Xylose: after overnight fast, 25 g xylose given in oral aqueous solution | | |
| Urine, collected for following 5 h | 25% of ingested dose | 25% of ingested dose |
| Serum, 2 h after dose | 2.0–3.5 mmol/L | 30–52 mg/dL |
| Vitamin A: a fasting blood specimen is obtained and 200,000 units of vitamin A in oil is given orally | Serum level should rise to twice fasting level in 3–5 h | Serum level should rise to twice fasting level in 3–5 h |
| Bentiromide test (pancreatic function): 500 mg bentiromide (chymex) orally; <i>p</i> -aminobenzoic acid (PABA) measured | | |
| Plasma | | >3.6 (± 1.1) $\mu\text{g/mL}$ at 90 min |
| Urine | >50% recovered in 6 h | >50% recovered in 6 h |
| Gastric juice | | |
| Volume | | |
| 24 h | 2–3 L | 2–3 L |
| Nocturnal | 600–700 mL | 600–700 mL |
| Basal, fasting | 30–70 mL/h | 30–70 mL/h |
| Reaction | | |
| pH | 1.6–1.8 | 1.6–1.8 |
| Titrateable acidity of fasting juice | 4–9 $\mu\text{mol/s}$ | 15–35 meq/h |
| Acid output | | |
| Basal | | |
| Females (mean ± 1 SD) | 0.6 \pm 0.5 $\mu\text{mol/s}$ | 2.0 \pm 1.8 meq/h |
| Males (mean ± 1 SD) | 0.8 \pm 0.6 $\mu\text{mol/s}$ | 3.0 \pm 2.0 meq/h |
| Maximal (after SC histamine acid phosphate, 0.004 mg/kg body weight, and preceded by 50 mg promethazine, or after betazole, 1.7 mg/kg body weight, or pentagastrin, 6 $\mu\text{g/kg}$ body weight) | | |
| Females (mean ± 1 SD) | 4.4 \pm 1.4 $\mu\text{mol/s}$ | 16 \pm 5 meq/h |
| Males (mean ± 1 SD) | 6.4 \pm 1.4 $\mu\text{mol/s}$ | 23 \pm 5 meq/h |
| Basal acid output/maximal acid output ratio | ≤ 0.6 | ≤ 0.6 |
| Gastrin, serum | 0–200 $\mu\text{g/L}$ | 0–200 pg/mL |
| Secretin test (pancreatic exocrine function): 1 unit/kg body weight, IV | | |
| Volume (pancreatic juice) in 80 min | >2.0 mL/kg | >2.0 mL/kg |
| Bicarbonate concentration | >80 mmol/L | >80 meq/L |
| Bicarbonate output in 30 min | >10 mmol | >10 meq |

TABLE A-13

NORMAL VALUES OF DOPPLER ECHOCARDIOGRAPHIC MEASUREMENTS IN ADULTS

| | RANGE | MEAN |
|---|---------|---------------|
| RVD (cm), measured at the base in apical 4-chamber view | 2.6–4.3 | 3.5 \pm 0.4 |
| LVID (cm), measured in the parasternal long axis view | 3.6–5.4 | 4.7 \pm 0.4 |
| Posterior LV wall thickness (cm) | 0.6–1.1 | 0.9 \pm 0.4 |
| IVS wall thickness (cm) | 0.6–1.1 | 0.9 \pm 0.4 |
| Left atrial dimension (cm), antero-posterior dimension | 2.3–3.8 | 3.0 \pm 0.3 |
| Aortic root dimension (cm) | 2.0–3.5 | 2.4 \pm 0.4 |
| Aortic cusps separation (cm) | 1.5–2.6 | 1.9 \pm 0.4 |
| Percentage of fractional shortening | 34–44% | 36% |
| Mitral flow (m/s) | 0.6–1.3 | 0.9 |
| Tricuspid flow (m/s) | 0.3–0.7 | 0.5 |
| Pulmonary artery (m/s) | 0.6–0.9 | 0.75 |
| Aorta (m/s) | 1.0–1.7 | 1.35 |

Note: RVD, right ventricular dimension; LVID, left ventricular internal dimension; LV, left ventricle; IVS, interventricular septum.

SUMMARY OF VALUES USEFUL IN PULMONARY PHYSIOLOGY

| | | TYPICAL VALUES | |
|--|-----------------------------------|--|--------------------------------------|
| SPECIMEN | SYMBOL | MAN, AGE 40, 75 kg, 175 cm TALL | WOMAN, AGE 40, 60 kg, 160 cm TALL |
| Pulmonary Mechanics | | | |
| Spirometry—volume-time curves | | | |
| Forced vital capacity | FVC | 5.1 L | 3.6 L |
| Forced expiratory volume in 1 s | FEV ₁ | 4.1 L | 2.9 L |
| FEV ₁ /FVC | FEV ₁ % | 80% | 82% |
| Maximal midexpiratory flow | MMF (FEF 25–27) | 4.8 L/s | 3.6 L/s |
| Maximal expiratory flow rate | MEFR (FEF 200–1200) | 9.4 L/s | 6.1 L/s |
| Spirometry—flow-volume curves | | | |
| Maximal expiratory flow at 50% of expired vital capacity | V _{max} 50 (FEF 50%) | 6.1 L/s | 4.6 L/s |
| Maximal expiratory flow at 75% of expired vital capacity | V _{max} 75 (FEF 75%) | 3.1 L/s | 2.5 L/s |
| Resistance to airflow | | | |
| Pulmonary resistance | RL (R _L) | <3.0 (cmH ₂ O/s)/L | |
| Airway resistance | Raw | <2.5 (cmH ₂ O/s)/L | |
| Specific conductance | SGaw | >0.13 cmH ₂ O/s | |
| Pulmonary compliance | | | |
| Static recoil pressure at total lung capacity | Pst TLC | 25 ± 5 cmH ₂ O | |
| Compliance of lungs (static) | CL | 0.2 L cmH ₂ O | |
| Compliance of lungs and thorax | C(L + T) | 0.1 L cmH ₂ O | |
| Dynamic compliance of 20 breaths per minute | C dyn 20 | 0.25 ± 0.05 L/cmH ₂ O | |
| Maximal static respiratory pressures | | | |
| Maximal inspiratory pressure | MIP | >90 cmH ₂ O | >50 cmH ₂ O |
| Maximal expiratory pressure | MEP | >150 cmH ₂ O | >120 cmH ₂ O |
| Lung Volumes | | | |
| Total lung capacity | TLC | 6.7 L | 4.9 L |
| Functional residual capacity | FRC | 3.7 L | 2.8 L |
| Residual volume | RV | 2.0 L | 1.6 L |
| Inspiratory capacity | IC | 3.3 L | 2.3 L |
| Expiratory reserve volume | ERV | 1.7 L | 1.1 L |
| Vital capacity | VC | 5.0 L | 3.4 L |
| Gas Exchange (Sea Level) | | | |
| Arterial O ₂ tension | Pa _{O₂} | 12.7 ± 0.7 kPa (95 ± 5 mmHg) | |
| Arterial CO ₂ tension | Pa _{CO₂} | 5.3 ± 0.3 kPa (40 ± 2 mmHg) | |
| Arterial O ₂ saturation | Sa _{O₂} | 0.97 ± 0.02 (97 ± 2%) | |
| Arterial blood pH | pH | 7.40 ± 0.02 | |
| Arterial bicarbonate | HCO ₃ [−] | 24 + 2 meq/L | |
| Base excess | BE | 0 ± 2 meq/L | |
| Diffusing capacity for carbon monoxide (single breath) | DL _{CO} | 0.42 mL CO/s per mmHg (25 mL CO/min per mmHg) | |
| Dead space volume | V _D | 2 mL/kg body wt | |
| Physiologic dead space; dead space-tidal volume ratio | | | |
| Rest | | ≤35% V _T | |
| Exercise | | ≤20% V _T | |
| Alveolar-arterial difference for O ₂ | P(A − a) _{O₂} | ≤2.7 kPa ≤20 kPa (≤20 mmHg) | |

TABLE A-15

BODY FLUIDS AND OTHER MASS DATA

| | REFERENCE RANGE | |
|------------------------------------|-----------------------------|---|
| | SI UNITS | CONVENTIONAL UNITS |
| Body fluid | | |
| Total volume (lean) of body weight | 50% (in obese) to 70% | |
| Intracellular | 0.3–0.4 of body weight | |
| Extracellular | 0.2–0.3 of body weight | |
| Blood | | |
| Total volume | | |
| Males | 69 mL per kg body weight | |
| Females | 65 mL per kg body weight | |
| Plasma volume | | |
| Males | 39 mL per kg body weight | |
| Females | 40 mL per kg body weight | |
| Red blood cell volume | | |
| Males | 30 mL per kg body weight | 1.15–1.21 L/m ² of body surface area |
| Females | 25 mL per kg body weight | 0.95–1.00 L/m ² of body surface area |
| Body mass index | 18.5–24.9 kg/m ² | 18.5–24.9 kg/m ² |

TABLE A-16

RADIATION-DERIVED UNITS

| QUANTITY | OLD UNIT | SI UNITS | NAME FOR SI UNIT (and Abbreviation) | CONVERSION |
|-----------------|--------------|----------------------------------|-------------------------------------|--|
| Activity | Curie (Ci) | Disintegrations per second (dps) | Becquerel (Bq) | 1 Ci = 3.7×10^{10} Bq 1 mCi = 37 mBq 1 μ Ci = 0.037 MBq or 37 GBq |
| Absorbed dose | Rad | Joule per kilogram (J/kg) | Gray (Gy) | 1 Bq = 2.703×10^{-11} Ci 1 Gy = 100 rad 1 rad = 0.01 Gy 1 mrad = 10^{-3} cGy |
| Exposure | Roentgen (R) | Coulomb per kilogram (C/kg) | — | 1 C/kg = 3876 R 1 R = 2.58×10^{-4} C/kg 1 mR = 258 pC/kg |
| Dose equivalent | Rem | Joule per kilogram (J/kg) | Sievert (Sv) | 1 Sv = 100 rem 1 rem = 0.01 Sv 1 mrem = 10 μ Sv |

ACKNOWLEDGMENT

The authors acknowledge the contributions of Dr. Patrick M. Sluss, Dr. James L. Januzzi, and Dr. Kent B. Lewandrowski to this chapter in previous editions of *Harrison's Principles of Internal Medicine*.

QUESTIONS

DIRECTIONS: Choose the **one best** response to each question.

1. Which type of bite represents a potential medical emergency in an asplenic patient?

A. Cat bite
B. Dog bite
C. Fish bite
D. Human bite
2. A 24-year-old man with advanced HIV infection presents to the emergency department with a tan painless nodule on the lower extremity (Fig. 2). He is afebrile and has no other lesions. He does not take antiretroviral therapy, and his last CD4+ T-cell count was 20/ μ L. He lives with a friend who has cats and kittens. A biopsy shows lobular proliferation of blood vessels lined by enlarged endothelial cells and a mixed acute and chronic inflammatory infiltrate. Tissue stains show gram-negative bacilli. Which of the following is most likely to be effective therapy for the lesion?

FIGURE 2

2. (Continued)
A. Azithromycin
B. Cephazolin
C. Interferon α
D. Penicillin
E. Vancomycin
3. A 26-year-old woman comes to your clinic complaining of 3–4 weeks of a malodorous white vaginal discharge. She recently began having unprotected sexual intercourse with a new male partner. He is asymptomatic. Her only medication is oral contraceptives. Examination reveals a thin white discharge that evenly coats the vagina. Further examination of the discharge reveals that it has a pH of 5.0 and has a “fishy” odor when 10% KOH is added to the discharge. Microscopic examination reveals vaginal cells coated with coccobacillary organisms. Which of the following therapies is indicated?

A. Acyclovir, 400 mg PO tid \times 7 days
B. Metronidazole, 2 g PO \times 1
C. Metronidazole, 500 mg PO bid \times 7 days
D. Fluconazole, 100 mg PO \times 1
E. Vaginal douching
4. All of the following infections associated with sexual activity correlate with increased acquisition of HIV infection in women *except*

A. bacterial vaginosis
B. *Chlamydia*
C. gonorrhea
D. herpes simplex virus-2
E. *Trichomonas vaginalis*
F. all of the above are associated with increased acquisition
5. A 9-year-old boy is brought to a pediatric emergency room by his father. He has had 2 days of headache, neck stiffness, and photophobia and this morning had a temperature of 38.9°C (102°F). He has also had several episodes of vomiting and diarrhea

*Questions and answers were selected by Miriam J. Baron, MD, from Wiener C, et al (eds). *Harrison's Principles of Internal Medicine Self-Assessment and Board Review*, 17th ed. New York: McGraw-Hill, 2008.

5. (Continued)
overnight. A lumbar puncture is performed, which reveals pleocytosis in the cerebrospinal fluid (CSF). Which of the following is true regarding enteroviruses as a cause of aseptic meningitis?
- An elevated CSF protein rules out enteroviruses as a cause of meningitis.
 - Enteroviruses are responsible for up to 90% of aseptic meningitis in children.
 - Lymphocytes will predominate in the CSF early on, with a shift to neutrophils at 24 h.
 - Symptoms are more severe in children than in adults.
 - They occur more commonly in the winter and spring.
6. A 48-year-old female presents to her physician with a 2-day history of fever, arthralgias, diarrhea, and headache. She recently returned from an eco-tour in tropical sub-Saharan Africa, where she went swimming in inland rivers. Notable findings on physical examination include a temperature of 38.7°C (101.7°F); 2-cm tender mobile lymph nodes in the axilla, cervical, and femoral regions; and a palpable spleen. Her white blood cell count is 15,000/ μ L with 50% eosinophils. She should receive treatments with which of the following medications?
- Chloroquine
 - Mebendazole
 - Metronidazole
 - Praziquantel
 - Thiabendazole
7. A 39-year-old woman received a liver transplant 2 years ago and is maintained on prednisone, 5 mg, and cyclosporine A, 8 mg/kg per day. She has had two episodes of rejection since transplant, as well an episode of cytomegalovirus syndrome and *Nocardia* pneumonia. She intends to take a 2-week gorilla-watching trip to Rwanda and seeks your advice regarding her health while abroad. Which of the following potential interventions is strictly contraindicated?
- Malaria prophylaxis
 - Meningococcal vaccine
 - Rabies vaccine
 - Typhoid purified polysaccharide vaccine
 - Yellow fever vaccine
8. A 17-year-old woman presents to the clinic complaining of vaginal itchiness and malodorous discharge. She is sexually active with multiple partners, and she is interested in getting tested for sexually transmitted diseases. A wet-mount microscopic examination is performed, and trichomonal parasites are identified. Which of the following statements regarding trichomoniasis is true?
- A majority of women are asymptomatic.
 - No treatment is necessary as disease is self-limited.
 - The patient's sexual partner need not be treated.
 - Trichomoniasis can only be spread sexually.
 - Trichomoniasis is 100% sensitive to metronidazole.
8. (Continued)
9. The most common clinical presentation of infection with *Babesia microti* is
- acute hepatitis
 - chronic meningitis
 - generalized lymphadenopathy
 - overwhelming hemolysis, high-output congestive heart failure, respiratory failure, and disseminated intravascular coagulation
 - self-limited flulike illness
10. When given as a first-line agent for invasive *Aspergillus* infection, voriconazole commonly causes all of the following side effects *except*
- drug-drug interactions
 - hepatotoxicity
 - photosensitivity skin rashes
 - renal toxicity
 - visual disturbances
11. A 42-year-old man with AIDS and a CD4+ lymphocyte count of 23 presents with shortness of breath and fatigue in the absence of fevers. On examination, he appears chronically ill with pale conjunctiva. Hematocrit is 16%. Mean corpuscular volume is 84. Red cell distribution width is normal. Bilirubin, lactate dehydrogenase, and haptoglobin are all within normal limits. Reticulocyte count is zero. White blood cell count is 4300, with an absolute neutrophil count of 2500. Platelet count is 105,000. Which of the following tests is most likely to produce a diagnosis?
- Bone marrow aspirate and biopsy
 - Iron studies
 - Parvovirus B19 IgG
 - Parvovirus B19 polymerase chain reaction (PCR)
 - Parvovirus B19 IgM
 - Peripheral blood smear
12. While attending the University of Georgia, a group of friends go on a 5-day canoeing and camping trip in rural southern Georgia. A few weeks later, one of the campers develops a serpiginous, raised, pruritic, erythematous eruption on the buttocks. *Strongyloides* larvae are found in his stool. Three of his companions, who are asymptomatic, are also found to have strongyloides larvae in their stool. Which of the following is indicated in the asymptomatic carriers?

12. (Continued)
A. Fluconazole
B. Ivermectin
C. Mebendazole
D. Mefloquine
E. Treatment only for symptomatic illness
13. A 79-year-old man has had a diabetic foot ulcer overlying his third metatarsal head for 3 months but has not been compliant with his physician's request to offload the affected foot. He presents with dull, throbbing foot pain and subjective fevers. Examination reveals a putrid-smelling wound notable also for a pus-filled 2.5-cm wide ulcer. A metal probe is used to probe the wound and it detects bone as well as a 3-cm deep cavity. Gram stain of the pus shows gram-positive cocci in chains, gram-positive rods, gram-negative diplococci, enteric-appearing gram-negative rods, tiny pleomorphic gram-negative rods, and a predominance of neutrophils. Which of the following empirical antibiotic regimens is recommended while blood and drainage cultures are processed?
- A. Ampicillin/sulbactam, 1.5 g IV q6h
B. Clindamycin, 600 mg PO tid
C. Linezolid, 600 mg IV bid
D. Metronidazole, 500 mg PO qid
E. Vancomycin, 1g IV bid
14. You are a physician working on a cruise ship traveling from Miami to the Yucatán Peninsula. In the course of 24 h, 32 people are seen with acute gastrointestinal illness that is marked by vomiting and watery diarrhea. The most likely causative agent of the illness is
- A. enterohemorrhagic *Escherichia coli*
B. norovirus
C. rotavirus
D. *Shigella*
E. *Salmonella*
15. The standard starting regimen for acid-fast bacilli smear-positive active pulmonary tuberculosis is
- A. isoniazid
B. isoniazid, rifampin
C. isoniazid, moxifloxacin, pyrazinamide, ethambutol
D. isoniazid, rifampin, pyrazinamide, ethambutol
E. rifampin, moxifloxacin, pyrazinamide, ethambutol
16. All of the following are common manifestations of cytomegalovirus (CMV) infection following lung transplantation *except*
- A. bronchiolitis obliterans
B. CMV esophagitis
C. CMV pneumonia
D. CMV retinitis
E. CMV syndrome (fever, malaise, cytopenias, transaminitis, and CMV viremia)
17. Which of the following statements regarding severe acute respiratory syndrome (SARS) is true?
- A. SARS displays poor human-to-human transmission.
B. SARS is more severe among children than adults.
C. The etiologic agent of SARS is in the Adenovirus family.
D. There have been no reported cases of SARS since 2004.
E. There is no known environmental reservoir for the virus causing SARS.
18. A 72-year-old woman is admitted to the intensive care unit with respiratory failure. She has fever, obtundation, and bilateral parenchymal consolidation on chest imaging. Which of the following is true regarding the diagnosis of *Legionella* pneumonia?
- A. Acute and convalescent antibodies are not helpful due to the presence of multiple serotypes.
B. *Legionella* can never be seen on a Gram stain.
C. *Legionella* cultures grow rapidly on the proper media.
D. *Legionella* urinary antigen maintains utility after antibiotic use.
E. Polymerase chain reaction (PCR) for *Legionella* DNA is the "gold standard" diagnostic test.
19. A 23-year-old woman is newly diagnosed with genital herpes simplex virus (HSV)-2 infection. What can you tell her that the chance of reactivation disease will be during the first year after infection?
- A. 5%
B. 25%
C. 50%
D. 75%
E. 90%
20. The most common cause of traveler's diarrhea in Mexico is
- A. *Campylobacter jejuni*
B. *Entamoeba histolytica*
C. enterotoxigenic *Escherichia coli*
D. *Giardia lamblia*
E. *Vibrio cholerae*
21. A patient comes to clinic and describes progressive muscle weakness over several weeks. He has also experienced nausea, vomiting, and diarrhea. One month ago he had been completely healthy and describes a bear hunting trip in Alaska, where they ate some of the game they killed. Soon after he returned, his gastrointestinal (GI) symptoms began, followed by muscle weakness in his jaw and neck that has now spread to his arms and lower back. Examination confirms decreased muscle strength in the upper extremities and neck. He also has slowed extraocular movements. Laboratory examination

21. (Continued)
shows panic values for elevated eosinophils and serum creatine phosphokinase. Which of the following organisms is most likely the cause of his symptoms?
- Campylobacter*
 - Cytomegalovirus
 - Giardia*
 - Taenia solium*
 - Trichinella*
22. Abacavir is a nucleoside transcription inhibitor that carries which side effect unique for HIV antiretroviral agents?
- Fanconi's anemia
 - Granulocytopenia
 - Lactic acidosis
 - Lipoatrophy
 - Severe hypersensitivity reaction
23. A 30-year-old healthy woman presents to the hospital with severe dyspnea, confusion, productive cough, and fevers. She had been ill 1 week prior with a flu-like illness characterized by fever, myalgias, headache, and malaise. Her illness almost entirely improved without medical intervention until 36 h ago, when she developed new rigors followed by progression of the respiratory symptoms. On initial examination, her temperature is 39.6°C, pulse is 130 beats per minute, blood pressure is 95/60 mmHg, respiratory rate is 40, and oxygen saturation is 88% on 100% face mask. On examination she is clammy, confused, and very dyspneic. Lung examination reveals amphoric breath sounds over her left lower lung fields. She is intubated and resuscitated with fluid and antibiotics. Chest CT scan reveals necrosis of her left lower lobe. Blood and sputum cultures grow *Staphylococcus aureus*. This isolate is likely to be resistant to which of the following antibiotics?
- Doxycycline
 - Linezolid
 - Methicillin
 - Trimethoprim/sulfamethoxazole (TMP/SMX)
 - Vancomycin
24. A 24-year-old woman presents with diffuse arthralgias and morning stiffness in her hands, knees, and wrists. Two weeks earlier she had a self-limited febrile illness notable for a red facial rash and lacy reticular rash on her extremities. On examination, her bilateral wrists, metacarpophalangeal joints, and proximal interphalangeal joints are warm and slightly boggy. What test is most likely to reveal her diagnosis?
- Antinuclear antibody
 - Chlamydia trachomatis* ligase chain reaction of the urine
 - Joint aspiration for crystals and culture
24. (Continued)
D. Parvovirus B19 IgM
E. Rheumatoid factor
25. *Candida albicans* is isolated from the following patients. Rate the likelihood in order from *greatest to least* that the positive culture represents true infection rather than contaminant or noninfectious colonization?
- Patient X:* A 63-year-old man admitted to the intensive care unit (ICU) with pneumonia who has recurrent fevers after receiving 5 days of levofloxacin for pneumonia. A urinalysis drawn from a Foley catheter shows positive leukocyte esterase, negative nitrite, 15 white blood cells/hpf, 10 red blood cells/hpf, and 10 epithelial cells/hpf. Urine culture grows *Candida albicans*.
- Patient Y:* A 38-year-old female on hemodialysis presents with low-grade fevers and malaise. Peripheral blood cultures grow *Candida albicans* in one out of a total of three sets of blood cultures in the aerobic bottle only.
- Patient Z:* A 68-year-old man presents with a 2-day history of fever, productive cough, and malaise. Chest roentgenogram reveals a left lower lobe infiltrate. A sputum Gram stain shows many PMNs, few epithelial cells, moderate gram-positive cocci in chains, and yeast consistent with *Candida*.
- Patient X > patient Z > patient Y
 - Patient Y > patient Z > patient X
 - Patient Y > patient X > patient Z
 - Patient X > patient Y > patient Z
 - Patient Z > patient X > patient Y
26. A 38-year-old man with HIV/AIDS presents with 4 weeks of diarrhea, fever, and weight loss. Which of the following tests makes the diagnosis of cytomegalovirus (CMV) colitis?
- CMV IgG
 - Colonoscopy with biopsy
 - Serum CMV polymerase chain reaction (PCR)
 - Stool CMV antigen
 - Stool CMV culture
27. A 46-year-old veterinary researcher who frequently operates on rats presents to the emergency room with jaundice and scant hemoptysis. She recalls having a fairly deep cut on her hand during an operation about 14 days prior. She has had no recent travel or other animal exposures. Her illness started ~9 days prior with fever, chills, severe headache, intense myalgias, and nausea. She also noted bilateral conjunctival injection. Thinking that she had influenza infection, she stayed home from work and started to feel better 5 days into the illness. However, within a day her symptoms had returned with worsening headache, and

27. (Continued)
soon thereafter she developed jaundice. On initial evaluation, her temperature is 38.6°C, pulse is 105 beats per minute, and blood pressure is 156/89 mmHg with O₂ saturations of 92% on room air. She appears acutely ill and is both icteric and profoundly jaundiced. Her liver is enlarged and tender, but there are no palpable masses and she has no splenomegaly. Laboratory results are notable for a BUN of 64, creatinine of 3.6, total bilirubin of 64.8 (direct 59.2), AST = 84, ALT = 103, alkaline phosphatase = 384, white blood cell (WBC) count is 11,000 with 13% bands and 80% polymorphonuclear forms, hematocrit of 33%, and platelets = 142. Urinalysis reveals 20 WBCs/hpf, 3+ protein, and granular casts. Coagulation studies are within normal limits. Lumbar puncture reveals a sterile pleocytosis. CT scan of the chest shows diffuse flame-like infiltrates consistent with pulmonary hemorrhage. What is the likely diagnosis?
- Acute interstitial pneumonitis
 - Acute myeloid leukemia
 - Polyarteritis nodosum
 - Rat bite fever (*Streptobacillus moniliformis* infection)
 - Weil's syndrome (*Leptospira interrogans* infection)
28. A 17-year-old boy in Arkansas presents to a clinic in August with fever, headache, myalgias, nausea, and anorexia 8 days after returning from a 1-week camping trip. Physical examination is remarkable for a temperature of 38.6°C and a generally fatigued but nontoxic appearing, well-developed young man. He does not have a rash, and orthostatic vital sign measurements are negative. What would be a reasonable course of action?
- Initiate ceftriaxone, 1g IM × 1
 - Initiate doxycycline, 100 mg PO bid
 - Initiate oseltamivir, 75 mg PO qd
 - Reassure the patient and order a heterophile antibody titer (Monospot)
 - Reassure the patient and order rickettsial serologies
29. A patient presents to the clinic complaining of nausea, vomiting, crampy abdominal pain, and markedly increased flatus. The patient has not experienced any diarrhea or vomiting but notes that he has been belching more than usual and he describes a "sulfur-like" odor when he does so. He returned from a 3-week trip to Peru and Ecuador several days ago and notes that his symptoms began about a week ago. Giardiasis is considered in the differential. Which of the following is true regarding *Giardia*?
- Boiling water prior to ingestion will not kill *Giardia* cysts.
 - Giardia* is a disease of developing nations; if this patient had not travelled, there would be no likelihood of giardiasis.
29. (Continued)
- Hematogenous dissemination and eosinophilia are common.
 - Ingestion of as few as 10 cysts can cause human disease.
 - Lack of diarrhea makes the diagnosis of *Giardia* very unlikely.
30. An 18-year-old man presents with a firm, nontender lesion around his anal orifice. The lesion is about 1.5 cm in diameter and has a cartilaginous feel on clinical examination. The patient reports that it has progressed to this stage from a small papule. It is not tender. He reports recent unprotected anal intercourse. Bacterial culture of the lesion is negative. A rapid plasmin reagin (RPR) test is also negative. Therapeutic interventions should include
- IM ceftriaxone, 1g
 - IM penicillin G benzathine, 2.4 million U
 - oral acyclovir, 200 mg 5 times per day
 - observation
 - surgical resection with biopsy
31. One month after receiving a 14-day course of omeprazole, clarithromycin, and amoxicillin for *Helicobacter pylori*-associated gastric ulcer disease, a 44-year-old woman still has mild dyspepsia and pain after meals. What is the appropriate next step in management?
- Empirical long-term proton pump inhibitor therapy
 - Endoscopy with biopsy to rule out gastric adenocarcinoma
 - H. pylori* serology testing
 - Reassurance
 - Second-line therapy for *H. pylori* with omeprazole, bismuth subsalicylate, tetracycline, and metronidazole
 - Urea breath test
32. Which of the following statements regarding the currently licensed human papillomavirus (HPV) vaccine (Gardasil) is true?
- It does not protect against genital warts.
 - It is an inactivated live virus vaccine.
 - It is targeted toward all oncogenic strains of HPV but is only 70% effective at decreasing infection in an individual.
 - Once sexually active, women will derive little protective benefit from the vaccine.
 - Vaccinees should continue to receive standard Pap smear testing.
33. A 25-year-old woman presents with 1 day of fever to 38.3°C (101°F), sore throat, dysphagia, and a number of grayish-white papulovesicular lesions on the soft palate, uvula, and anterior pillars of the tonsils (Fig. 33). The patient is most likely infected with which of the following?

FIGURE 33

33. (Continued)
- Candida albicans*
 - Coxsackievirus
 - Herpesvirus
 - HIV
 - Staphylococcus lugdunensis*
34. A 19-year-old female from Guatemala presents to your office for a routine screening physical examination. At age 4 she was diagnosed with acute rheumatic fever. She does not recall the specifics of her illness and remembers only that she was required to be on bed rest for 6 months. She has remained on penicillin V orally at a dose of 250 mg bid since that time. She asks if she can safely discontinue this medication. She has had only one other flare of her disease, at age 8, when she stopped taking penicillin at the time of her emigration to the United States. She is currently working as a day care provider. Her physical examination is notable for normal point of maximal impulse (PMI) with a grade III/VI holosystolic murmur that is heard best at the apex of the heart and radiates to the axilla. What do you advise the patient to do?
- An echocardiogram should be performed to determine the extent of valvular damage before deciding if penicillin can be discontinued.
 - Penicillin prophylaxis can be discontinued because she has had no flares in 5 years.
 - She should change her dosing regimen to IM benzathine penicillin every 8 weeks.
 - She should continue on penicillin indefinitely as she had a previous recurrence, has presumed rheumatic heart disease, and is working in a field with high occupational exposure to group A streptococcus.
 - She should replace penicillin prophylaxis with polyvalent pneumococcal vaccine every 5 years.
35. In a patient with bacterial endocarditis, which of the following echocardiographic lesions is most likely to lead to embolization?
35. (Continued)
- 5-mm mitral valve vegetation
 - 5-mm tricuspid valve vegetation
 - 11-mm aortic valve vegetation
 - 11-mm mitral valve vegetation
 - 11-mm tricuspid valve vegetation
36. A 19-year-old man presents to the emergency department with 4 days of watery diarrhea, nausea, vomiting, and low-grade fever. He recalls no unusual meals, sick contacts, or travel. He is hydrated with IV fluid, given antiemetics, and discharged home after feeling much better. Three days later two out of three blood cultures are positive for *Clostridium perfringens*. He is called at home and says that he feels fine and is back to work. What should your next instruction to the patient be?
- Return for IV penicillin therapy
 - Return for IV penicillin therapy plus echocardiogram
 - Return for IV penicillin therapy plus colonoscopy
 - Return for surveillance blood culture
 - Reassurance
37. All of the following are clinical manifestations of *Ascaris lumbricoides* infection *except*
- asymptomatic carriage
 - fever, headache, photophobia, nuchal rigidity, and eosinophilia
 - nonproductive cough and pleurisy with eosinophilia
 - right upper quadrant pain and fever
 - small-bowel obstruction
38. An 87-year-old nursing home resident is brought by ambulance to a local emergency room. He is obtunded and ill-appearing. Per nursing home staff, the patient has experienced low-grade temperatures, poor appetite, and lethargy over several days. A lumbar puncture is performed, and the Gram stain returns gram-positive rods and many white blood cells. *Listeria meningitis* is diagnosed and appropriate antibiotics are begun. Which of the following best describes a clinical difference between *Listeria* and other causes of bacterial meningitis?
- More frequent nuchal rigidity.
 - More neutrophils are present on the cerebrospinal fluid (CSF) differential.
 - Photophobia is more common.
 - Presentation is often more subacute.
 - White blood cell (WBC) count is often more elevated in the CSF
39. All of the following statements regarding human T cell lymphotropic virus-I (HTLV-I) infection are true *except*

39. (Continued)
- Acute T cell leukemia is associated with HTLV-I infection.
 - HTLV-I endemic regions include southern Japan, the Caribbean, and South America.
 - HTLV-I infection is associated with a gradual decline in T cell function and immunosuppression.
 - HTLV-I is transmitted parenterally, sexually, and from mother to child.
 - Tropical spastic paraparesis is associated with HTLV-I infection.
40. A 3-year-old boy is brought by his parents to clinic. They state that he has experienced fevers, anorexia, weight loss, and, most recently, has started wheezing at night. He had been completely healthy until these symptoms started 2 months ago. The family had travelled through Europe several months prior and reported no unusual exposures or exotic foods. They have a puppy at home. On examination, the child is ill-appearing and is noted to have hepatosplenomegaly. Laboratory results show a panic value of 82% eosinophils. Total white blood cells are elevated. A complete blood count is repeated to rule out a laboratory error and eosinophils are 78%. Which of the following is the most likely organism or process?
- Cysticercus*
 - Giardiasis
 - Staphylococcus lugdunensis*
 - Toxocariasis
 - Trichinellosis
41. An otherwise healthy 5-year-old child presents with low-grade fevers, sore throat, and red, itchy eyes. He attends summer camp, where several other campers were ill. On examination, the patient is noted to have pharyngitis and bilateral conjunctivitis. Which of the following is the most likely etiologic agent?
- Adenovirus
 - Enterovirus
 - Influenza virus
 - Metapneumovirus
 - Rhinovirus
42. A 35-year-old male is seen 6 months after a cadaveric renal allograft. The patient has been on azathioprine and prednisone since that procedure. He has felt poorly for the past week with fever to 38.6°C (101.5°F), anorexia, and a cough productive of thick sputum. Chest x-ray reveals a left lower lobe (5 cm) nodule with central cavitation. Examination of the sputum reveals long, crooked, branching, beaded gram-positive filaments. The most appropriate initial therapy would include the administration of which of the following antibiotics?
- Ceftazidime
 - Erythromycin
 - Penicillin
 - Sulfisoxazole
 - Tobramycin
43. A 53-year-old male with a history of alcoholism presents with an enlarging mass at the angle of the jaw. The patient describes the mass slowly enlarging over a period of 6 weeks with occasional associated pain. He has also noted intermittent fevers throughout this period. Recently, he has developed yellowish drainage from the inferior portion of the mass. He takes no medications and has no other past history. He drinks six beers daily. On physical examination, the patient has a temperature of 37.9°C (100.2°F). His dentition is poor. There is diffuse soft tissue swelling and induration at the angle of the mandible on the left. It is mildly tender, and no discrete mass is palpable. The area of swelling is ~8 × 8 cm. An aspirate is sent for Gram stain and culture. The culture initially grows *Eikenella corrodens*. After 7 days you receive a call reporting growth of a gram-positive bacillus branching at acute angles on anaerobic media. What organism is causing this man's clinical presentation?
- Actinomyces*
 - Eikenella corrodens*
 - Mucormycosis*
 - Nocardia*
 - Peptostreptococcus*
44. A 19-year-old man presents to an urgent care clinic with urethral discharge. He reports three new female sexual partners over the past 2 months. What should his management be?
- Nucleic acid amplification test for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* and return to clinic in 2 days
 - Cefpodoxime, 400 mg PO × 1, and azithromycin, 1g PO × 1 for the patient and his partners
 - Nucleic acid amplification test for *N. gonorrhoeae* and *C. trachomatis* plus cefpodoxime, 400 mg PO × 1, and azithromycin, 1 g PO × 1, for the patient
 - Nucleic acid amplification test for *N. gonorrhoeae* and *C. trachomatis* plus cefpodoxime, 400 mg PO × 1, and azithromycin, 1g PO × 1, for the patient and his recent partners
 - Nucleic acid amplification test for *N. gonorrhoeae* and *C. trachomatis* plus cefpodoxime, 400 mg PO × 1, azithromycin, 1g PO × 1, and flagyl, 2 g PO × 1, for the patient and his partners
45. A 19-year-old college student is brought to the emergency department by friends from his dormitory for confusion and altered mental status. They state that many colleagues have upper respiratory

45. (Continued)

tract infections. He does not use alcohol or illicit drugs. His physical examination is notable for confusion, fever, and a rigid neck. Cerebrospinal fluid (CSF) examination reveals a white blood cell count of 1800 cells/ μ L with 98% neutrophils, glucose of 1.9 mmol/L (35 mg/dL), and protein of 1.0 g/L (100 mg/dL). Which of the following antibiotic regimens is most appropriate as initial therapy?

- A. Ampicillin plus vancomycin
- B. Ampicillin plus gentamicin
- C. Cefazolin plus doxycycline
- D. Cefotaxime plus doxycycline
- E. Cefotaxime plus vancomycin

46. A 38-year-old woman presents to the emergency department with severe abdominal pain. She has no past medical or surgical history. She recalls no recent history of abdominal discomfort, diarrhea, melena, bright red blood per rectum, nausea, or vomiting prior to this acute episode. She ate ceviche (lime-marinated raw fish) at a Peruvian restaurant 3 h prior to presentation. On examination, she is in terrible distress and has dry heaves. Temperature is 37.6°C; heart rate is 128 beats per minute; blood pressure is 174/92 mmHg. Examination is notable for an extremely tender abdomen with guarding and rebound tenderness. Bowel sounds are present and hyperactive. Rectal examination is normal and guaiac test is negative. Pelvic examination is unremarkable. White blood cell count is 6738/ μ L; hematocrit is 42%. A complete metabolic panel and lipase and amylase levels are all within normal limits. CT of the abdomen shows no abnormality. What is the next step in her management?

- A. CT angiogram of the abdomen
- B. Pelvic ultrasonography
- C. Proton pump inhibitor therapy and observation
- D. Right upper quadrant ultrasonography
- E. Upper endoscopy

47. Which of the following clinical features can be used to rule out malaria in favor of another tropical febrile illness in a returning traveler?

- A. Diarrhea
- B. Lack of paroxysmal nature of the fevers
- C. Lack of splenomegaly
- D. Severe myalgias and retroorbital headache
- E. None of the above

48. Which of the following statements regarding liver abscesses is true?

- A. Amebic liver abscess should be ruled out only by direct sampling and culture of pus.
- B. Alkaline phosphatase is the most likely liver function test to be abnormal in the presence of a liver abscess.

48. (Continued)

- C. *Candida* species are most commonly isolated from patients with abscesses that develop as a result of peritoneal or pelvic pathology.
- D. Patients with liver abscesses nearly always have right upper quadrant pain.
- E. All of the above are true.

49. A 40-year-old male is admitted to the hospital with 2–3 weeks of fever, tender lymph nodes, and right upper quadrant abdominal pain. He reports progressive weight loss and malaise over a year. On examination, he is found to be febrile and frail with temporal wasting and oral thrush. Matted, tender anterior cervical lymphadenopathy <1 cm and tender hepatomegaly are noted. He is diagnosed with AIDS (CD4+ lymphocyte count = 12/ μ L and HIV RNA 650,000 copies/mL). Blood cultures grow *Mycobacterium avium*. He is started on rifabutin and clarithromycin, as well as dapsone for *Pneumocystis* prophylaxis, and discharged home 2 weeks later after his fevers subside. He follows up with an HIV provider 4 weeks later and is started on tenofovir, emtricitabine, and efavirenz. Two weeks later he returns to clinic with fevers, neck pain, and abdominal pain. His temperature is 39.2°C, heart rate is 110 beats per minute, blood pressure is 110/64 mmHg, and oxygen saturations are normal. His cervical nodes are now 2 cm in size and extremely tender, and one has fistulized to his skin and is draining yellow pus that is acid-fast bacillus stain-positive. His hepatomegaly is pronounced and tender. What is the *most likely* explanation for his presentation?

- A. Cryptococcal meningitis
- B. HIV treatment failure
- C. Immune reconstitution syndrome to *Mycobacterium avium*
- D. Kaposi's sarcoma
- E. *Mycobacterium avium* treatment failure due to drug resistance

50. Which of the following statements regarding prevention of human respiratory syncytial virus (HRSV) infection in children is true?

- A. All children who are admitted to the hospital more than twice a year should be vaccinated against HRSV.
- B. Barrier precautions remain the only effective means of prevention.
- C. Children should be vaccinated at birth.
- D. Inactivated, whole-virus vaccine should be considered in children <2 years old.
- E. RSV immune globulin should be given monthly to children <2 years old who were born prematurely.

51. A 52-year-old woman with alcoholic cirrhosis, portal hypertension, esophageal varices, and history of hepatic encephalopathy presents to the hospital with confusion over several days. Her husband remarks that

51. (Continued)

the patient has been adherent to her medicines. These medicines include labetalol, furosemide, aldactone, and lactulose. Physical examination is notable for temperature of 38.3°C, heart rate of 115 beats per minute, blood pressure of 105/62 mmHg, respiratory rate of 12 breaths per minute, and oxygen saturation of 96% on room air. The patient is extremely drowsy, only intermittently able to answer questions, and disoriented. She has slight asterixis. Lungs are clear. Cardiac examination is unremarkable. Her abdomen is distended and tense but non-tender. She has 3+ lower extremity edema extending to her thighs. She is guaiac negative. Her cranial nerves and extremity strength are symmetric and normal. Laboratory studies reveal a leukocyte count of 4830/μL, hematocrit = 33% (baseline = 30%), and platelet count of 94,000/μL. Basic metabolic panel is unremarkable. What is an essential component of the diagnostic workup?

- A. CT scan of the head
- B. Esophagogastroduodenoscopy
- C. Paracentesis
- D. Therapeutic trial of lactulose
- E. Serum ammonia level

52. A 34-year-old immigrant from Burundi presents with fever, headache, severe myalgias, photophobia, conjunctival injection, and prostration. He lived in a refugee camp for the previous 10 years. In the camp, he was treated for several unknown febrile illnesses. Since arriving in the United States 7 years ago, he has worked as a computer analyst and lived only in a metropolitan Northwest city with no significant travel. Initial blood cultures are negative. Five days into the illness he develops hypotension, pneumonitis, encephalopathy, and gangrene of his distal digits as well as a petechial, hemorrhagic rash over his entire body except for his face. A biopsy of his rash reveals immunohistochemical changes consistent with a rickettsial infection. Which of the following rickettsial pathogens is most likely in this patient?

- A. *Coxiella burnetii* (Q fever)
- B. *Rickettsia africae* (African tick-borne fever)
- C. *Rickettsia prowazekii* (Louse-borne typhus)
- D. *Rickettsia rickettsii* (Rocky Mountain spotted fever)
- E. *Rickettsia typhi* (Murine typhus)

53. *Borrelia burgdorferi* serology testing is indicated for which of the following patients, all of whom reside in Lyme-endemic regions?

- A. A 19-year-old female camp counselor who presents with her second episode of an inflamed, red and tender left knee and right ankle
- B. A 23-year-old male house painter who presents with a primary erythema migrans lesion at the site of a witnessed tick bite

53. (Continued)

- C. A 36-year-old female state park ranger who presents with a malar rash, diffuse arthralgias/arthritis of her shoulders, knees, metacarpophalangeal and proximal interphalangeal joints; pericarditis; and acute glomerulonephritis
- D. A 42-year-old woman with chronic fatigue, myalgias, and arthralgias
- E. A 46-year-old male gardener who presents with fevers, malaise, migratory arthralgias/myalgias, and three erythema migrans lesions

54. A 39-year-old injection drug user with a history of right-sided endocarditis and HIV infection notes back pain and fevers over the past week. He had an abscess recently on his right arm that he drained on his own. He is part of a needle-exchange program and always cleans his arm before shooting heroin into the vein in his antecubital fossa. On physical examination, he has a temperature of 38.1°C, heart rate of 124 beats per minute, and blood pressure of 75/30 mmHg. He is in a great deal of distress and is slightly confused. He has a 4/6 left lower sternal border murmur that varies with the respiratory cycle. His jugular venous pressure is monophasic and to the jaw when seated at 90°. Lung examination is clear. Abdomen is benign. He is very tender over his lower spine. His extremities are warm. Leg strength is 5/5 on the right, with 4/5 left hip flexion and extension, 3/5 left knee flexion and extension, and 3/5 left foot extension. His Babinski reflex is upgoing on the left and downgoing on the right. What is the next step in management?

- A. Avoidance of antibiotics until more definitive culture data is obtained; serial neurologic examinations
- B. Urgent MRI and neurosurgical consultation; vancomycin after blood cultures are drawn
- C. Urgent MRI and neurosurgical consultation; vancomycin plus cefepime after blood cultures are drawn
- D. Urgent MRI and neurosurgical consultation; avoidance of antibiotics until more definitive culture data is obtained
- E. Vancomycin plus cefepime after blood cultures are drawn; serial neurologic examinations

55. An HIV-positive patient with a CD4 count of 110/μL who is not taking any medications presents to an urgent care center with complaints of a headache for the past week. He also notes nausea and intermittently blurred vision. Examination is notable for normal vital signs without fever but mild papilledema. Head CT does not show dilated ventricles. The definitive diagnostic test for this patient is

- A. cerebrospinal fluid (CSF) culture
- B. MRI with gadolinium imaging

55. (Continued)
C. ophthalmologic examination including visual field testing
D. serum cryptococcal antigen testing
E. urine culture
56. Current Centers for Disease Control and Prevention (CDC) recommendations are that screening for HIV be performed in which of the following?
- A. All high-risk groups (injection drug users, men who have sex with men, and high-risk heterosexual women)
 - B. All U.S. adults
 - C. Injection drug users
 - D. Men who have sex with men
 - E. Women who have sex with more than two men per year
57. A 26-year-old woman presents late in the third trimester of her pregnancy with high fevers, myalgias, backache, and malaise. She is admitted and started on empirical broad-spectrum antibiotics. Blood cultures return positive for *Listeria monocytogenes*. She delivers a 5-lb infant 24 h after admission. Which of the following statements regarding antibiotic treatment for this infection is true?
- A. Clindamycin should be used in patients with penicillin allergy.
 - B. Neonates should receive weight-based ampicillin and gentamicin.
 - C. Penicillin plus gentamicin is first-line therapy for the mother.
 - D. Quinolones should be used for *Listeria* bacteremia in late-stage pregnancy.
 - E. Trimethoprim-sulfamethoxazole has no efficacy against *Listeria*.
58. A 23-year-old previously healthy female letter carrier works in a suburb in which the presence of rabid foxes and skunks has been documented. She is bitten by a bat, which then flies away. Initial examination reveals a clean break in the skin in the right upper forearm. She has no history of receiving treatment for rabies and is unsure about vaccination against tetanus. The physician should
- A. clean the wound with a 20% soap solution
 - B. clean the wound with a 20% soap solution and administer tetanus toxoid
 - C. clean the wound with a 20% soap solution, administer tetanus toxoid, and administer human rabies immune globulin intramuscularly
 - D. clean the wound with a 20% soap solution, administer tetanus toxoid, administer human rabies immune globulin IM, and administer human diploid cell vaccine
 - E. clean the wound with a 20% soap solution and administer human diploid cell vaccine
59. A 23-year-old woman develops cytomegalovirus (CMV) pneumonitis 5 months after a lung transplant. She developed severe side effects from ganciclovir while receiving prophylaxis. Foscarnet is prescribed for this episode. Which of the following side effects is most likely?
- A. Bone marrow suppression
 - B. Electrolyte wasting
 - C. Embryotoxic
 - D. Lethargy and tremors
 - E. Hyperkalemia
60. A 38-year-old woman is seen in clinic for a decrease in cognitive and executive function. Her husband is concerned because she is no longer able to pay bills, keep appointments, or remember important dates. She also seems to derive considerably less pleasure from caring for her children and her hobbies. She is unable to concentrate for long enough to enjoy movies. This is a clear change from her functional status 6 months prior. A workup reveals a positive HIV antibody by enzyme immunoassay and Western blot. Her CD4+ lymphocyte count is 378/ μ L with a viral load of 78,000/mL. She is afebrile with normal vital signs. Her affect is blunted, and she seems disinterested in the medical interview. Neurologic examination for strength, sensation, cerebellar function, and cranial nerve function is nonfocal. Fundoscopic examination is normal. Mini-Mental Status Examination score is 22/30. A serum rapid plasmin reagin (RPR) test is negative. MRI of the brain shows only cerebral atrophy disproportionate to her age but no focal lesions. What is the next step in her management?
- A. Antiretroviral therapy
 - B. Cerebrospinal fluid (CSF) JV virus polymerase chain reaction (PCR)
 - C. CSF mycobacterial PCR
 - D. CSF VDRL test
 - E. Serum cryptococcal antigen
 - F. *Toxoplasma* IgG
61. A 72-year-old male is admitted to the hospital with bacteremia and pyelonephritis. He is HIV-negative and has no other significant past medical history. Two weeks into his treatment with antibiotics a fever evaluation reveals a blood culture positive for *Candida albicans*. Examination is unremarkable. White blood cell count is normal. The central venous catheter is removed, and systemic antifungal agents are initiated. What further evaluation is recommended?
- A. Abdominal CT scan to evaluate for abscess
 - B. Chest x-ray
 - C. Fundoscopic examination
 - D. Repeat blood cultures
 - E. Transthoracic echocardiogram

62. A 40-year-old man with HIV (CD4+ lymphocyte count = 180, viral load = 1000 copies/mL) was treated for secondary syphilis based on generalized painless lymphadenopathy, a diffuse maculopapular rash that included his palms and soles, and a preceding primary genital chancre. He reported no neurologic or ophthalmic symptoms at the time and received one dose of IM penicillin G benzathine. At the time of diagnosis, his rapid plasmin reagin (RPR) titer was 1:64 and fluorescent treponemal antibody-absorption (FTA-ABS) test was positive. He follows up a year later and is found to have an RPR titer of 1:64 and his FTA-ABS remains positive. What is the appropriate intervention at this time?
- A. Aqueous penicillin G 24 mU/d IV given as 4 mU q4h \times 10 days
 - B. Doxycycline, 100 mg PO bid
 - C. Lumbar puncture
 - D. Penicillin desensitization
 - E. Penicillin G benzathine 2.4 mU IM weekly \times 3 doses
63. A person with liver disease caused by *Schistosoma mansoni* would be most likely to have
- A. ascites
 - B. esophageal varices
 - C. gynecomastia
 - D. jaundice
 - E. spider nevi
64. A previously healthy 28-year-old male describes several episodes of fever, myalgia, and headache that have been followed by abdominal pain and diarrhea. He has experienced up to 10 bowel movements per day. Physical examination is unremarkable. Laboratory findings are notable only for a slightly elevated leukocyte count and an elevated erythrocyte sedimentation rate. Wright's stain of a fecal sample reveals the presence of neutrophils. Colonoscopy reveals inflamed mucosa. Biopsy of an affected area discloses mucosal infiltration with neutrophils, monocytes, and eosinophils; epithelial damage, including loss of mucus; glandular degeneration; and crypt abscesses. The patient notes that several months ago he was at a church barbecue where several people contracted a diarrheal illness. Although this patient could have inflammatory bowel disease, which of the following pathogens is most likely to be responsible for his illness?
- A. *Campylobacter*
 - B. *Escherichia coli*
 - C. Norwalk agent
 - D. *Staphylococcus aureus*
 - E. *Salmonella*
65. Deficits in the complement membrane attack complex (C5-8) are associated with recurrent infections of what variety?
- A. *Pseudomonas aeruginosa*
 - B. Catalase-positive bacteria
 - C. *Streptococcus pneumoniae*
 - D. *Salmonella* spp.
 - E. *Neisseria meningitis*
66. Which of the following pathogens are cardiac transplant patients at unique risk for acquiring from the donor heart early after transplant when compared to other solid organ transplant patients?
- A. *Cryptococcus neoformans*
 - B. Cytomegalovirus
 - C. *Pneumocystis jiroveci*
 - D. *Staphylococcus aureus*
 - E. *Toxoplasma gondii*
67. A 68-year-old woman has been in the medical intensive care unit for 10 days with a chronic obstructive pulmonary disease flare and pneumonia, including the initial 6 days on a mechanical ventilator. She just finished a course of moxifloxacin and glucocorticoid taper when she develops abdominal discomfort over 2 days. Vital signs reveal a temperature of 38.2°C, heart rate of 94 beats per minute, blood pressure of 162/94 mmHg, respiratory rate of 18 per minute, and oxygen saturation of 90%. On examination, she is in moderate distress. She is not using accessory muscles but is tachypneic. She has a slight bilateral wheeze with good air movement. Heart sounds are distant and unchanged. Her abdomen is moderately distended and tense, with scant bowel sounds present. There is no guarding or rebound, but she is tender throughout. Review of her records reveals no bowel movement over the past 72 h and no stool is palpable in the rectal vault. White blood cell count has increased from 7100/ μ L to 38,000/ μ L over the past 2 days. Abdominal plain film shows what is read as a probable ileus in the right lower quadrant. Aside from nasogastric (NG) tube placement with suction and NPO status, which of the following should your management also include?
- A. Intravenous immunoglobulin (IVIg)
 - B. Metronidazole, 500 mg IV tid
 - C. Piperacillin/tazobactam, 3.37 g IV q6h
 - D. Restart moxifloxacin, 400 PO qd
 - E. Vancomycin, 500 mg PO qid
68. Regarding the epidemiology of influenza viruses, which of the following is true?
- A. Antigenic drift requires a change in both hemagglutinin (H) and neuraminidase (N) antigens.
 - B. Antigenic shift is defined by an exchange of hemagglutinin (H) and neuraminidase (N) antigens between influenza A and influenza B viruses.

68. (Continued)

- C. Avian influenza outbreaks in humans occur when human influenza A viruses undergo antigenic shifts with influenza A from poultry.
- D. Influenza C virus infections, while uncommon, are more virulent on a population basis due to its increased ability to undergo antigenic shift.
- E. The lethality associated with avian influenza is related to its ability to spread via person-to-person contact.

69. A 62-year-old man returns from a vacation to Arizona with fever, pleurisy, and a nonproductive cough. All of the following factors on history and laboratory examination favor a diagnosis of pulmonary coccidioidomycosis rather than community-acquired pneumonia *except*

- A. eosinophilia
- B. erythema nodosum
- C. mediastinal lymphadenopathy on chest roentgenogram
- D. positive *Coccidioides* complement fixation titer
- E. travel limited to Northern Arizona (Grand Canyon area)

70. A sputum culture from a patient with cystic fibrosis showing which of the following organisms has been associated with a rapid decline in pulmonary function and a poor clinical prognosis?

- A. *Burkholderia cepacia*
- B. *Pseudomonas aeruginosa*
- C. *Staphylococcus aureus*
- D. *Staphylococcus epidermidis*
- E. *Stenotrophomonas maltophilia*

71. A 34-year-old injection drug user presents with a 2-day history of slurred speech, blurry vision that is worse with bilateral gaze deviation, dry mouth, and difficulty swallowing both liquids and solids. He states that his arms feel weak as well but denies any sensory deficits. He has had no recent illness but does describe a chronic ulcer on his left lower leg that has felt slightly warm and tender of late. He frequently injects heroin into the edges of the ulcer. On review of systems, he reports mild shortness of breath but denies any gastrointestinal symptoms, urinary retention, or loss of bowel or bladder continence. Physical examination reveals a frustrated, nontoxic appearing man who is alert and oriented but noticeably dysarthric. He is afebrile with stable vital signs. Cranial nerve examination reveals bilateral cranial nerve six deficits and an inability to maintain medial gaze in both eyes. He has mild bilateral ptosis, and both pupils are reactive but sluggish. His strength is 5/5 in all extremities except for his shoulder shrug, which is 4/5. Sensory examination and deep tendon reflexes are within normal limits in all four extremities. His oropharynx

71. (Continued)

is dry. Cardiopulmonary and abdominal examinations are normal. He has a 4 cm × 5 cm well-granulated lower extremity ulcer with redness, warmth, and erythema noted on the upper margin of the ulcer. What is the treatment of choice?

- A. Glucocorticoids
- B. Equine antitoxin to *Clostridium botulinum* neurotoxin
- C. Intravenous heparin
- D. Naltrexone
- E. Plasmapheresis

72. In an HIV-infected patient, *Isospora belli* infection is different from *Cryptosporidium* infection in which of the following ways?

- A. *Isospora* causes a more fulminant diarrheal syndrome leading to rapid dehydration and even death in the absence of rapid rehydration.
- B. *Isospora* infection may cause biliary tract disease, whereas cryptosporidiosis is strictly limited to the lumen of the small and large bowel.
- C. *Isospora* is more likely to infect immunocompetent hosts than *Cryptosporidium*.
- D. *Isospora* is less challenging to treat and generally responds well to trimethoprim/sulfamethoxazole treatment.
- E. *Isospora* occasionally causes large outbreaks among the general population.

73. A 27-year-old man presents to your clinic with 2 weeks of sore throat, malaise, myalgias, night sweats, fevers, and chills. He visited an urgent care center and was told that he likely had the flu. He was told that he had a “negative test for mono.” The patient is homosexual, states that he is in a monogamous relationship and has unprotected receptive and insertive anal and oral intercourse with one partner. He had several partners prior to his current partner 4 years ago but none recently. He reports a negative HIV-1 test 2 years ago and recalls being diagnosed with *Chlamydia* infection 4 years ago. He is otherwise healthy with no medical problems. You wish to rule out the diagnosis of acute HIV. Which blood test should you order?

- A. CD4+ lymphocyte count
- B. HIV enzyme immunoassay (EIA)/Western blot combination testing
- C. HIV resistance panel
- D. HIV RNA by polymerase chain reaction (PCR)
- E. HIV RNA by ultrasensitive PCR

74. A 20-year-old female is 36 weeks pregnant and presents for her first evaluation. She is diagnosed with *Chlamydia trachomatis* infection of the cervix. Upon delivery, what complication is her infant most at risk for?

74. (Continued)
A. Jaundice
B. Hydrocephalus
C. Hutchinson triad
D. Conjunctivitis
E. Sensorineural deafness
75. A 45-year-old woman with known HIV infection and medical nonadherence to therapy is admitted to the hospital with 2–3 weeks of increasing dyspnea on exertion and malaise. Chest radiograph shows bilateral alveolar infiltrates and induced sputum is positive for *Pneumocystis jiroveci*. Which of the following clinical conditions is an indication for administration of adjunct glucocorticoids?
- A. Acute respiratory distress syndrome
B. CD4+ lymphocyte count < 100/ μ L
C. No clinical improvement 5 days into therapy
D. Pneumothorax
E. Room air PaO₂ < 70 mmHg
76. Caspofungin is a first-line agent for which of the following conditions?
- A. Candidemia
B. Histoplasmosis
C. Invasive aspergillosis
D. Mucormycosis
E. Paracoccidioidomycosis
F. Tinidazole
77. What is the most common side effect of oral ribavirin when used with pegylated interferon for the treatment of hepatitis C?
- A. Drug-associated lupus
B. Hemolytic anemia
C. Hyperthyroidism
D. Leukopenia
E. Rash
78. A previously unvaccinated health care worker incurs a needle stick from a patient with known active hepatitis B infection. What is the appropriate management for the health care worker?
- A. Hepatitis B immunoglobulins
B. Hepatitis B vaccine
C. Hepatitis B vaccine plus hepatitis B immunoglobulins
D. Hepatitis B vaccine plus lamivudine
E. Lamivudine plus tenofovir
79. (Continued)
questions. Neurologic examination is notable for normal cranial nerves and sensation. He has marked myoclonus provoked by startle or bright lights, but it also occurs spontaneously during sleep. Prior evaluation revealed normal serum chemistries, negative serologic tests for syphilis, and normal cerebrospinal fluid (CSF) studies. Head CT scan is normal. The infectious agent that caused his neurologic syndrome is most likely a(n)
- A. DNA virus
B. fungus
C. protein lacking nucleic acid
D. protozoan
E. RNA virus
80. A previously healthy 19-year-old man presents with several days of headache, cough with scant sputum, and fever of 38.6°C. On examination, pharyngeal erythema is noted and lung fields are clear. Chest radiograph reveals focal bronchopneumonia in the lower lobes. His hematocrit is 24.7%, down from a baseline measure of 46%. The only other laboratory abnormality is an indirect bilirubin of 3.4. A peripheral smear reveals no abnormalities. A cold agglutinin titer is measured at 1:64. What is the most likely infectious agent?
- A. *Coxiella burnetii*
B. *Legionella pneumophila*
C. Methicillin-resistant *Staphylococcus aureus*
D. *Mycoplasma pneumoniae*
E. *Streptococcus pneumoniae*
81. A 79-year-old Filipino-American man with diabetes mellitus, coronary artery disease, and emphysema develops the acute onset of low back pain and night sweats. Ten days prior, he underwent a prolonged lithotripsy procedure for septic ureteral stones. He was treated for a positive PPD 23 years ago. He moved to the United States 20 years ago and was a rice farmer in the Philippines prior to moving. Examination reveals tenderness over the lumbar spine. He has 5/5 strength in his lower extremities. MRI shows findings consistent with osteomyelitis of L3 and L4, with narrowing of the disc space and a small contiguous epidural abscess that is not compressing his spinal cord. A needle culture of the epidural abscess drawn prior to administration of antibiotics will most likely reveal which of the following?
- A. *Brucella melitensis*
B. *Escherichia coli*
C. *Mycobacterium tuberculosis*
D. *Staphylococcus aureus*
E. Polymicrobial content with gram-positive cocci in chains, enteric gram-negative rods, and anaerobic pleomorphic forms

82. A 64-year-old man in Wisconsin develops a high fever and malaise over 2 days. He has spent his weekends over the past month chopping wood in his backyard. Initial laboratory examination reveals a neutrophil count of $1000/\mu\text{L}$, platelet count of $84,000/\mu\text{L}$, AST of 140 U/L, and ALT of 183 U/L. A peripheral blood smear reveals prominent morulae in neutrophils. What is the most likely diagnosis?

- A. Anaplasmosis
- B. Human monocytotropic ehrlichiosis
- C. Lyme disease
- D. Rocky Mountain spotted fever
- E. Systemic lupus erythematosus

83. A 26-year-old asthmatic continues to have coughing fits and dyspnea despite numerous steroid tapers and frequent use of albuterol over the past few months. Persistent infiltrates are seen on chest roentgenogram. A pulmonary consultation suggests an evaluation for allergic bronchopulmonary aspergillosis. What is the diagnostic test of choice?

- A. Bronchoalveolar lavage (BAL) with fungal culture
- B. Galactomannan enzyme immunoassay (EIA)
- C. High-resolution CT
- D. Pulmonary function tests
- E. Serum IgE level

84. A patient who has undergone prosthetic valve surgery 6 weeks ago is readmitted with signs and symptoms consistent with infective endocarditis. Which of the following is the most likely etiologic organism?

- A. *Candida albicans*
- B. Coagulase-negative staphylococci
- C. *Enterococcus*
- D. *Escherichia coli*
- E. *Pseudomonas aeruginosa*

85. A 47-year-old woman with known HIV/AIDS (CD4^+ lymphocyte = $106/\mu\text{L}$ and viral load = 35,000/mL) presents with painful growths on the side of her tongue (Fig. 85). What is the most likely diagnosis?

FIGURE 85

85. (Continued)

- A. Aphthous ulcers
- B. Hairy leukoplakia
- C. Herpes stomatitis
- D. Oral candidiasis
- E. Oral Kaposi's sarcoma

86. A 25-year-old male is seen in the emergency department for symptoms of fevers and abdominal swelling, early satiety, and weight loss. His symptoms began abruptly 2 weeks ago. He was previously healthy and is taking no medications. He denies illicit drug use and recently immigrated to the United States from Bangladesh. On physical examination, temperature is 39.0°C (102.2°F) and pulse is 120, with normal blood pressure and respiratory rate. The remainder of the exam is notable for cachexia and a distended abdomen with a massively enlarged spleen. The spleen is tender and soft. The liver is not palpable. Mild peripheral adenopathy is present. Which of the following statements is correct regarding this patient with presumed kala azar leishmaniasis?

- A. He probably has normal cell counts on peripheral blood smear.
- B. *Leishmania donovani* is not endemic in Bangladesh.
- C. *Leishmania*-specific cell-mediated immunity probably is present.
- D. Splenic aspiration offers the highest diagnostic yield.
- E. Treatment can be delayed until the diagnosis is confirmed.

87. All of the following are examples of an indication for checking an HIV-resistance genotype *except*

- A. a 23-year-old man presents to the clinic with a new diagnosis of HIV infection.
- B. a 34-year-old man with HIV-1 infection was started on antiretroviral therapy (ART) [tenofovir (TDF), emtricitabine (FTC), efavirenz (EFV)] 1 month ago. At that time his CD4^+ lymphocyte count was $213/\mu\text{L}$ and HIV-1 viral load was 65,000 (4.8 log). On recheck 1 month later, his HIV-1 viral load is 37,000 (4.6 log). He states that he is taking his medicine 100% of the time.
- C. a 42-year-old man with HIV/AIDS who was started on ART [TDF, FTC, and ritonavir-boosted atazanavir (ATV/r)] 1 year ago was lost to follow-up. Originally his HIV-1 viral load was 197,000 (5.3 log) and CD4^+ lymphocyte count was $11/\mu\text{L}$. He was 100% compliant with his pills until he ran out of medicines 2 months ago. Viral load on recheck is 184,000 (log 5.3) with CD4^+ lymphocyte count of $138/\mu\text{L}$.
- D. a 52-year-old woman who has had full viral suppression (HIV-1 viral load $<30/\text{mL}$) and 100% medical compliance on ART [zidovudine (AZT), lamivudine (3TC), EFV] for 2 years has relapsed on IV heroin over the past 3 months. She states that she continued to take her ART with "a few missed doses here and there." Repeat viral load is 3800/mL and CD4^+ lymphocyte count is stable at $413/\mu\text{L}$.

88. Patients with which of the following have the *lowest* risk of invasive pulmonary *Aspergillus* infection?

- A. Allogeneic stem cell transplant with graft-vs-host disease
- B. HIV infection
- C. Long-standing high-dose glucocorticoids
- D. Post-solid organ transplant with multiple episodes of rejection
- E. Relapsed/uncontrolled leukemia

89. Rifampin lowers serum levels of all of the following medicines *except*

- A. amiodarone
- B. anticonvulsants
- C. cyclosporine
- D. hormonal contraceptives
- E. protease inhibitors
- F. warfarin

90. Which single clinical feature has the most specificity in differentiating *Pseudomonas aeruginosa* sepsis from other causes of severe sepsis in a hospitalized patient?

- A. Ecthyma gangrenosum
- B. Hospitalization for severe burn
- C. Profound bandemia
- D. Recent antibiotic exposure
- E. Recent mechanical ventilation for >14 days

91. Which of the following individuals with a known history of prior latent tuberculosis infection (without therapy) has the greatest likelihood of developing reactivation tuberculosis?

- A. A 28-year-old woman with anorexia nervosa, a body mass index of 16 kg/m², and a serum albumin of 2.3 g/dL
- B. A 36-year-old intravenous drug user who does not have HIV but is homeless
- C. A 42-year-old man who is HIV-positive with a CD4 count of 350/μL on highly active antiretroviral therapy
- D. A 68-year-old man who worked as a stone mason for many years and has silicosis
- E. A 73-year-old man who was infected while stationed in Korea in 1958

92. A 42-year-old Nigerian man comes to the emergency room because of fevers, fatigue, weight loss, and cough for 3 weeks. He complains of fevers and a 4.5-kg weight loss. He describes his sputum as yellow in color. It has rarely been blood streaked. He immigrated to the United States 1 year ago and is an undocumented alien. He has never been treated for tuberculosis, has never had a purified protein derivative (PPD) skin test placed, and does not recall receiving BCG vaccination. He denies HIV risk factors. He is married and reports no ill contacts. He smokes a pack of cigarettes daily and

92. (Continued)

drinks a pint of vodka on a daily basis. On physical examination, he appears chronically ill with temporal wasting. His body mass index is 21 kg/m². Vital signs are: blood pressure 122/68 mmHg, heart rate 89 beats per minute, respiratory rate 22 breaths per minute, SaO₂ 95% on room air, and temperature 37.9°C. There are amphoric breath sounds posteriorly in the right upper lung field with a few scattered crackles in this area. No clubbing is present. The examination is otherwise unremarkable. The portion of the CT scan of his lungs is shown in Fig. 92.

FIGURE 92

A stain for acid-fast bacilli is negative. What is the most appropriate approach to the ongoing care of this patient?

- A. Admit the patient on airborne isolation until three expectorated sputums show no evidence of acid-fast bacilli.
- B. Admit the patient without isolation as he is unlikely to be infectious with a negative acid-fast smear.
- C. Perform a biopsy of the lesion and consult oncology.
- D. Place a PPD test on his forearm and have him return for evaluation in 3 days.
- E. Start a 6-week course of antibiotic treatment for anaerobic bacterial abscess.

93. A 34-year-old man seeks the advice of his primary care physician because of an asymptomatic rash on his chest. There are coalescing light brown to salmon-colored macules present on the chest. A scraping of the lesions is viewed after a wet preparation with 10% potassium hydroxide solution. There are both hyphal and spore forms present, giving the slide an appearance of “spaghetti and meatballs.” In addition, the lesions fluoresce to a yellow-green appearance under a Wood’s lamp. Tinea versicolor is diagnosed. Which of the following microorganisms is responsible for this skin infection?

- A. *Fusarium solani*
- B. *Malassezia furfur*
- C. *Sporothrix schenckii*
- D. *Trichophyton rubrum*

94. A 68-year-old woman seeks evaluation for an ulcerative lesion on her right hand. She reports the area on the back of her right hand was initially red and not painful. There appeared to be a puncture wound in the center of the area, and she thought she had a simple scratch acquired while gardening. Over the next several days, the lesion became verrucous and ulcerated. Now, the patient has noticed several nodular areas along the arm, one of which ulcerated and began draining a serous fluid today. She is also noted to have an enlarged and tender epitrochlear lymph node on the right arm. A biopsy of the edge of the lesion shows ovoid and cigar-shaped yeasts. Sporotrichosis is diagnosed. What is the most appropriate therapy for this patient?
- A. Amphotericin B intravenously
 - B. Caspofungin intravenously
 - C. Clotrimazole topically
 - D. Itraconazole orally
 - E. Selenium sulfide topically
95. A 44-year-old man presents to the emergency room for evaluation of a severe sore throat. His symptoms began this morning with mild irritation on swallowing and have gotten progressively severe over the course of 12 h. He has been experiencing a fever to as high as 39°C at home and also reports progressive shortness of breath. He denies antecedent rhinorrhea or tooth or jaw pain. He has had no ill contacts. On physical examination, the patient appears flushed and in respiratory distress with use of accessory muscles of respiration. Inspiratory stridor is present. He is sitting leaning forward and is drooling with his neck extended. His vital signs are as follows: temperature 39.5°C, blood pressure 116/60 mmHg, heart rate 118 beats per minute, respiratory rate 24 breaths per minute, SaO_2 95% on room air. Examination of his oropharynx shows erythema of the posterior oropharynx without exudates or tonsillar enlargement. The uvula is midline. There is no sinus tenderness and no cervical lymphadenopathy. His lung fields are clear to auscultation, and cardiovascular examination reveals a regular tachycardia with a II/VI systolic ejection murmur heard at the upper right sternal border. Abdominal, extremity, and neurologic examinations are normal. Laboratory studies reveal a white blood cell count of 17,000 μL with a differential of 87% neutrophil, 8% band forms, 4% lymphocytes, and 1% monocytes. Hemoglobin is 13.4 g/dL with a hematocrit of 44.2%. An arterial blood gas on room air has a pH of 7.32, a PaCO_2 of 48 mmHg, and PaO_2 of 92 mmHg. A lateral neck film shows an edematous epiglottis. What is the next most appropriate step in evaluation and treatment of this individual?
- A. Ampicillin, 500 mg IV q6h
 - B. Ceftriaxone, 1 g IV q24h
95. (*Continued*)
- C. Endotracheal intubation and ampicillin, 500 mg IV q6h
 - D. Endotracheal intubation, ceftriaxone, 1 g IV q24h, and clindamycin, 600 mg IV q6h
 - E. Laryngoscopy and close observation
96. A 45-year-old man from western Kentucky presents to the emergency room in September complaining of fevers, headaches, and muscle pains. He recently had been on a camping trip with several friends during which they hunted for their food, including fish, squirrels, and rabbits. He did not recall any tick bites during the trip, but does recall having several mosquito bites. For the past week, he has had an ulceration on his right hand with redness and pain surrounding it. He also has noticed some pain and swelling near his right elbow. None of the friends he camped with have been similarly ill. His vital signs are blood pressure 106/65 mmHg, heart rate 116 beats per minute, respiratory rate 24 breaths per minute, and temperature 38.7°C. His oxygen saturation is 93% on room air. He appears mildly tachypneic and flushed. His conjunctiva are not injected and his mucous membranes are dry. The chest examination reveals crackles in the right mid-lung field and left base. His heart rate is tachycardic but regular. There is a II/VI systolic ejection murmur heard best at the lower left sternal border. His abdominal examination is unremarkable. On the right hand, there is an erythematous ulcer with a punched-out center covered by a black eschar. He has no cervical lymphadenopathy, but there are markedly enlarged and tender lymph nodes in the right axillae and epitrochlear regions. The epitrochlear node has some fluctuance with palpation. A chest x-ray shows fluffy bilateral alveolar infiltrates. Over the first 12 h of his hospitalization, the patient becomes progressively hypotensive and hypoxic, requiring intubation and mechanical ventilation. What is the most appropriate therapy for this patient?
- A. Ampicillin, 2 g IV q6h
 - B. Ceftriaxone, 1 g IV daily
 - C. Ciprofloxacin, 400 mg IV twice daily
 - D. Doxycycline, 100 mg IV twice daily
 - E. Gentamicin, 5 mg/kg twice daily
97. A 24-year-old man seeks evaluation for painless penile ulcerations. He noted the first lesion about 2 weeks ago, and since that time, two adjacent areas have also developed ulceration. He states that there has been blood staining his underwear from slight oozing of the ulcers. He has no past medical history and takes no medication. He returned 5 weeks ago from a vacation in Brazil where he did have unprotected sexual intercourse with a local woman. He denies other high-risk sexual behaviors and has never had sex with prostitutes. He was last tested for

97. (Continued)
HIV 2 years ago. He has never had a chlamydial or gonococcal infection. On examination, there are three well-defined red, friable lesions measuring 5 mm or less on the penile shaft. They bleed easily with any manipulation. There is no pain with palpation. There is shotty inguinal lymphadenopathy. On biopsy of one lesion, there is a prominent intracytoplasmic inclusion of bipolar organisms in an enlarged mononuclear cell. Additionally, there is epithelial cell proliferation with an increased number of plasma cells and few neutrophils. A rapid plasma reagin test is negative. Cultures grow no organisms. What is the most likely causative organism?
- A. *Calymmatobacterium granulomatis* (donovanosis)
 - B. *Chlamydia trachomatis* (lymphogranuloma venereum)
 - C. *Haemophilus ducreyi* (chancroid)
 - D. *Leishmania amazonensis* (cutaneous leishmaniasis)
 - E. *Treponema pallidum* (secondary syphilis)
98. A 19-year-old man plans on traveling through Central America by bus. He comes to clinic interested in travel advice and any vaccinations he may need. He has no medical history and takes no medicines. In addition to DEET and mosquito netting, which of the following recommendations would be important for prophylaxis against malaria?
- A. Atovaquone
 - B. Chloroquine
 - C. Doxycycline
 - D. Mefloquine
 - E. Primaquine
99. Which of the following is the most common source of fever in travelers returning from Southeast Asia?
- A. Dengue fever
 - B. Malaria
 - C. Mononucleosis
 - D. Salmonella
 - E. Yellow fever
100. A 54-year-old woman presents to the emergency room complaining of pain and redness of her left face and cheek. The area of redness began abruptly yesterday. At that time, the area was about 5 mm² near the nasolabial fold. There was rapid progression of the redness to an area that is now about 5 cm². In addition, she is complaining of intense pain in this area. On examination, there is a well-demarcated 5 cm² area of erythema along her left nasolabial fold. The borders are raised and indurated. The entire area is very tender to touch. Over the next 24 h, the affected area begins to develop a flaccid bullae. What is the most appropriate treatment for this patient?
- A. Amphotericin B
 - B. Caspofungin
 - C. Itraconazole
 - D. Moxifloxacin
 - E. Voriconazole
100. (Continued)
A. Acyclovir
B. Clindamycin
C. Clindamycin and penicillin
D. Penicillin
E. Trimethoprim and sulfamethoxazole
101. In the urgent care clinic, you are evaluating a 47-year-old woman with poorly controlled diabetes who has a chief complaint of "sinusitis." She does not have a history of atopy. She first noticed a headache 2 days ago and now feels very congested in her upper nasal passages. She has hyperesthesia over her nasal bridge as well and is inquiring about antibiotics to treat her infection. She has a bloody nasal discharge with occasional black specks. On examination, the sinuses are full and tender. She has a temperature of 38.3°C. Oral examination shows a black eschar on the roof of her mouth surrounded by discolored hyperemic areas on the palate. What is the most appropriate intervention at this time?
- A. Ciprofloxacin and quarantine for possible anthrax
 - B. ENT consultation if no improvement with oral antibiotics
 - C. Immediate biopsy of the involved areas and lipid amphotericin
 - D. Immediate biopsy of the lesion and voriconazole
 - E. Intranasal decongestants and close follow-up
102. A 63-year-old man from Mississippi comes to your office for evaluation of a chronic sore on his thigh. He has an open sore on his anterior thigh that has been draining purulent material for many months. The thigh is non-tender but is warm to touch. The material is purulent and foul-smelling. He has been given multiple antibiotic courses and recently finished a course of itraconazole without relief of his symptoms. He has an intact neurovascular examination of his lower extremities. His erythrocyte sedimentation rate is 64, white blood cell count is 15,000/ μ L, and hemoglobin is 8 mg/dL. A plain radiograph of the affected thigh shows a periosteal reaction of the femur with osteopenia. There is suggestion of a sinus tract between the femur and the skin. A Gram stain of the pus shows broad-based budding yeast and you make a presumptive diagnosis of blastomyces osteomyelitis. What is the treatment of choice for this patient?
- A. Amphotericin B
 - B. Caspofungin
 - C. Itraconazole
 - D. Moxifloxacin
 - E. Voriconazole

ANSWERS

1. The answer is B.

(Chap. 14) Cat bites are the most likely animal bites to lead to cellulitis due to deep inoculation and the frequent presence of *Pasteurella multocida*. In the immunocompetent host, only cat bites warrant empirical antibiotics. Often the first dose is given parenterally. Ampicillin/sulbactam followed by oral amoxicillin/clavulanate is effective empirical therapy for cat bites. However, in the asplenic patient, a dog bite can lead to rapid overwhelming sepsis as a result of *Capnocytophaga canimorsus* bacteremia. These patients should be followed closely and given third-generation cephalosporins early in the course of infection. Empirical therapy should also be considered for dog bites in the elderly, for deep bites, and for bites on the hand.

2. The answer is A.

(Chap. 61) This patient has bacillary angiomatosis due to cutaneous infection with *Bartonella quintana* or *B. henselae*. Kittens are the likely source of the infection in this case. Bacillary angiomatosis occurs in HIV-infected patients with CD4+ T cell counts <100/μL. The cutaneous lesions of bacillary angiomatosis are typically painless cutaneous lesions but may appear as subcutaneous nodules, ulcerated plaques, or verrucous growths. They may be single or multiple. The differential diagnosis includes Kaposi's sarcoma, pyogenic granuloma, and tumors. Biopsy findings are as described in this case, and the diagnosis is best made with histology. Treatment is with azithromycin or doxycycline. Oxacillin or vancomycin is the treatment for staphylococcal or streptococcal skin infections.

3. The answer is C.

(Chap. 28) This patient has a classic presentation and microscopic examination of bacterial vaginosis. Bacterial vaginosis, which is linked with HIV acquisition, herpes simplex virus (HSV) 2 shedding and acquisition, gonorrhea and *Chlamydia* acquisition, increased risk of preterm delivery, and subacute pelvic inflammatory disease, is unfortunately very difficult to treat. With the best available regimens, women recur at a rate of about 25%. Metronidazole, either as an oral formulation or vaginal gel, is recommended for at least 7 days for primary infection and 10–14 days for recurrence. Intravaginal clindamycin for this duration is also an option but has been associated with more anaerobic drug resistance. Treatment of male partners with metronidazole does not prevent recurrence of bacterial vaginosis. Metronidazole, 2 g PO × 1, is standard treatment for *Trichomonas* but is too short a duration for bacterial vaginosis. Fluconazole is used for vaginal candidiasis. Douching has no proven role in bacterial vaginosis infection. Acyclovir is the recommended treatment for HSV-2 genital infection.

4. The answer is F.

(Chap. 28) HIV is the leading cause of death in some developing countries. Efforts to decrease transmission include screening and treatment of sexually associated infections. All of the listed conditions have been linked with higher acquisition of HIV, based on epidemiologic

studies and high biologic plausibility. Up to 50% of women of reproductive age in developing countries have bacterial vaginosis. All of the bacterial infections are curable, and treatment can decrease the frequency of genital herpes recurrences. This highlights an additional reason that primary care doctors should screen for each of these infections in female patients with detailed historic questions, genitourinary and rectal examinations, and evidence-based routine screening for these infections based on age and risk category.

5. The answer is B.

(Chap. 94) Enteroviruses are responsible for up to 90% of aseptic meningitis in which an etiologic agent can be identified. Symptoms are typically more severe in adults than children. Illness is more frequent in the summer and fall in temperate climates, whereas other causes of viral meningitis are more common in winter and spring. CSF analysis always shows an elevated (though usually <1000 cells/μL) white blood cell count. Early, there may be a neutrophil predominance; however, this typically shifts toward lymphocyte predominance by 24 h. CSF glucose and protein are usually normal, though the latter can sometimes be elevated. The illness is typically self-limiting and prognosis is excellent.

6. The answer is D.

(Chaps. 113 and 126) This patient has Katayama fever caused by infection with *Schistosoma mansoni*. Approximately 4–8 weeks after exposure the parasite migrates through the portal and pulmonary circulations. This phase of the illness may be asymptomatic but in some cases evokes a hypersensitivity response and a serum sickness-type illness. Eosinophilia is usual. Since there is not a large enteric burden of parasites during this phase of the illness, stool studies may not be positive and serology may be helpful, particularly in patients from nonendemic areas. Praziquantel is the treatment of choice because Katayama fever may progress to include neurologic complications. Chloroquine is used for treatment of malaria; mebendazole for ascariasis, hookworm, trichinosis, and visceral larval migrans; metronidazole for amebiasis, giardiasis, and trichomoniasis; and thiabendazole for strongyloides.

7. The answer is E.

(Chap. 3) Live attenuated viruses are generally contraindicated as vaccines for immunocompromised hosts for fear of vaccine-induced disease. The most cited example of this is smallpox vaccine resulting in disseminated vaccinia infection. However, yellow fever vaccine is another example of a live virus vaccine. The other examples listed in this example are inactivated organisms (rabies, IM typhoid) or polysaccharide (meningococcal) and are therefore noninfectious. Oral typhoid vaccine is a live attenuated strain, so the IM form is likely preferable in this host. Malaria prophylaxis currently involves chemoprophylaxis rather than vaccination. While safe from an infectious standpoint, potential interactions with cyclosporine should be monitored.

8. The answer is D.

(Chap. 122) Trichomoniasis is transmitted via sexual contact with an infected partner. Many men are asymptomatic but may have symptoms of urethritis, epididymitis, or prostatitis. Most women will have symptoms of infection that include vaginal itching, dyspareunia, and malodorous discharge. These symptoms do not distinguish *Trichomonas* infection from other forms of vaginitis, such as bacterial vaginosis. Trichomoniasis is not a self-limited infection and should be treated for symptomatic and public health reasons. Wet-mount examination for motile trichomonads has a sensitivity of 50–60% in routine examination. Direct immunofluorescent antibody staining of secretions is more sensitive and can also be performed immediately. Culture is not widely available and takes 3–7 days. Treatment should consist of metronidazole either as a single 2-g dose or 500-mg doses twice daily for 7 days; all sexual partners should be treated. Trichomoniasis resistant to metronidazole has been reported and is managed with increased doses of metronidazole or with tinidazole.

9. The answer is E.

(Chap. 117) Babesiosis due to *B. microti* is transmitted to humans by the hard-bodied tick. The infection occurs mostly in coastal southern New England and eastern Long Island; however, cases have been reported in New York, Pennsylvania, Wisconsin, and Minnesota. Most cases of babesiosis are probably never recognized because the most common (25% of adults) presentation is either asymptomatic or indistinguishable from many other self-limited acute febrile illnesses. After an incubation of 1–6 weeks after a tick bite, patients may develop fever (intermittent or sustained as high as 40°C), malaise, shaking chills, myalgias, and arthralgias. Severe infection is most common in asplenic patients and the elderly and in immunosuppressed patients (HIV, malignancy, immunosuppressive medications). Patients co-infected with *Borrelia burgdorferi* (Lyme disease) are also at risk of severe infection. It is notable for an enormous parasitemia that can reach as high as 85% and is associated with hemolysis, high-output congestive heart failure, and renal and respiratory failure.

10. The answer is D.

(Chap. 102) Voriconazole is an azole antifungal with a broader spectrum of activity than fluconazole against *Candida* species (including *C. glabrata* and *C. krusei*) and has activity against *Aspergillus* species. It is available in oral and parenteral forms. Voriconazole's visual disturbances are common, transient, and harmless, but patients should be warned to expect them. Voriconazole interacts significantly with many other medications, including immunosuppressive agents, such as tacrolimus, that are often used in patients at risk for systemic fungal infections. Voriconazole may also cause liver toxicity and photosensitivity. Renal toxicity is an issue with amphotericin B products rather than the azoles.

11. The answer is D.

(Chap. 85) Immunocompromised patients occasionally cannot clear parvovirus infection due to lack of T-cell

function. As parvovirus B19 selectively infects red cell precursors, persistent infection can lead to a prolonged red cell aplasia and persistent drop in hematocrit, with low or absent reticulocytes. Pure red cell aplasia has been reported in HIV infection, lymphoproliferative diseases, and after transplantation. Iron studies will show adequate iron but decreased utilization. The peripheral smear usually shows no abnormalities other than normocytic anemia and the absence of reticulocytes. Antibody tests are not useful in this setting as immunocompromised patients do not produce adequate antibodies against the virus. Therefore, a PCR is the most useful diagnostic test. Bone marrow biopsy may be suggestive as it will show no red cell precursors, but usually a less invasive PCR test is adequate. Immediate therapy is with red cell transfusion, followed by IV immunoglobulins, which contain adequate titers of antibody against parvovirus B19.

12. The answer is B.

(Chap. 124) Strongyloides is the only helminth that can replicate in the human host, allowing autoinfection. Humans acquire strongyloides when larvae in fecally contaminated soil penetrate the skin or mucus membranes. The larvae migrate to the lungs via the bloodstream, break through the alveolar spaces, ascend the respiratory airways, and are swallowed to reach the small intestine where they mature into adult worms. Adult worms may penetrate the mucosa of the small intestine. Strongyloides is endemic in Southeast Asia, Sub-Saharan Africa, Brazil, and the Southern United States. Many patients with strongyloides are asymptomatic or have mild gastrointestinal symptoms or the characteristic cutaneous eruption, larval currens, as described in this case. Small-bowel obstruction may occur with early heavy infection. Eosinophilia is common with all clinical manifestations. In patients with impaired immunity, particularly glucocorticoid therapy, hyperinfection or dissemination may occur. This may lead to colitis, enteritis, meningitis, peritonitis, and acute renal failure. Bacteremia or gram-negative sepsis may develop due to bacterial translocation through disrupted enteric mucosa. Because of the risk of hyperinfection, all patients with strongyloides, even asymptomatic carriers, should be treated with ivermectin, which is more effective than albendazole. Fluconazole is used to treat candidal infections. Mebendazole is used to treat trichuriasis, enterobiasis (pinworm), ascariasis, and hookworm. Mefloquine is used for malaria prophylaxis.

13. The answer is A.

(Chap. 22) The Gram stain is polymicrobial and the putrid smell is very specific for anaerobic organisms. The diagnosis of acute osteomyelitis is also very likely based on the positive probe to bone test and wide ulcer. Broad-spectrum antibiotics are indicated. Vancomycin and linezolid cover methicillin-resistant *Staphylococcus aureus* (MRSA) and streptococcal isolates but would miss gram-negative rods and anaerobic bacteria. Metronidazole covers only anaerobes, missing gram-positives that are key in the initiation of diabetic foot infections. Clindamycin covers gram-positives and anaerobes but misses gram-negative rods. Ampicillin-sulbactam is broad

spectrum and covers all three classes of organism. If the patient has a history of MRSA or MRSA risk factors, then the addition of vancomycin or linezolid is a strong consideration.

14. The answer is B.

(Chap. 25) Norovirus, or the so-called Norwalk-like agent, was initially described as a cause of food-borne illness in Norwalk, Ohio, in 1968. Since that time the virus responsible has been identified as a small RNA virus of the Caliciviridae family. The initial detection of the Norwalk agent was poor, relying on electron microscopy or immune electron microscopy. Using these techniques, the Norwalk agent was identified as the causative agent in 19–42% of nonbacterial diarrheal outbreaks. With the development of more sensitive molecular assays (reverse transcriptase PCR, enzyme-linked immunosorbent assay), Norwalk-like viruses are being found as increasingly frequent causes of diarrheal outbreaks. Treatment is supportive as symptoms improve within 10–51 h. Rotavirus is the most common cause of viral diarrhea in infants but is uncommon in adults. Salmonella, shigella, and *E. coli* present with more colonic and systemic manifestations.

15. The answer is D.

(Chap. 69) Drugs used to treat *Mycobacterium tuberculosis* are classified as first-line or second-line. First-line agents, which are proven most effective and are necessary for any short-course treatment regimen, include isoniazid, rifampin, ethambutol, and pyrazinamide. First-line supplemental agents, which are highly effective with acceptable toxicity, include rifabutin, rifapentine, and streptomycin. Second-line agents, which are either less clinically active or have greater toxicity, include para-aminosalicylic acid, ethionamide, cycloserine, amikacin, and capreomycin. The fluoroquinolones, levofloxacin and moxifloxacin, are active against *M. tuberculosis* but are not yet considered first-line therapy. While not approved for treatment of *M. tuberculosis* in the United States, promising trials are underway. Some experts consider moxifloxacin a supplemental first-line therapy. It is necessary to have at least three active agents during the 2-month induction phase of active tuberculosis therapy. Ethambutol is initially used as a fourth agent to account for the possibility of drug resistance to one of the other agents. Consolidation phase includes rifampin and isoniazid, and is 4–7 months in length, depending on anatomic location of infection as well as clearance of sputum cultures at 2 months.

16. The answer is D.

(Chaps. 12 and 83) CMV retinitis, a common CMV infection in HIV patients, occurs very rarely in solid organ transplant patients. CMV does affect the lung in a majority of transplant patients if either donor or recipient is CMV-seropositive pretransplant. CMV disease in transplant recipients typically develops 30–90 days post-transplant. It rarely occurs within 2 weeks of transplantation. CMV very commonly causes a pneumonitis that clinically is difficult to distinguish from acute rejection.

Prior CMV infection has been associated with bronchiolitis obliterans syndrome (chronic rejection) in lung transplant recipients. As with HIV, the gastrointestinal tract is commonly involved with CMV infection. Endoscopy with biopsy showing characteristic giant cells, not serum polymerase chain reaction (PCR), is necessary to make this diagnosis. The CMV syndrome is also common in lung transplant patients. Serum CMV PCR should be sent as part of the workup for all nonspecific fevers, worsening lung function, liver function abnormalities, or falling leukocyte counts occurring more than a couple of weeks after transplant.

17. The answer is D.

(Chap. 87) In 2002, an outbreak of a severe systemic illness, named *severe acute respiratory syndrome*, or SARS, began in China. Ultimately 8000 cases were recorded in 28 countries. The etiologic agent proved to be a virus associated with the Coronavirus family, now named SARS-CoV. The natural reservoir appears to be the horseshoe bat, though human exposure may have come from domesticated animals such as the palm civet. While some patients acquired the virus from animals or the environment, the majority appear to have contracted the illness from other people. Human-to-human transmission, either by aerosol or fecal-oral routes, is efficient. Environmental transmission (water, sewage) may also have played a role, particularly in the outbreak centered in an apartment complex. In the outbreak, children had a much less severe clinical course compared to adults. In 2003 the outbreak ceased, and no new cases have arisen since 2004. Many unanswered questions linger in the wake of this illness.

18. The answer is D.

(Chap. 49) *Legionella* urine antigen is detectable within 3 days of symptoms and will remain positive for 2 months. It is not affected by antibiotic use. The urinary antigen test is formulated to detect only *L. pneumophila* (which causes 80% of *Legionella* infections) but cross-reactivity with other *Legionella* species has been reported. The urinary test is sensitive and highly specific. Typically, Gram's staining of specimens from sterile sites such as pleural fluid show numerous white blood cells but no organisms. However, *Legionella* may appear as faint, pleomorphic gram-negative bacilli. *Legionella* may be cultured from sputum even when epithelial cells are present. Cultures, grown on selective media, take 3–5 days to show visible growth. Antibody detection using acute and convalescent serum is an accurate means of diagnosis. A fourfold rise is diagnostic, but this takes up to 12 weeks so is most useful for epidemiologic investigation. *Legionella* PCR has not been shown to be adequately sensitive and specific for clinical use. It is used for environmental sampling.

19. The answer is E.

(Chap. 80) Primary genital herpes due to HSV-2 is characterized by fever, headache, malaise, inguinal lymphadenopathy, and diffuse genital lesions of varying stage.

The cervix and urethra are usually involved in women. While both HSV-2 and HSV-1 can involve the genitals, the recurrence rate of HSV-2 is much higher (90% in the first year) than with HSV-1 (55% in the first year). The rate of reactivation for HSV-2 is very high. Acyclovir (or its congeners valacyclovir and famciclovir) is effective in shortening the duration of symptoms and lesions in genital herpes. Chronic daily therapy can reduce the frequency of recurrences in those with frequent reactivation. Valacyclovir has been shown to reduce transmission of HSV-2 between sexual partners.

20. The answer is C.

(Chap. 25) Enterotoxigenic *E. coli* is responsible for 50% of traveler's diarrhea in Latin America and 15% in Asia. Enterotoxigenic and enteroaggregative *E. coli* are the most common isolates from persons with classic secretory traveler's diarrhea. Treatment of frequent watery stools due to presumed *E. coli* infection may be with ciprofloxacin, or because of concerns regarding increasing ciprofloxacin resistance, azithromycin. *E. histolytica* and *V. cholerae* account for smaller percentages of traveler's diarrhea in Mexico. *Campylobacter* is more common in Asia and during the winter in subtropical areas. *Giardia* is associated with contaminated water supplies and in campers who drink from freshwater streams.

21. The answer is E.

(Chap. 123) Trichinellosis occurs when infected meat products are eaten, most frequently pork. The organism can also be transmitted through the ingestion of meat from dogs, horses, and bears. Recent outbreaks in the United States and Canada have been related to consumption of wild game, particularly bear meat. During the first week of infection, diarrhea, nausea, and vomiting are prominent features. As the parasites migrate from the GI tract, fever and eosinophilia are often present. Larvae encyst after 2–3 weeks in muscle tissue, leading to myositis and weakness. Myocarditis and maculopapular rash are less common features of this illness. *Giardia* and *Campylobacter* are organisms that are frequently acquired by drinking contaminated water; neither will produce this pattern of disease. While both will cause GI symptoms (and *Campylobacter* will cause fever), neither will cause eosinophilia or myositis. *Taenia solium*, or pork tape-worm, shares a similar pathogenesis to *Trichinella* but does not cause myositis. Cytomegalovirus has varied presentations but none that lead to this presentation.

22. The answer is E.

(Chap. 90) Abacavir use is associated with a potentially severe hypersensitivity reaction in about 5% of patients. There is likely a genetic component, with HLAB*5701 being a significant risk factor for hypersensitivity syndrome. Symptoms, which usually occur within 2 weeks of therapy but can take >6 weeks to emerge, include fever, maculopapular rash, fatigue, malaise, gastrointestinal symptoms, and/or dyspnea. Once a diagnosis is suspected, the drug should be stopped and never given again because rechallenge can be fatal. For this reason,

both the diagnosis and patient education once the diagnosis is made must be performed thoroughly and carefully. It is important to note that two available combination pills contain abacavir (epzicom, trizivir), so patients must know to avoid these as well. Fanconi's anemia is a rare disorder associated with tenofovir. Zidovudine causes anemia and sometimes granulocytopenia. Stavudine and other nucleoside reverse transcriptase inhibitors are associated with lipoatrophy of the face and legs.

23. The answer is C.

(Chap. 35) In recent years, the emergence of "community acquired" methicillin-resistant *Staphylococcus aureus* (CA-MRSA) in numerous populations has been well documented. This pathogen most commonly leads to pyogenic infections of the skin but has also been associated with necrotizing fasciitis, infectious pyomyositis, endocarditis, and osteomyelitis. The most feared complication is a necrotizing pneumonia that often follows influenza upper respiratory infection and can affect previously healthy people. This pathogen produces the Panton-Valentine leukocidin protein that forms holes in the membranes of neutrophils as they arrive at the site of infection, and serves as marker for this pathogen. An easy way to identify this strain of MRSA is its sensitivity profile. Unlike MRSA isolates of the past, which were sensitive only to vancomycin, daptomycin, quinupristin/dalfopristin, and linezolid, CA-MRSA are almost uniformly susceptible to TMP/SMX and doxycycline as well. The organism is also usually sensitive to clindamycin. The term *community-acquired* has probably outlived its usefulness as this isolate has become the most common *S. aureus* isolate causing infection in many hospitals around the world.

24. The answer is D.

(Chap. 85) The most likely diagnosis based on her antecedent illness with a facial rash is parvovirus infection. Parvovirus commonly leads to a diffuse symmetric arthritis in the immune phase of illness when IgM antibodies are developed. Occasionally the arthritis persists over months and can mimic rheumatoid arthritis. The acute nature of these complaints makes systemic lupus erythematosus and rheumatoid arthritis less likely. Reactive arthritis due to *Chlamydia* or a list of other bacterial pathogens tends to effect large joints such as the sacroiliac joints and spine. It is also sometimes accompanied by uveitis and urethritis. The large number of joints involved with a symmetric distribution argues against crystal or septic arthropathy.

25. The answer is C.

(Chap. 107) Isolation of yeast from the blood stream can virtually never be considered a contaminant. Presentation may be indolent with malaise only, or fulminant with overwhelming sepsis in the neutropenic host. All indwelling catheters need to be removed to ensure clearance of infection, and evaluation for endocarditis and endophthalmitis should be strongly considered, particularly in patients with persistently positive cultures or

fever. Both of these complications of fungemia often entail surgical intervention for cure. A positive yeast culture in the urine is often difficult to interpret, particularly in patients on antibiotics and in the ICU. Most frequently, a positive culture for yeast represents contamination, even if the urinalysis suggests bladder inflammation. An attractive option is to remove the Foley catheter and recheck a culture. Antifungals are indicated if the patient appears ill, in the context of renal transplant where fungal balls can develop in the graft, and often in neutropenic patients. *Candida* pneumonia is uncommon, even in immunocompromised patients. A positive yeast culture of the sputum is usually representative of commensal oral flora and should not be managed as an infection, particularly as in this case where acute bacterial pneumonia is likely.

26. The answer is B.

(Chap. 90) CMV colitis should be considered in AIDS patients with CD4+ lymphocyte count $<50/\mu\text{L}$, fevers, and diarrhea. Diarrhea is often bloody but can be watery. Initial evaluation often involves stool studies to rule out other parasitic or bacterial causes of diarrhea in AIDS patients. A standard panel will include some or all of the following depending on epidemiologic and historical data: *Clostridium difficile* stool antigen, stool culture, stool *Mycobacterium avium intracellulare* culture, stool ova and parasite examination and special stains for *Cryptosporidium*, *Isospora*, *Cyclospora*, and *Microsporidium*. There is no stool or serum test that is useful for the evaluation of CMV colitis in an HIV-infected patient. A positive CMV IgG is merely a marker of past infection. If this test is negative, then the pretest probability of developing active CMV decreases substantially. Serum CMV PCR has gained utility in solid organ and bone marrow transplant patients for following treatment response for invasive CMV infection. However, in HIV-infected patients, CMV viremia correlates imprecisely with colitis. Further, because CMV is a latent-lytic herpesvirus, a positive serum PCR does not imply disease unless drawn in the right clinical context, for which there is none in HIV infection. Colonic histology is sensitive and specific for the diagnosis of CMV colitis, with large-cell inclusion bodies being diagnostic.

27. The answer is E.

(Chap. 72) The patient has Weil's syndrome due to infection with *Leptospira interrogans* as evidenced by her flu-like prodrome followed by profound hyperbilirubinemia with only minor hepatocellular dysfunction as well as renal failure. Rats are the most important reservoir. The organism is excreted in urine and can survive in water for months. Important sources of exposure include occupational, recreation in contaminated waters, and being homeless in contaminated living areas. Weil's represents the immune phase of the disease in its most severe form. A bleeding diathesis is common, as is pulmonary hemorrhage. The conjunctival suffusion during the initial spirochetemic phase of the disease is an important diagnostic clue. Penicillin G is appropriate therapy for severe leptospirosis, but its comparative efficacy

is not yet proven in the literature. Acute myelogenous leukemia would likely cause more characteristic abnormalities in blood counts with this degree of illness. Acute interstitial pneumonitis (Haman-Rich syndrome) affects only the lung and would not be associated with the severe increases in bilirubin. Polyarteritis nodosa rarely involved the lung and would not be expected to cause such a high bilirubin, even in the setting of hepatic ischemia. Rat-bite fever causes intermittent fevers, polyarthritides, and a nonspecific rash.

28. The answer is B.

(Chap. 75) Rocky Mountain spotted fever, caused by *Rickettsia rickettsii*, occurs throughout the United States, Canada, Mexico, Central America, and South America. It is transmitted by the dog tick in the eastern two-thirds of the United States and by the wood tick in the western United States. Humans are typically infected during tick season from May through September. In the preantibiotic era, the case fatality rate approached 25%. Currently the mortality remains ~5%, mostly due to delayed recognition and therapy. The incubation period after a tick bite is approximately 1 week. The initial signs and symptoms of Rocky Mountain spotted fever are entirely nonspecific, and the typical rash is often not seen in early disease. It may be difficult to distinguish from many self-limited viral syndromes. Only 60% of patients recall a tick bite, and only 3% of patients have the classic history of tick bite, fever, and rash. Therefore, assessment for this potentially deadly disease should be based on epidemiologic grounds. His recent high-risk travel period for tick bite in a highly endemic region makes this patient a high pretest probability. Empirical treatment is warranted and will not affect the diagnostic workup. A diagnostic indirect immunofluorescent antibody test will not be positive ($\geq 1:64$ titer) until 7–10 days after symptoms. The only diagnostic test that is useful during the acute illness is immunohistochemical staining for *R. rickettsii* of a biopsy from a skin rash. Doxycycline is effective therapy and should be continued until the patient is afebrile and improving.

29. The answer is D.

(Chap. 122) *Giardia lamblia* is one of the most common parasitic diseases, with worldwide distribution. It occurs in developed and developing countries. Infection follows ingestion of environmental cysts, which excyst in the small intestine releasing flagellated trophozoites. *Giardia* does not disseminate hematogenously; it remains in the small intestine. Cysts are excreted in stool, which accounts for person-to-person spread; however, they do not survive for prolonged periods in feces. Ingestion of contaminated water sources is another major form of infection. *Giardia* cysts can thrive in cold water for months. Filtering or boiling water will remove cysts. As few as 10 cysts can cause human disease, which has a broad spectrum of presentations. Most infected patients are asymptomatic. Symptoms in infected patients are due to small-intestinal dysfunction. Typical early symptoms include diarrhea, abdominal pain, bloating, nausea, vomiting, flatus, and belching. Diarrhea is a very common

complaint, particularly early, but in some patients constipation will occur. Later, diarrhea may resolve, with malabsorption symptoms predominating. The presence of fever, eosinophilia, blood or mucus in stools, or colitis symptoms should suggest an alternative diagnosis. Diagnosis is made by demonstrating parasite antigens, cysts, or trophozoites in the stool.

30. The answer is B.

(Chap. 70) The patient's clinical examination is consistent with primary syphilis and he should receive appropriate therapy. In primary syphilis, 25% of patients will have negative nontreponemal tests for syphilis (RPR or VDRL). A single dose of long-acting benzathine penicillin is the recommended treatment for primary, secondary, and early latent syphilis. Ceftriaxone is the treatment of choice for gonorrhea, but this lesion is not consistent with that diagnosis. Ceftriaxone given daily for 7–10 days is an alternative treatment for primary and secondary syphilis. Acyclovir is the drug of choice for genital herpes. Herpetic lesions are classically multiple and painful. Observation is not an option because the chancre will resolve spontaneously without treatment and the patient will remain infected and infectious.

31. The answer is F.

(Chap. 52) It is impossible to know whether the patient's continued dyspepsia is due to persistent *H. pylori* as a result of treatment failure or to some other cause. A quick noninvasive test to look for the presence of *H. pylori* is a urea breath test. This test can be done as an outpatient and gives a rapid, accurate response. Patients should not have received any proton pump inhibitors or antimicrobials in the meantime. Stool antigen test is another good option if urea breath testing is not available. If the urea breath test is positive >1 month after completion of first-line therapy, second-line therapy with a proton pump inhibitor, bismuth subsalicylate, tetracycline, and metronidazole may be indicated. If the urea breath test is negative, the remaining symptoms are unlikely due to persistent *H. pylori* infection. Serology is useful only for diagnosing infection initially, but it can remain positive and therefore misleading in those who have cleared *H. pylori*. Endoscopy is a consideration to rule out ulcer or upper gastrointestinal malignancy but is generally preferred after two failed attempts to eradicate *H. pylori*. (See Fig. 52-1.)

32. The answer is E.

(Chap. 86) Genital human papilloma virus is thought to be the most common sexually transmitted infection in the United States. A recent study of initially seronegative college-aged women found 60% became infected within 5 years. This underscores the importance of the recent development of effective vaccines and continued cervical cancer screening strategies. Approximately 20–25% of the U.S. population past 11–12 years old is seropositive for HSV-2. The high prevalence of this infection in the general population is due to several factors including lifelong infection, ongoing transmission during latent infection due to asymptomatic

shedding of HSV-2 in the genital mucosa, and high rates of transmission within monogamous partnerships. These features are markedly different than those associated with bacterial STIs such as gonorrhea and syphilis, which require high rates of partner change to persist in subpopulations. HIV-1 infections are still concentrated within high-risk populations (men who sleep with men, injection drug users, high-risk heterosexuals, and immigrants from high prevalence regions).

There are two available HPV vaccines. Gardasil (Merck) is currently licensed and contains HPV types 6, 11, 16, and 18; Cervarix (Glaxo-SmithKline) is pending final regulatory approval and contains HPV types 16 and 18. HPV types 6 and 11 cause 90% of anogenital warts. HPV 16 and 18 cause 70% of cervical cancers. Both vaccines consist of virus-like particles without any viral nucleic acid, therefore are not active. Both provide nearly 100% protection against two common oncogenic strains of HPV (16 and 18) but neglect to cover the other strains that cause up to 30% of cervical cancer. Because the vaccines do not protect against all oncogenic HPV serotypes, it is recommended that Pap screening of women for cervical cancer continue according to prior schedules. The vaccine should be given to girls and young women between the ages of 9 and 26 provided that they do not have evidence of infection with both HPV 16 and 18 already.

33. The answer is B.

(Chap. 94) These lesions are diagnostic of herpangina, which is caused by coxsackievirus A. They are typically round and discrete, which helps differentiate them from thrush caused by *Candida* species. Unlike HSV stomatitis, herpangina lesions are not associated with gingivitis. Herpangina usually presents with dysphagia, odynophagia, and fever; these lesions can persist for several weeks. The lesions do not ulcerate.

34. The answer is D.

(Chap. 36) Recurrent episodes of rheumatic fever are most common in the first 5 years after the initial diagnosis. Penicillin prophylaxis is recommended for at least this period. After the first 5 years secondary prophylaxis is determined on an individual basis. Ongoing prophylaxis is currently recommended for patients who have had recurrent disease, have rheumatic heart disease, or work in occupations that have a high risk for reexposure to group A streptococcal infection. Prophylactic regimens are penicillin V, PO 250 mg bid, benzathine penicillin, 1.2 million units IM every 4 weeks, and sulfadiazine, 1 g PO daily. Polyvalent pneumococcal vaccine has no cross-reactivity with group A streptococcus.

35. The answer is D.

(Chap. 19) While any valvular vegetation can embolize, vegetations located on the mitral valve and vegetations >10 mm are at the greatest risk of embolizing. Of the choices given, C, D, and E are large enough to increase the

risk of embolization. However, only choice D demonstrates the risks of both size and location. Hematogenously seeded infection from an embolized vegetation may involve any organ, but particularly affects those organs with the highest blood flow. Embolisms are seen in up to 50% of patients with endocarditis. Tricuspid lesions will lead to pulmonary septic emboli, common in injection drug users. Mitral and aortic lesions can lead to embolic infections in the skin, spleen, kidneys, meninges, and skeletal system. A dreaded neurologic complication is mycotic aneurysm, focal dilations of arteries at points in the arterial wall that have been weakened by infection in the vasa vasorum or septic emboli, leading to hemorrhage.

36. The answer is E.

(Chap. 42) Clostridia are gram-positive spore-forming obligate anaerobes that reside normally in the gastrointestinal (GI) tract. Several clostridial species can cause severe disease. *C. perfringens*, which is the second most common clostridial species to normally colonize the GI tract, is associated with food poisoning, gas gangrene, and myonecrosis. *C. septicum* is seen often in conjunction with GI tumors. *C. sordellii* is associated with septic abortions. All can cause a fulminant overwhelming bacteremia, but this condition is rare. The fact that this patient is well several days after his acute complaints rules out this fulminant course. A more common scenario is transient, self-limited bacteremia due to transient gut translocation during an episode of gastroenteritis. There is no need to treat when this occurs, and no further workup is necessary. *Clostridium* spp. sepsis rarely causes endocarditis because overwhelming disseminated intravascular coagulation and death occur so rapidly. Screening for GI tumor is warranted when *C. septicum* is cultured from the blood or a deep wound infection.

37. The answer is B.

(Chap. 124) *Ascaris lumbricoides* is the longest nematode (15–40 cm) parasite of humans. It resides in tropical and subtropical regions. In the United States, it is found mostly in the rural Southeast. Transmission is through fecally contaminated soil. Most commonly the worm burden is low and it causes no symptoms. Clinical disease is related to larval migration to the lungs or to adult worms in the gastrointestinal tract. The most common complications occur due to a high gastrointestinal adult worm burden leading to small-bowel obstruction (most often in children with a narrow-caliber small-bowel lumen) or migration leading to obstructive complications such as cholangitis, pancreatitis, or appendicitis. Rarely, adult worms can migrate to the esophagus and be orally expelled. During the lung phase of larval migration (9–12 days after egg ingestion) patients may develop a nonproductive cough, fever, eosinophilia, and pleuritic chest pain. Eosinophilic pneumonia syndrome (Löfller's syndrome) is characterized by symptoms and lung infiltrates. Meningitis is not a known complication of ascariasis but can occur with disseminated strongyloidiasis in an immunocompromised host.

38. The answer is D.

(Chap. 39) *Listeria meningitis* typically affects the elderly and the chronically ill. It is frequently a more subacute (developing over days) illness than other etiologies of bacterial meningitis. It may be mistaken for aseptic meningitis. Meningeal signs, including nuchal rigidity, are less common, as is photophobia, than in other, more acute causes of bacterial meningitis. Typically WBC counts in the CSF range from 100–5000/ μ L with a less pronounced neutrophilia. 75% of patients will have a WBC count $<1000/\mu$ L. Gram's stain is only positive in 30–40% of cases. Case fatality rates are ~20%.

39. The answer is C.

(Chap. 89) HTLV-I is a retrovirus that is a chronic infection like HIV, but it does not cause similar sequelae. It was the first identified human retrovirus. Gradual decline of CD4+ lymphocyte number and function is a feature of HIV but not of HTLV-I. While many people in endemic areas have serologic evidence of infection, most do not develop disease. The two major complications of HTLV-I are tropical spastic paraparesis and acute T cell leukemia. Tropical spastic paraparesis is an upper motor neuron disease of insidious onset leading to weakness, lower extremity stiffness, urinary incontinence, and eventually a thoracic myelopathy, leading to a bedridden state in about a third of patients after 10 years. It is more common in women than men. It can easily be confused with multiple sclerosis; this is why it is important to be able to recall the geographic regions where HTLV-I is endemic when evaluating a myelopathy. Acute T cell leukemia is a difficult-to-treat leukemia that is specific to chronic HTLV-I infection. HTLV-I is thought to be transmitted in a similar fashion to HIV.

40. The answer is D.

(Chap. 123) Visceral larva migrans, caused in this case by the canine roundworm *Toxocara canis*, most commonly affects young children who are exposed to canine stool. *Toxocara* eggs are ingested and begin their life cycle in the small intestine. They migrate to many tissues in the body. Particularly characteristic of this illness are hepatosplenomegaly and profound eosinophilia, at times close to 90% of the total white blood cell count. Staphylococci will not typically cause eosinophilia. Trichinellosis, caused by ingesting meat from carnivorous animals that has been infected with *Trichinella* cysts, does not cause hepatosplenomegaly and is uncommon without eating a suspicious meal. Giardiasis is characterized by profuse diarrhea and abdominal pain without systemic features or eosinophilia. Cysticercosis typically causes myalgias and can spread to the brain, where it is often asymptomatic but can lead to seizures.

41. The answer is A.

(Chap. 87) While most of the choices listed above can cause pharyngitis in children, adenovirus classically presents with bilateral granular conjunctivitis as well as pharyngitis, and is frequently the cause of an outbreak among children who are in close contact with one another. Symptom-based and supportive therapies are

indicated for all infections other than disseminated infections in immunocompromised patients. Rhinovirus infections manifest clinically as a common cold with sore throat and rhinorrhea. Human metapneumovirus (HMPV) is a recently described respiratory pathogen. Infections usually occur in winter, and antibodies are present in most children by age 5. Clinically HMPV appears similar to human respiratory syncytial virus, with upper and lower respiratory symptoms. Serious infections may occur in immunocompromised patients. Parainfluenza predominantly is a mild coldlike illness in older children and adults, presenting with hoarseness often without cough. Enteroviruses most frequently cause an acute undifferentiated febrile illness but may cause rhinitis, pharyngitis, and pneumonia.

42. The answer is D.

(Chaps. 12 and 63) This patient is chronically immunosuppressed from his antirejection prophylactic regimen, which includes both glucocorticoids and azathioprine. However, the finding of a cavitary lesion on chest x-ray considerably narrows the possibilities and increases the likelihood of nocardial infection. The other clinical findings, including production of profuse thick sputum, fever, and constitutional symptoms, are also quite common in patients who have pulmonary nocardiosis. The Gram stain, which demonstrates filamentous branching gram-positive organisms, is characteristic. Most species of *Nocardia* are acid-fast if a weak acid is used for decolorization (e.g., modified Kinyoun method). These organisms can also be visualized by silver staining. They grow slowly in culture, and the laboratory must be alerted to the possibility of their presence on submitted specimens. Once the diagnosis, which may require an invasive approach, is made, sulfonamides are the drugs of choice. Sulfadiazine or sulfisoxazole from 6–8 g/d in four divided doses generally is administered, but doses up to 12 g/d have been given. The combination of sulfamethoxazole and trimethoprim has also been used, as have the oral alternatives minocycline and ampicillin and IV amikacin. There is little experience with the newer β -lactam antibiotics, including the third-generation cephalosporins and imipenem. Erythromycin alone is not effective, although it has been given successfully along with ampicillin. In addition to appropriate antibiotic therapy, the possibility of disseminated nocardiosis must be considered; sites include brain, skin, kidneys, bone, and muscle.

43. The answer is A.

(Chap. 64) The most common site of actinomycosis infection is the craniofacial area. Often the infection is associated with poor dentition, facial trauma, or tooth extraction. Clinically this presents as a chronic cellulitis of the face, often with drainage through sinus tracts. The infection may spread without regard for tissue planes, and adjacent bony structures may be involved. Diagnosis requires a high degree of suspicion. The drainage is frequently contaminated with other organisms, especially gram-negative rods. The characteristic sulfur granules may not be seen unless deep tissue is sampled. On Gram's stain, the characteristic appearance

shows an intense gram-positive center and branching rods at the periphery. As opposed to the strictly aerobic *Nocardia* species, *Actinomyces* grows slowly in anaerobic and microaerobic conditions. Therapy requires a long course of antibiotics, even though the organism is very sensitive to penicillin therapy. This is presumed to be due to the difficulty of using antibiotics to penetrate the thick-walled masses and sulfur granules. Current recommendations are for penicillin IV for 2–6 weeks followed by oral therapy for a total of 6–12 months. Surgery should be reserved for patients who are not responsive to medical therapy.

44. The answer is D.

(Chap. 28) Urethritis in men causes dysuria with or without discharge, usually without frequency. The most common causes of urethritis in men include *N. gonorrhoeae*, *C. trachomatis*, *Mycoplasma genitalium*, *Ureaplasma urealyticum*, *Trichomonas vaginalis*, herpes simplex virus, and possibly adenovirus. Until recently, *C. trachomatis* accounted for 30–40% of cases; however, this number may be falling. Recent studies suggest that *M. genitalium* is a common cause of non-chlamydial cases. Currently, the initial diagnosis of urethritis in men includes specific tests only for *N. gonorrhoeae* and *C. trachomatis*. Tenets of urethral discharge treatment include providing treatment for the most common causes of urethritis with the assumption that the patient may be lost to follow up. Therefore, prompt empirical treatment for gonorrhea and *Chlamydia* infections should be given on the day of presentation to the clinic. Azithromycin will also be effective for *M. genitalium*. If pus can be milked from the urethra, cultures should be sent for definitive diagnosis and to allow for contact tracing by the health department, as both of the above are reportable diseases. Urine nucleic acid amplification tests are an acceptable substitute in the absence of pus. It is also critical to provide empirical treatment for at-risk sexual contacts. If symptoms do not respond to the initial empirical therapy, patients should be reevaluated for compliance with therapy, reexposure, and *T. vaginalis* infection.

45. The answer is E.

(Chaps. 36, 44, and 29) In a previously healthy student, particularly one living in a dormitory, *Staphylococcus pneumoniae* and *Neisseria meningitidis* are the pathogens most likely to be causing community-acquired bacterial meningitis. As a result of the increasing prevalence of penicillin- and cephalosporin-resistant streptococci, initial empirical therapy should include a third- or fourth-generation cephalosporin plus vancomycin. Dexamethasone has been shown in children and adults to decrease meningeal inflammation and unfavorable outcomes in acute bacterial meningitis. In a recent study of adults the effect on outcome was most notable in patients with *S. pneumoniae* infection. The first dose (10 mg IV) should be administered 15–20 min before or with the first dose of antibiotics and is unlikely to be of benefit unless it is begun 6 h after the initiation of antibiotics. Dexamethasone may decrease the penetration of vancomycin into the CSF.

46. The answer is E.
(Chap. 124) This patient's most likely diagnosis is anisakiasis. This is a nematode infection where humans are an accidental host. It occurs hours to days after ingesting eggs that previously settled into the muscles of fish. The main risk factor for infection is eating raw fish. Presentation mimics an acute abdomen. History is critical as upper endoscopy is both diagnostic and curative. The implicated nematodes burrow into the mucosa of the stomach causing intense pain and must be manually removed by endoscope or, on rare occasion, surgery. There is no medical agent known to cure anisakiasis.
47. The answer is E.
(Chap. 116) All febrile travelers returning from, or immigrants arriving from, *Plasmodium falciparum*-endemic regions should be assumed to have infection with this most severe form of malaria until proven otherwise. *P. falciparum* is the most common infection in returning travelers, may be fatal if not treated, and none of the listed features have sufficient predictive value to rule out malaria. Splenomegaly is a common feature of malaria but is not present in all cases. *P. vivax* and *P. ovale* infections often have paroxysmal fevers but not enough so as to carry significant predictive value; this feature is rarely present in *P. falciparum*-infected persons. Severe myalgias and retroorbital headache often appropriately prompt interest in a diagnosis of dengue fever, but these symptoms are common in malaria as well. Abdominal pain is a very common feature of malaria, and diarrhea can also occur.
48. The answer is B.
(Chap. 24) Microbiologic data are critical in establishing the source of a liver abscess. Polymicrobial samples of pus or blood cultures with gram-negative rods, enterococcus, and anaerobes suggest an abdominal or pelvic source. Hepatosplenic candidiasis once commonly occurred in leukemia or stem cell transplant patients not receiving antifungal prophylaxis. Fungemia was thought to develop in the portal vasculature with poor clearance of yeast during neutropenia. The rejuvenation of neutrophils correlated with symptoms of hepatic abscess. Hepatosplenic candidiasis is now quite rare, given the widespread use of fluconazole prophylaxis in patients with prolonged neutropenia. Certain species such as *Streptococcus milleri* or *Staphylococcus aureus* likely indicate a primary bacteremia and warrant a search for the source of this, depending on the typical ecologic niche of the organism isolated. Amebic abscesses should be considered in the context of host epidemiology: those with a low to medium pretest probability based on travel history, who also have a negative amebic serology, are effectively ruled out for disease, without needing to sample the abscess percutaneously. Fever is the most common presenting sign of liver abscess. Only 50% of patients with liver abscess have right upper quadrant pain, hepatomegaly, or jaundice. Therefore, half of patients may have no signs localizing to the liver. An elevated alkaline phosphatase level is the most sensitive laboratory finding in liver abscess, present in ~70% of cases. Other liver function abnormalities are less common.
49. The answer is C.
(Chap. 90) Immune reconstitution syndrome (IRIS) is commonly seen after the initiation of antiretroviral therapy (ART) in patients with AIDS and a concomitant opportunistic infection (OI). It is a syndrome where either a previously recognized OI worsens after ART despite an initial period of improvement after standard therapy for that particular infection, or when an OI that was not previously recognized is unmasked after ART therapy. The latter scenario occurs presumably as immune cells become reactivated and recognize the presence of a pathogen that disseminated in the absence of adequate T cell response with the patient remaining subclinical prior to ART. Many opportunistic pathogens are known to behave this way but *Cryptococcus*, *Mycobacterium tuberculosis*, and *Mycobacterium avium* complex (MAI/MAC) are the most likely to be associated with IRIS. Risk factors for IRIS are low CD4+ lymphocyte count at ART initiation, initiation of ART within 2 months of treatment initiation for the OI, adequate virologic response to ART, and increase in CD4+ lymphocyte count as a result of ART. IRIS can be diagnostically challenging and is very diverse in terms of clinical presentation and severity. Depending on the organ system and pathogen involved, drug-resistant OI and new OI must be considered, sometimes necessitating invasive biopsies and cultures. In this case, the overlap of organ system with the original presentation, low likelihood of MAI drug resistance, and timing of the syndrome favor IRIS. Therapy is with nonsteroidal anti-inflammatory drugs and sometimes glucocorticoids. OI treatment is continued, and all efforts are made to continue ART as well, except under the most dire of clinical circumstances.
50. The answer is E.
(Chap. 87) Human respiratory syncytial virus (HRSV), previously known as RSV, is an RNA paramyxovirus. HRSV is the major respiratory pathogen in children, the foremost cause of lower respiratory illness in infants, and a cause of a common cold-like syndrome. It is a common and important nosocomial pathogen. RSV Ig, also known as *palivizumab*, has been approved as a monthly injection for children <2 years old who have congenital heart or lung disease or who were born prematurely as a means of preventing RSV infection. It has not been shown to be beneficial in HRSV pneumonia. Barrier precautions should be used, especially in locations where there are high transmission rates; however, with the advent of RSV Ig this is not the only means of prevention. An inactivated, whole-virus RSV vaccine trial found that patients receiving the vaccine appeared more likely to acquire RSV infection. An adequate vaccine has not been developed to date.
51. The answer is C.
(Chap. 24) Primary bacterial peritonitis is a complication of ascites associated with cirrhosis. Clinical presentation can be misleading as only 80% of patients have fever, and abdominal symptoms are only variably present. Therefore, when patients with known cirrhosis

develop worsening encephalopathy, fever, and/or malaise, the diagnosis should strongly be considered and ruled out. In this case, a peritoneal polymorphonuclear leukocyte count of $>250/\mu\text{L}$ would be diagnostic of bacterial peritonitis even if Gram's stain were negative. The paracentesis also might provide microbiologic confirmation. CT of the head would be useful for the diagnosis of cerebral edema associated with severe hepatic encephalopathy or in the presence of focal neurologic findings suggesting an epidural bleed. Cirrhotic patients are at great risk of gastrointestinal (GI) bleeding and it may worsen hepatic encephalopathy by increasing the protein load in the colon. Esophagoduodenoscopy would be a reasonable course of action, particularly if stools were guaiac positive or there was gross evidence of hematemesis or melena. In this case, there is no evidence of GI bleeding and there is mild hemoconcentration, possibly from peritonitis. Lactulose, and possibly neomycin or rifaximin, is a logical therapeutic trial in this patient if peritonitis is not present. Serum ammonia level may suggest hepatic encephalopathy, if elevated, but does not have sufficient predictive value on its own to rule in or rule out this diagnosis.

52. The answer is C.

(Chap. 75) Only two rickettsial infections, *R. prowazekii* and *C. burnetii*, have a recrudescent or chronic stage. This patient has louse-borne (epidemic) typhus caused by *R. prowazekii*. Louse-borne typhus occurs most commonly in outbreaks in overcrowded, poorly hygienic areas such as refugee camps. There was an outbreak of ~100,000 people living in refugee camps in Burundi in 1997. It is the second most severe form of rickettsial disease and can recur years after acute infection, as in this patient. This is thought to occur as a result of waning immunity. Rocky Mountain spotted fever would be consistent with this patient's presentation but he has no epidemiologic risk factors apparent for this disease. African tick-borne fever is considerably less severe and is often associated with a black eschar at the site of a tick bite. Murine typhus is usually less severe and does not exist in a recrudescent form. Q fever can cause chronic disease but this is almost always in the form of endocarditis.

53. The answer is A.

(Chap. 74) Lyme serology tests should be done only in patients with an intermediate pretest probability of having Lyme disease. The presence of erythema migrans in both patient B and patient E is diagnostic of Lyme disease in the correct epidemiologic context. The diagnosis is entirely clinical. Patient C's clinical course sounds more consistent with systemic lupus erythematosus, and initial laboratory evaluation should focus on this diagnosis. Patients with chronic fatigue, myalgias, and cognitive change are occasionally concerned about Lyme disease as a potential etiology for their symptoms. However, the pretest probability of Lyme is low in these patients, assuming the absence of antecedent erythema migrans, and a positive serology is unlikely to be a true positive test. Lyme arthritis typically occurs months after the

initial infection and occurs in ~60% of untreated patients. The typical attack is large joint, oligoarticular, and intermittent, lasting weeks at a time. Oligoarticular arthritis carries a broad differential diagnosis including sarcoidosis, spondyloarthropathy, rheumatoid arthritis, psoriatic arthritis, and Lyme disease. Lyme serology is appropriate in this situation. Patients with Lyme arthritis usually have the highest IgG antibody responses seen in the infection.

54. The answer is C.

(Chap. 22) This patient has at minimum severe sepsis and has a very high pretest probability of an epidural abscess compressing his spinal cord, based on the development of weakness and upper motor neuron signs. Both represent true emergencies. From a sepsis standpoint, the most likely organisms are gram-positive skin flora with methicillin-resistant or sensitive *Staphylococcus aureus* representing a distinct possibility. Vancomycin given intravenously is therefore imperative. However, other gram-negative organisms such as *Pseudomonas* and the HACEK organisms are sometimes causes of bacteremia and endocarditis in injection drug users. Given this patient's unstable hemodynamic state, it would be sensible to empirically cover gram-negative rods as well with cefepime. As the infection is life threatening, it would not be prudent to await operative culture data prior to starting broad-spectrum antibiotics. An epidural abscess needs to be diagnosed and surgically decompressed as rapidly as possible to prevent permanent loss of neurologic function.

55. The answer is A.

(Chap. 106) Cryptococcal meningoencephalitis presents with early manifestations of headache, nausea, gait disturbance, confusion, and visual changes. Fever and nuchal rigidity are often mild or absent. Papilledema is present in ~30% of cases. Asymmetric cranial nerve palsies occur in 25% of cases. Neuroimaging is often normal. If there are focal neurologic findings, an MRI may be used to diagnose cryptococcomas in the basal ganglia or caudate nucleus, although they are more common in immunocompetent patients with *C. neoformans* var. *gattii*. Imaging does not make the diagnosis. The definitive diagnosis remains CSF culture. However, capsular antigen testing in both the serum and the CSF is very sensitive and can provide a presumptive diagnosis. Approximately 90% of patients, including all with a positive CSF smear, and the majority of AIDS patients have detectable cryptococcal antigen. The result is often negative in patients with pulmonary disease. However, because of a very small false-positive rate in antigen testing, CSF culture remains the definitive diagnostic test. In this condition *C. neoformans* often can also be cultured from the urine; however, other testing methods are more rapid and useful.

56. The answer is B.

(Chap. 90) CDC guidelines now state that all adults should receive HIV testing, with the availability of a

patient opt-out mechanism rather than informed consent. The basis for this is that ~25% of the 1 million Americans infected with HIV are unaware of their status, there is good available treatment for HIV that serves to extend the lifespan and decrease HIV transmission, and HIV testing is shown to correlate with a decrease in risk-taking behaviors. Cost-benefit analysis has suggested this approach has advantages to current approaches focusing on screening high-risk populations. Pretest counseling is desirable but not always built into the testing process so physicians should provide some degree of preparation for a positive test. If the diagnosis is made, support systems should be activated that may include trained nurses, social workers, or community support centers.

57. The answer is B.

(Chap. 39) *Listeria* bacteremia in pregnancy is a relatively rare but serious infection both for mother and fetus. Vertical transmission may occur, with 70–90% of fetuses developing infection from the mother. Preterm labor is common. Prepartum treatment of the mother increases the chances of a healthy delivery. Mortality among fetuses approaches 50% and is much lower in neonates receiving appropriate antibiotics. First-line therapy is with ampicillin, with gentamicin often added for synergy. This recommendation is the same for mother and child. In patients with true penicillin allergy, the therapy of choice is trimethoprim-sulfamethoxazole. Quinolones have shown animal model and in vitro efficacy against *Listeria*, but there is not enough clinical evidence to recommend these agents as first-line therapy.

58. The answer is D.

(Chap. 98) The patient has been bitten by a member of a species known to carry rabies in an area in which rabies is endemic. Based on the animal vector and the facts that the skin was broken and that saliva possibly containing the rabies virus was present, postexposure rabies prophylaxis should be administered. If an animal involved in an unprovoked bite can be captured, it should be killed humanely and the head should be sent immediately to an appropriate laboratory for rabies examination by the technique of fluorescent antibody staining for viral antigen. If a healthy dog or cat bites a person in an endemic area, the animal should be captured, confined, and observed for 10 days. If the animal remains healthy for this period, the bite is highly unlikely to have transmitted rabies. Postexposure prophylactic therapy includes vigorous cleaning of the wound with a 20% soap solution to remove any virus particles that may be present. Tetanus toxoid and antibiotics should also be administered. Passive immunization with anti-rabies antiserum in the form of human rabies immune globulin (rather than the corresponding equine antiserum because of the risk of serum sickness) is indicated at a dose of 10 units/kg into the wound and 10 units/kg IM into the gluteal region. Second, one should actively immunize with an antirabies vaccine [either human diploid cell vaccine or rabies vaccine absorbed (RVA)] in four 1-mL doses given IM, preferably in the deltoid or anterior lateral thigh area. The

four doses are given over a 28-day period. The administration of either passive or active immunization without the other modality results in a higher failure rate than does the combination therapy.

59. The answer is B.

(Chap. 79) Foscarnet is a potent agent used for drug-resistant CMV, herpes simplex virus (HSV) and varicella-zoster virus (VZV), or for patients who are intolerant of first-line agents. It may cause acute renal failure. It also binds divalent metals, commonly causing hypokalemia, hypocalcemia, hypophosphatemia, and hyperphosphatemia. It is often poorly tolerated as a result of nausea and malaise as well. Ganciclovir commonly causes bone marrow suppression and potential significant neutropenia when used for CMV infections, necessitating a switch to foscarnet. Foscarnet commonly causes renal failure. Acyclovir (used for HSV and VZV) is generally very well tolerated but may cause lethargy and tremors. Aerosolized ribavirin is used to treat respiratory syncytial virus infection in infants. It is a mutagen and teratogen and is embryotoxic.

60. The answer is A.

(Chap. 90) This patient most likely has HIV encephalopathy of moderate severity. Other neurologic conditions associated with HIV may be considered with a broad initial workup, but her reasonably high CD4+ count, lack of focal deficits and lack of mass lesions on high-resolution brain imaging makes toxoplasmosis, central nervous system (CNS) tuberculoma, progressive multifocal leukoencephalopathy (PML), or CNS lymphoma all less unlikely. Immediate highly active antiretroviral therapy is the treatment of choice for HIV encephalopathy, and she warrants this despite her CD4+ lymphocyte count placing her in a gray zone according to current guidelines in regard to starting therapy. A lumbar puncture looking for VDRL is unnecessary as a serum RPR test is a very good screening test for any type of syphilis; JC virus detected in the CSF would suggest PML, but her pretest probability for this is low because it usually affects patients with a low CD4+ T-cell count. Serum cryptococcal antigen has excellent performance characteristics, but there is little reason to suspect cryptococcal meningitis in the absence of headache or elevated intracerebral pressure.

61. The answer is C.

(Chap. 107) *Candidemia* may lead to seeding of other organs. Among nonneutropenic patients up to 10% develop retinal lesions; therefore, it is very important to perform thorough funduscopy. Focal seeding can occur within 2 weeks of the onset of candidemia and may occur even if the patient is afebrile or the infection clears. The lesions may be unilateral or bilateral and are typically small white retinal exudates. However, retinal infection may progress to retinal detachment, vitreous abscess, or extension into the anterior chamber of the eye. Patients may be asymptomatic initially but may also report blurring, ocular pain, or scotoma. Abdominal abscess are possible but usually occur in patients

recovering from profound neutropenia. Fungal endocarditis is also possible but is more common in patients who use IV drugs and may have a murmur on cardiac examination. Fungal pneumonia and pulmonary abscesses are very rare and are not likely in this patient.

62. The answer is C.

(Chap. 70) This patient has failed therapy for syphilis as his RPR titer has not decreased fourfold over the course of a year. The FTA-ABS may remain positive even after effective treatment. There is no indication for penicillin desensitization. A lumbar puncture is indicated when there is not a fourfold decrease in RPR titre 6–12 months after appropriate therapy, particularly in patients with HIV. A lumbar puncture showing pleocytosis, elevated protein, and/or a positive VDRL will confirm the diagnosis and the need for 10–14 days of IV penicillin. If the CSF is negative, re-treatment with three doses of IM penicillin for late latent syphilis is adequate. There is no reason to begin treatment for neurosyphilis until the diagnosis is made. Doxycycline, 100 mg PO bid for 30 days, is an alternative treatment for syphilis of unknown duration or >1 year duration, but not for neurosyphilis.

63. The answer is B.

(Chap. 126) *Schistosoma mansoni* infection of the liver causes cirrhosis from vascular obstruction resulting from periportal fibrosis but relatively little hepatocellular injury. Hepatosplenomegaly, hypersplenism, and esophageal varices develop quite commonly, and schistosomiasis is usually associated with eosinophilia. Spider nevi, gynecomastia, jaundice, and ascites are observed less commonly than they are in alcoholic and post-necrotic fibrosis.

64. The answer is A.

(Chap. 56) *Campylobacter* are motile, curved gram-negative rods. The principal diarrheal pathogen is *C. jejuni*. This organism is found in the gastrointestinal tract of many animals used for food production and is usually transmitted to humans in raw or undercooked food products or through direct contact with infected animals. Over half the cases are due to insufficiently cooked contaminated poultry. *Campylobacter* is a common cause of diarrheal disease in the United States. The illness usually occurs within 2–4 days after exposure to the organism in food or water. Biopsy of an affected patient's jejunum, ileum, or colon reveals findings indistinguishable from those of Crohn's disease and ulcerative colitis. Although the diarrheal illness is usually self-limited, it may be associated with constitutional symptoms, lasts more than 1 week, and recurs in 5–10% of untreated patients. Complications include pancreatitis, cystitis, arthritis, meningitis, and Guillain-Barré syndrome. The symptoms of *Campylobacter* enteritis are similar to those resulting from infection with *Salmonella*, *Shigella*, and *Yersinia*; all these agents cause fever and the presence of fecal leukocytes. The diagnosis is made by isolating *Campylobacter* from the stool, which requires selective media. *E. coli* (enterotoxigenic) generally

is not associated with the finding of fecal leukocytes; nor is the Norwalk agent. *Campylobacter* is a far more common cause of a recurrent relapsing diarrheal illness that could be pathologically confused with inflammatory bowel disease than are *Yersinia*, *Salmonella*, *Shigella*, and enteropathogenic *E. coli*.

65. The answer is E.

(Chap. 1) Deficiencies in the complement system predispose patients to a variety of infections. Most of these deficits are congenital. Patients with sickle cell disease have acquired functional defects in the alternative complement pathway. They are at risk of infection from *S. pneumoniae* and *Salmonella* spp. Patients with liver disease, nephrotic syndrome, and systemic lupus erythematosus may have defects in C3. They are at particular risk for infections with *Staphylococcus aureus*, *S. pneumoniae*, *Pseudomonas* spp, and *Proteus* spp. Patients with congenital or acquired (usually systemic lupus erythematosus) deficiencies in the terminal complement cascade (C5–8) are at particular risk of infection from *Neisseria* spp such as *N. meningitis* or *N. gonorrhoeae*.

66. The answer is E.

(Chaps. 12 and 121) *T. gondii* commonly achieves latency in cysts during acute infection. Reactivation in the central nervous system in AIDS patients is well known. However, *Toxoplasma* cysts also reside in the heart. Thus, transplanting a *Toxoplasma*-positive heart into a negative recipient may cause reactivation in the months after transplant. Serologic screening of cardiac donors and recipients for *T. gondii* is important. To account for this possibility, prophylactic doses of trimethoprim-sulfamethoxazole, which is also effective prophylaxis against *Pneumocystis* and *Nocardia*, is standard after cardiac transplantation. Cardiac transplant recipients, similar to all other solid organ transplant recipients, are at risk of developing infections related to impaired cellular immunity, particularly >1 month to 1 year posttransplant. Wound infections or mediastinitis from skin organisms may complicate the early transplant (<1 month) period.

67. The answer is B.

(Chap. 43) Severe *C. difficile*-associated disease may mimic a surgical abdomen and patients may not have diarrhea. The lack of diarrhea should not overshadow the other signs and risk factors that are suggestive of *C. difficile*-associated disease, including significant leukocytosis, long hospitalization, prior antibiotics, and probable enteral tube feeds while on the ventilator. Adynamic ileus is a serious and well-known complication of *C. difficile*-associated disease. All potentially serious manifestations that could be *C. difficile*-associated disease should be empirically treated as such until stool antigen tests are negative and an alternative clinical explanation is found. Intravenous metronidazole may be less optimal than oral vancomycin for severe cases, and this patient may fail therapy. However, oral medicines are less likely to reach the target organ in the presence of an adynamic ileus, necessitating IV metronidazole. Some advocate combining administration of oral vancomycin by

NG tube with IV metronidazole. All potentially offending antibiotics should be stopped (if possible, as is the case here with the patient having recovered from her pneumonia) rather than continued. Surgical colectomy may be necessary in fulminant cases when there is no response to medical therapy. Intravenous immunoglobulins, which may provide antibodies to *C. difficile* toxin, are reserved for severe or multiple recurrent cases of *C. difficile*-associated disease.

68. The answer is C.

(Chap. 88) Avian influenza epidemics occur when human influenza A undergoes an antigenic exchange with influenza found in poultry. Recent outbreaks have not been associated with effective human-to-human spread; nearly all patients reported exposure to infected poultry. Past influenza pandemics, including the 1918–1919 pandemic, appear to have originated from antigenic exchange between human and avian influenza viruses. Antigenic shifts are defined as major changes in the hemagglutinin (H) and neuraminidase (N) antigens and occur only with influenza A. Minor antigenic changes are known as antigenic drift and can occur with hemagglutinin alone or with both hemagglutinin (H) and neuraminidase (N). While influenza A and B are genetically and morphologically similar, the latter virus' inability to undergo antigenic shifts lessens its virulence and involvement in pandemic flu. Influenza C is a rare cause of disease in humans and is typically a clinically mild, self-limited infection.

69. The answer is E.

(Chap. 104) There is no *Coccidioides* in Northern Arizona (i.e., the Grand Canyon region). The organism can be cultured from dry top soil in the high desert of Southern Arizona surrounding Phoenix and Tucson. Eosinophilia is a common laboratory finding in acute coccidioidomycosis and erythema nodosum is a common cutaneous clinical feature. Mediastinal lymphadenopathy is more commonly seen on radiographs for all acute pneumonias due to endemic mycoses, including *Coccidioides*, rather than due to bacterial pneumonia. A positive complement fixation test is one method to definitively diagnose acute infection.

70. The answer is A.

(Chaps. 53) *B. cepacia* is an opportunistic pathogen that has been responsible for nosocomial outbreaks. It also colonizes and infects the lower respiratory tract of patients with cystic fibrosis, chronic granulomatous disease, and sickle cell disease. In patients with cystic fibrosis it portends a rapid decline in pulmonary function and a poor clinical prognosis. It also may cause a resistant necrotizing pneumonia. *B. cepacia* is often intrinsically resistant to a variety of antimicrobials, including many β -lactams and aminoglycosides. Trimethoprim-sulfamethoxazole (TMP/SMX) is usually the first-line treatment. *P. aeruginosa* and *S. aureus* are common colonizers and pathogens in patients with cystic fibrosis. *Stenotrophomonas maltophilia* is the pathogen, particularly in patients with cancer, transplants, and critical illness. *S. maltophilia* is a cause of

pneumonia, urinary tract infection, wound infection, and bacteremia. TMP/SMX is usually the treatment of choice for *Stenotrophomonas*.

71. The answer is B.

(Chap. 41). This patient most likely has wound botulism. The use of "black-tar" heroin has been identified as a risk factor for this form of botulism. Typically the wound appears benign, and unlike in other forms of botulism, gastrointestinal symptoms are absent. Symmetric *descending* paralysis suggests botulism, as does cranial nerve involvement. This patient's ptosis, diplopia, dysarthria, dysphagia, lack of fevers, normal reflexes, and lack of sensory deficits are all suggestive. Botulism can be easily confused with Guillain-Barré syndrome (GBS), which is often characterized by an antecedent infection and rapid, symmetric *ascending* paralysis and treated with plasmapheresis. The Miller Fischer variant of GBS is known for cranial nerve involvement with ophthalmoplegia, ataxia, and areflexia being the most prominent features. Elevated protein in the cerebrospinal fluid also favors GBS over botulism. Both botulism and GBS can progress to respiratory failure, so making a diagnosis by physical examination is critical. Other diagnostic modalities that may be helpful are wound culture, serum assay for toxin, and examination for decreased compound muscle action potentials on routine nerve stimulation studies. Patients with botulism are at risk of respiratory failure due to respiratory muscle weakness or aspiration. They should be followed closely with oxygen saturation monitoring and serial measurement of forced vital capacity.

72. The answer is D.

(Chap. 90) *Isospora* and *Cryptosporidium* cause very similar clinical disease in AIDS patients that ranges from intermittent, self-resolved watery diarrhea with abdominal cramping and sometimes nausea, to a potentially fatal cholera-like presentation in the most immunocompromised hosts. *Cryptosporidium* may cause biliary disease and can lead to cholangitis. *Isospora* is limited to the gut lumen. *Cryptosporidium* is not always an opportunistic infection and has led to widespread community outbreaks. *Isospora* is not seen in immunocompetent hosts. Finally, treatment for *Isospora* is usually successful. In fact, this infection is rarely seen in the developed world because trimethoprim/sulfamethoxazole, which is commonly used for *Pneumocystis* prophylaxis, tends to eradicate *Isospora*. Cryptosporidiosis, on the other hand, is very difficult to cure and interventions are controversial. Some clinicians favor nitazoxanone, but cure rates are mediocre and immune reconstitution with antiretroviral therapy is ultimately critical to cure the gastrointestinal disease.

73. The answer is D.

(Chap. 90) Acute HIV should be suspected in any at-risk person who presents with a mono-like illness: it is diagnosed by positive plasma RNA PCR. Patients typically have not developed sufficient antibodies to the virus yet to develop a positive EIA, and the diagnosis

of HIV is usually missed if this test is sent within the first 2 months of HIV acquisition. It is tempting for clinicians to send an ultrasensitive PCR, but this only decreases specificity (false-positive tests with detection of very low levels of HIV are possible due to cross contamination in the laboratory) with no other benefit. There is typically a massive amount of HIV virus in the plasma during acute infection, and the ultrasensitive assay is never required for detection at this stage of disease. Ultra-sensitive assays are helpful in the context of therapy to ensure that there is not persistence of low-level viremia. CD4⁺ lymphocyte count decreases during many acute infections, including HIV, and is therefore not diagnostically appropriate. CD4⁺ lymphocyte counts are useful to risk stratify for opportunistic infection in stable patients with known HIV infection. Resistance tests are sent only when the diagnosis is confirmed.

74. The answer is D.

(Chap. 77) Congenital infection from maternal transmission can lead to severe consequences for the neonate; thus, prenatal care and screening for infection are very important. *C. trachomatis* is associated with up to 25% of exposed neonates who develop inclusion conjunctivitis. It can also be associated with pneumonia and otitis media in the newborn. Pneumonia in the newborn has been associated with later development of bronchitis and asthma. Hydrocephalus can be associated with toxoplasmosis. Hutchinson triad, which is Hutchinson teeth (blunted upper incisors), interstitial keratitis, and eighth nerve deafness, is due to congenital syphilis. Sensorineural deafness can be associated with congenital rubella exposure. Treatment of *C. trachomatis* in the infant consists of oral erythromycin.

75. The answer is E.

(Chap. 90) *P. jiroveci* lung infection is known to worsen after initiation of treatment, likely due to lysis of organism and immune response to its intracellular contents. It is thought that adjunct administration of glucocorticoids may reduce inflammation and subsequent lung injury in patients with moderate to severe pneumonia due to *P. jiroveci*. Adjunct administration of glucocorticoids in patients with moderate to severe disease as determined by a room air $\text{PaO}_2 < 70$ mmHg or an A – a gradient > 35 mmHg decrease mortality. Glucocorticoids should be given for a total duration of 3 weeks. Patients often do not improve until many days into therapy and often initially worsen; steroids should be used as soon as hypoxemia develops rather than wait for lack of improvement. Pneumothoraces and adult respiratory distress syndrome (ARDS) are common feared complications of *Pneumocystis* infection. If patients present with ARDS due to *Pneumocystis* pneumonia, they would meet the criterion for adjunct glucocorticoids due to the severe nature of disease.

76. The answer is A.

(Chap. 102) Caspofungin and the other echinocandins (anidulafungin, micafungin) inhibit fungal synthesis of

B-1,3-glucan synthase, a necessary enzyme for fungal cell wall synthesis that does not have a human correlate. These agents are available only parentally, not orally. They are fungicidal for *Candida* species and fungistatic against *Aspergillus* species. Caspofungin is as at least equivalently effective as amphotericin B for disseminated candidiasis and is as effective as fluconazole for candidal esophagitis. It is not a first-line therapy for *Aspergillus* infection but may be used as salvage therapy. The echinocandins, including caspofungin, have an extremely high safety profile. They do not have activity against mucormycosis, paracoccidiomycosis, or histoplasmosis.

77. The answer is B.

(Chap. 79) Oral ribavirin combined with pegylated interferon appears to be the most effective regimen for treating hepatitis C. Ribavirin does not exert antiviral effect but may be an immune modulator in combination with the interferon. Hemolytic anemia occurs in nearly 25% of patients receiving this therapy. Common approaches to this problem are dose reduction, cessation of ribavirin therapy, or use of red cell growth factors. Rash can occur but is less common. Interferon has common side effects as well, including flulike symptoms, depression, sleep disturbances, personality change, leukopenia, and thrombocytopenia.

78. The answer is C.

(Chap. 3) Hepatitis B is efficiently spread as a blood-borne pathogen. In approximately one-third of needle stick cases where the victim is not immunized (either by vaccine or prior clearance of infection), hepatitis B transmission will occur. This is in comparison to 3% for hepatitis C and 0.3% for HIV-1 infections. Moreover, hepatitis B, because it is a DNA virus, can survive for prolonged amount of times on unsterilized surfaces. This speaks to the goal of 100% vaccination against hepatitis B for all health care workers. Rapid administration of both hepatitis B vaccine and immunoglobulins are the most effective way to prevent transmission if a high-risk stick occurs to a nonimmune health care worker. No data exist to support the use of antiviral therapy for hepatitis B needle sticks, though this strategy has proven effective for HIV-1 associated needle sticks.

79. The answer is C.

(Chap. 101) Prions are infectious proteins that lack nucleic acids and cause neurodegenerative diseases. The most common prion disease in humans is sporadic Creutzfeldt-Jakob disease (s-CJD). Others include familial CJD, fatal familial insomnia, kuru, and iatrogenic CJD. Prions result when an abnormal prion protein binds to a normal isoform of the prion protein, stimulating its conversion into the abnormal isoform. Abnormal prion isoforms have a greater proportion of β -structure and less α -helix than do normal isoforms. The α -to- β structural transition underlies the etiology of the central nervous system degeneration. The patient described has a typical presentation of s-CJD with sleep disturbance, fatigue, and defects in higher cortical functions. CJD

progresses quickly to dementia. Over 90% of patients with CJD exhibit myoclonus during the illness. Typically the myoclonus is provoked by startle, loud noises, or bright lights and will occur even during sleep. The diagnosis requires an appropriate clinical presentation and no other etiologies on CSF examination. There is no widely available laboratory test for diagnosis. Brain biopsy may demonstrate spongiform degeneration and the presence of prion proteins.

80. The answer is D.

(Chap. 76) *Mycoplasma pneumoniae* is a common cause of pneumonia that is often underdiagnosed based on difficult and time-consuming culture techniques, it likely causes mild respiratory symptoms, and because it is adequately treated with standard antibiotic regimens for community-acquired pneumonia. It is spread easily person-to-person, and outbreaks in crowded conditions are common. Most patients develop a cough without radiographic abnormalities. Pharyngitis, rhinitis, and ear pain are also common. *M. pneumoniae* commonly induces the production of cold agglutinins, which in turn can cause an IgM- and complement-mediated intravascular hemolytic anemia. The presence of cold agglutinins is specific for *M. pneumoniae* infection only in the context of a consistent clinical picture for infection, as in this patient. Cold agglutinins are more common in children. Blood smear shows no abnormality, which is in contrast to IgG or warm-type hemolytic anemia where spherocytes are seen. Since there is no easy diagnostic test, empirical therapy is often administered.

81. The answer is B.

(Chap. 22) The most common overall cause of acute bacterial osteomyelitis of the spine is *S. aureus*, accounting for ~50% of cases due to a single organism, introduced via the bloodstream in patients at risk for bloodstream infections (injecting drug users, hemodialysis patients, open postoperative wounds). However, in older male patients with lumbar osteomyelitis, genitourinary or enteric pathogens, such as *E. coli*, are common, particularly after recent urinary tract infections and/or urologic surgeries, accounting for up to 25% of cases of vertebral osteomyelitis. Pathogenesis may occur via retrograde introduction of organism into the spine via the spinal venous plexus. Polymicrobial osteomyelitis is most often due to contiguous infection, such as a decubitus ulcer or diabetic foot infection, rather than bloodstream introductions that are more typical in the spine. Tuberculosis (Pott's disease) is always a consideration for osteomyelitis of the spine. However, this patient's presentation is likely too acute for tuberculosis, and the thoracic spine is a slightly more typical location than the lumbar spine. Brucellosis commonly involves the spine, but this patient's potential exposure to *Brucella* spp. is dated and the course of the infection is too acute for brucellosis. Hypothetically each of the listed infections is possible, highlighting the importance of holding antibiotics before culturing the epidural space, provided that the patient does not have sepsis on original presentation.

82. The answer is A.

(Chap. 75) Anaplasmosis (formerly human granulocytic ehrlichiosis) occurs mostly in the northeastern and upper midwestern United States. It shares the *Ixodes* tick vector with Lyme disease. It is typically a disease of older males (median age 51 years). Because seroprevalence rates are high in endemic areas, subclinical infection is likely common. The disease typically presents with fever (>90% of cases), myalgias, headache, and malaise. Thrombocytopenia, leukopenia, and elevated aminotransaminase activity is common. Adult respiratory distress syndrome, toxic shock-like syndrome, and opportunistic infections may occur, particularly in the elderly. Human granulocytotropic anaplasmosis should be considered on the differential of a flulike illness during May through December in endemic regions. Morulae, intracytoplasmic inclusions, are seen in the neutrophils of up to 80% of cases of human granulocytotropic anaplasmosis on peripheral blood smear and are diagnostic in the appropriate clinical context. This patient has high epidemiologic risk based on his long periods of time outside in an endemic region. Human monocytotropic ehrlichiosis, which can be a more severe illness, has morulae in mononuclear cells (not neutrophils) in a minority of cases. Lyme disease, which may be difficult to distinguish from human granulocytotropic anaplasmosis or human monocytotropic ehrlichiosis, will not cause morulae. Treatment of human granulocytotropic anaplasmosis is with doxycycline.

83. The answer is E.

(Chap. 108) Allergic bronchopulmonary aspergillosis (ABPA) is not a true infection but rather a hypersensitivity immune response to colonizing *Aspergillus* species. It occurs in ~1% of patients with asthma and in up to 15% of patients with cystic fibrosis. Patients typically have wheezing that is difficult to control with usual agents, infiltrates on chest radiographs due to mucus plugging of airways, a productive cough often with mucus casts, and bronchiectasis. Eosinophilia is common if glucocorticoids have not been administered. The total IgE is of value if >1000 IU/mL in that it represents a significant allergic response and is very suggestive of ABPA. In the proper clinical context, a positive skin test for *Aspergillus* antigen or detection of serum *Aspergillus*-specific IgG or IgE precipitating antibodies are supportive of the diagnosis. Galactomannan EIA is useful for invasive aspergillosis but has not been validated for ABPA. There is no need to try to culture an organism via BAL to make the diagnosis of ABPA. Chest CT, which may reveal bronchiectasis, or pulmonary function testing, which will reveal an obstructive defect, will not be diagnostic.

84. The answer is B.

(Chap. 19) Prosthetic cardiac valves are at high risk of developing endocarditis after bacteremia. Patients who develop endocarditis within 2 months of valve surgery most likely have acquired their infection nosocomially as a result of intra-operative contamination of the prosthesis or of a bacteremic postoperative event. Coagulase-negative staphylococci are the most common (33%)

nosocomial pathogens during this time frame, followed by *Staphylococcus aureus* (22%), facultative gram-negative bacilli (13%), enterococci (8%), diphtheroids (6%), and fungi (6%) (see Table 19-1). The modes of infection and typical organisms causing prosthetic valve endocarditis >12 months after surgery are similar to those in community-acquired endocarditis. Both sets of pathogens must be considered in the intermediate 2–12 months after surgery.

85. The answer is B.

(Chap. 90) Oral hairy leukoplakia is due to severe overgrowth of Epstein-Barr virus infection in T cell-deficient patients. It is not premalignant, is often unrecognized by the patient, but is sometimes a cosmetic, symptomatic, and therapeutic nuisance. The white thickened folds on the side of the tongue can be pruritic or painful and sometimes resolve with acyclovir derivatives or topical podophyllin resin. Ultimate resolution occurs after immune reconstitution with antiretroviral therapy. Oral candidiasis or thrush is a very common, relatively easy-to-treat condition in HIV patients and takes on an appearance of white plaques on the tongue, palate, and buccal mucosa that bleed with blunt removal. Herpes simplex virus (HSV) recurrences or aphthous ulcers present as painful ulcerating lesions. The latter should be considered when oral ulcers persist, do not respond to acyclovir, and do not culture HSV. Kaposi's sarcoma is uncommon in the oropharynx and takes on a violet hue, suggesting its highly vascularized content.

86. The answer is D.

(Chap. 119) This patient comes from an area endemic for visceral leishmaniasis that includes Bangladesh, India, Nepal, Sudan, and Brazil. Although many species can cause cutaneous or mucosal disease, the *L. donovani* complex generally is associated with visceral leishmaniasis. The organism is transmitted by the bite of the sand-fly in the majority of cases. Although many patients remain asymptomatic, malnourished persons are at particular risk for progression to symptomatic disease or kala azar, the life-threatening form. The presentation of this disease generally includes fever, cachexia, and splenomegaly. Hepatomegaly is rare compared with other tropical diseases associated with organomegaly, such as malaria, miliary tuberculosis, and schistosomiasis. Pancytopenia is associated with severe disease, as are hypergammaglobulinemia and hypoalbuminemia. Although active investigation is under way to determine a means of diagnosing leishmaniasis by molecular techniques, the current standard remains demonstration of the organism on a stained slide or in tissue culture of a biopsy specimen. Splenic aspiration has the highest yield, with reported sensitivity of 98%. In light of the high mortality associated with this disease, treatment should not be delayed. The mainstay of therapy is a pentavalent antimonial, but newer therapies including amphotericin and pentamidine can be indicated in certain situations. In this case it would be prudent to rule out malaria with a thick and a thin smear. Rarely, the intracellular amastigote forms of *Leishmania* spp. can be seen on a peripheral smear.

87. The answer is C.

(Chap. 90) HIV resistance testing is recommended in selecting initial ART where the prevalence of resistance is high (such as in the United States or Europe) and in determining new therapy for patients with virologic failure while on ART. In the United States, the predominant virus in up to 12% of new cases has one major genotypic resistance mutation (patient A). In the patient failing ART, a resistance genotype should be performed while the patient is on therapy. In the absence of ART, the majority of virus reverts to wild type and the genotype appears normal (genotypes only sample the dominant viral form, though many exist); however, archived viruses in latent pools that are not accessible with current commercially available assays may in fact harbor resistance. Therefore a genotype for patient C is likely to be of little value. Following the initiation of therapy the patient should have a 1 log (tenfold) reduction in plasma HIV RNA levels within 1–2 months. Failure to achieve this response (patient B) may warrant a change in therapy. Patient D has breakthrough failure after a period of intermittent compliance. To determine if she has developed a new resistance pattern, she should have a genotype performed while on therapy to allow for adequate selection pressure from the antiviral agents to select the resistant virus leading to failure as the dominant strain.

88. The answer is B.

(Chap. 108) The primary risk factor for developing invasive *Aspergillus* infection is neutropenia and glucocorticoid use. Risk is proportional to the degree and length of neutropenia and the dose of glucocorticoid. HIV patients rarely develop invasive aspergillosis, and if they do, it is in the context of prolonged neutropenia and/or advanced disease. Patients with graft-vs-host disease and uncontrolled leukemia are at particularly elevated risk. The infection is seen in solid organ transplant patients, particularly those requiring high cumulative doses of glucocorticoids for graft rejection. (See Fig. 108-1.)

89. The answer is A.

(Chap. 69) Rifampin is considered the most potent and important antituberculosis drug. It is also active against other organisms, including some gram-positive and gram-negative organisms, as well as against *Legionella* spp, *Mycobacterium marinum*, and *M. kansasii*. It is notable for turning body fluids a red-orange color. Its use should be avoided or carefully monitored in patients with severe hepatic disease, but it does not need to be dose-adjusted in renal failure. Rifampin is a potent P450 CY3PA inducer and may lower the half-life and therefore effective levels of many important drugs, including anticonvulsants, cyclosporine, hormonal contraceptives, protease inhibitors, narcotics, tricyclic antidepressants, azole antifungals, beta blockers, and many antibiotics. Patients need to be monitored for the effects of subtherapeutic levels whether by directly measuring drug levels (anticonvulsants, cyclosporine), direct effects of the drug (warfarin), or with clinical adjustment (contraceptives, protease inhibitors). While not studied extensively, rifabutin has

a similar, although likely lesser, effect on the same medications as rifampin. Amiodarone is not metabolized by CYP3A.

90. The answer is A.

(Chap. 53) Ecthyma gangrenosum is a disseminated collection of geographic, painful, reddish, maculopapular lesions that rapidly progress from pink to purple and finally to a black, dry necrosis. They are teeming with causative bacteria. In reviews on ecthyma, *Pseudomonas aeruginosa* is the most common isolate from blood and skin lesions. However, many organisms can cause this foreboding rash. Neutropenic patients and AIDS patients are at highest risk, but diabetics and intensive care unit (ICU) patients are also affected. Pseudomonal sepsis is severe with a high mortality. Its presentation is otherwise difficult to discern from other severe sepsis syndromes, with hypothermia, fever, hypotension, organ damage, encephalopathy, bacteremia, and shock being common findings. Though antibiotic use, severe burns, and long ICU stays increase the risk for *Pseudomonas* infection, these exposures are also risk factors for other bacterial infections, many of which also carry daunting resistant profiles. Because of *P. aeruginosa*'s propensity for multidrug resistance, two agents (usually an antipseudomonal β -lactam plus an aminoglycoside or ciprofloxacin) are warranted until culture data return confirming sensitivity to one or both agents. At this point the choice to narrow to one antibiotic or not is still debated and is largely physician preference.

91. The answer is C.

(Chap. 66) While all the patients listed have an increased risk of developing reactivation tuberculosis, the greatest risk factor for development of active tuberculosis is HIV positivity. The risk of developing active infection is greatest in those with the lowest CD4 counts; however, having a CD4 count above a threshold value does not negate the risk of developing an active infection. The reported incidence of developing active tuberculosis in HIV-positive individuals with a positive PPD is 10% per year, compared to a lifetime risk of 10% in immunocompetent individuals. The relative risk of developing active tuberculosis in an HIV-positive individual is 100 times that of an immunocompetent individual. All of the individuals listed as choices have risk factors for developing active tuberculosis. Malnutrition and severe underweight confers a twofold greater risk of developing active tuberculosis, whereas IV drug use increases the risk 10–30 times. Silicosis also increases the risk of developing active tuberculosis 30 times. While the risk of developing active tuberculosis is greatest in the first year after exposure, the risk also increases in the elderly.

92. The answer is A.

(Chap. 66) The CT scan shows a large cavitary lesion in the right upper lobe of the lung. In this man from an endemic area for tuberculosis, this finding should be treated as active pulmonary tuberculosis until proven

otherwise. In addition, this patient's symptoms suggest a chronic illness with low-grade fevers, weight loss, and temporal wasting that would be consistent with active pulmonary tuberculosis. If a patient is suspected of having active pulmonary tuberculosis, the initial management should include documentation of disease while protecting health care workers and the population in general. This patient should be hospitalized in a negative-pressure room on airborne isolation until three expectorated sputum samples have been demonstrated to be negative. The samples should preferably be collected in the early morning as the burden of organisms is expected to be higher on a more concentrated sputum. The sensitivity of a single sputum for the detection of tuberculosis in confirmed cases is only 40–60%. Thus, a single sputum sample is inadequate to determine infectivity and the presence of active pulmonary tuberculosis. Skin testing with a PPD of the tuberculosis mycobacterium is used to detect latent infection with tuberculosis and has no role in determining whether active disease is present.

The cavitary lung lesion shown on the CT imaging of the chest could represent malignancy or a bacterial lung abscess, but given that the patient is from a high-risk area for tuberculosis, tuberculosis would be considered the most likely diagnosis until ruled out by sputum testing.

93. The answer is B.

(Chap. 110) Tinea versicolor is the most common superficial skin infection. It is caused by lipophilic yeasts of the genus *Malassezia*, most commonly *M. furfur*. In tropical areas, the prevalence of tinea versicolor is 40–60%, whereas in temperate areas it is about 1%. In general, most individuals seek evaluation for cosmetic reasons as the lesions in tinea versicolor are asymptomatic or only mildly pruritic. The lesions typically appear as patches of pink or coppery-brown skin, but the areas may be hypopigmented in dark-skinned individuals. Diagnosis can be made by demonstrating the organism on potassium hydroxide preparation where a typical “spaghetti and meatballs” appearance may be seen. This is due to the presence of both spore forms and hyphal forms within the skin. Under long-wave UVA light (Wood's lamp), the affected areas fluoresce to yellow-green. The organism is sensitive to a variety of antifungals. Selenium sulfide shampoo, topical azoles, terbinafine, and ciclopirox have all been used with success. A 2-week treatment regimen typically shows good results, but the infection typically recurs within 2 years of initial treatment.

94. Answer is D.

(Chap. 110) *Sporothrix schenckii* is a thermally dimorphic fungus found in soil, plants, and moss and occurs most commonly in gardeners, farmers, florists, and forestry workers. Sporotrichosis develops after inoculation of the organism into the skin with a contaminated puncture or scratch. The disease typically presents as a fixed cutaneous lesion or with lymphocutaneous spread. The initial lesion typically ulcerates and become verrucous in appearance. The draining lymphatic channels become

affected in up to 80% of cases. This presents as painless nodules along the lymphatic channel, which ulcerate. A definitive diagnosis is made by culturing the organism. A biopsy of the lesion may show ovoid or cigar-shaped yeast forms. Treatment for sporotrichosis is systemic therapy. Options include oral itraconazole, saturated solution of potassium iodide, and terbinafine. However, terbinafine has not been approved for this indication in the United States. Topical antifungals are not effective. In cases of serious system disease such as pulmonary sporotrichosis, amphotericin B is the treatment of choice. Caspofungin is not effective against *S. schenckii*.

95. The answer is D.

(Chap. 47) Generally thought of as a disease of children, epiglottitis is increasingly becoming a disease of adults since the wide use of *Haemophilus influenzae* type B vaccination. Epiglottitis can cause life-threatening airway obstruction due to cellulitis of the epiglottis and supraglottic tissues, classically due to *H. influenzae* type B infection. However, other organisms are also common causes including nontypeable *H. influenzae*, *Streptococcus pneumoniae*, *H. parainfluenzae*, *Staphylococcus aureus*, and viral infection. The initial evaluation and treatment for epiglottitis in adults includes airway management and intravenous antibiotics. The patient presented here is demonstrating signs of impending airway obstruction with stridor, inability to swallow secretions, and use of accessory muscles of inspiration. A lateral neck x-ray shows the typical thumb sign indicative of a swollen epiglottis. In addition, the patient has evidence of hypoventilation with carbon dioxide retention. Thus, in addition to antibiotics, this patient should also be intubated and mechanically ventilated electively under a controlled setting as he is at high risk for mechanical airway obstruction. Antibiotic therapy should cover the typical organisms outlined above and include coverage for oral anaerobes.

In adults presenting without overt impending airway obstruction, laryngoscopy would be indicated to assess airway patency. Endotracheal intubation would be recommended for those with >50% airway obstruction. In children, endotracheal intubation is often recommended as laryngoscopy in children has provoked airway obstruction to a much greater degree than adults, and increased risk of mortality has been demonstrated in some series in children when the airway is managed expectantly.

96. The answer is E.

(Chap. 59) The most likely infecting organism in this patient is *Francisella tularensis*. Gentamicin is the antibiotic of choice for the treatment of tularemia. Fluoroquinolones have shown in vitro activity against *F. tularensis* and have successfully been used in a few cases of tularemia. Currently, however, it cannot be recommended as first-line therapy as data are limited in regard to its efficacy relative to gentamicin, but can be considered if an individual is unable to tolerate gentamicin. To date, there have been no clinical trials of fluoroquinolones to

definitively demonstrate equivalency with gentamicin. Third-generation cephalosporins have in vitro activity against *F. tularensis*. However, use of ceftriaxone in children with tularemia resulted in almost universal failure. Likewise, tetracycline and chloramphenicol also have limited usefulness with a higher relapse rate (up to 20%) when compared to gentamicin. *F. tularensis* is a small gram-negative, pleomorphic bacillus that is found both intra- and extracellularly. It is found in mud, water, and decaying animal carcasses, and ticks and wild rabbits are the source for most human infections in the southeast United States and Rocky Mountains. In western states, tabanid flies are the most common vectors. The organisms usually enter the skin through the bite of a tick or through an abrasion. On further questioning, the patient above reported that during the camping trip he was primarily responsible for skinning the animals and preparing dinner. He did suffer a small cut on his right hand at the site where the ulceration is apparent. The most common clinical manifestations of *F. tularensis* are ulceroglandular and glandular disease, accounting for 75–85% of cases. The ulcer appears at the site of entry of the bacteria and lasts for 1–3 weeks and may develop a black eschar at the base. The draining lymph nodes become enlarged and fluctuant. They may drain spontaneously. In a small percentage of patients, the disease becomes systemically spread, as is apparent in this case, with pneumonia, fevers, and sepsis syndrome. When this occurs, the mortality rate approaches 30% if untreated. However, with appropriate antibiotic therapy the prognosis is very good. Diagnosis requires a high clinical suspicion as demonstration of the organism is difficult. It rarely seen on Gram's stain because the organisms stain weakly and are so small that they are difficult to distinguish from background material. On polychromatically stained tissue, they may be seen both intra- and extracellularly, singly, or in clumps. Moreover, *F. tularensis* is a difficult organism to culture and requires cysteine-glucose–blood agar. However, most labs do not attempt to culture the organism because of the risk of infection in laboratory workers, requiring biosafety level 2 practices. Usually the diagnosis is confirmed by agglutination testing with titers >1:160 confirming diagnosis.

97. The answer is A.

(Chap. 62) Donovanosis is caused by the intracellular organism *Calymmatobacterium granulomatis* and most often presents as a painless erythematous genital ulceration after a 1–4 week incubation period. However, incubation periods can be as long as 1 year. The infection is predominantly sexually transmitted, and autoinoculation can lead to formation of new lesions by contact with adjacent infected skin. Typically the lesion is painless but bleeds easily. Complications include phimosis in men and pseudo-elephantiasis of the labia in women. If the infection is untreated, it can lead to progressive destruction of the penis or other organs. Diagnosis is made by demonstration of *Donovan bodies* within large mononuclear cells on smears from the lesion. Donovan bodies refers to the appearance of multiple intracellular organisms within the cytoplasm of mononuclear cells. These

organisms are bipolar and have an appearance similar to a safety pin. On histologic examination, there is an increase in the number of plasma cells with few neutrophils; additionally, epithelial hyperplasia is present and can resemble neoplasia. A variety of antibiotics can be used to treat donovanosis including macrolides, tetracyclines, trimethoprim-sulfamethoxazole, and chloramphenicol. Treatment should be continued until the lesion has healed, often requiring ≥ 5 weeks of treatment.

All of the choices listed in the question above are in the differential diagnosis of penile ulcerations. Lymphogranuloma venereum is endemic in the Caribbean. The ulcer of primary infection heals spontaneously, and the second phase of the infection results in markedly enlarged inguinal lymphadenopathy, which may drain spontaneously. *H. ducreyi* results in painful genital ulcerations, and the organism can be cultured from the lesion. The painless ulcerations of cutaneous leishmaniasis can appear similarly to those of donovanosis but usually occur on exposed skin. Histologic determination of intracellular parasites can distinguish leishmaniasis definitively from donovanosis. Finally, it is unlikely that the patient has syphilis in the setting of a negative rapid plasma reagin test, and the histology is inconsistent with this diagnosis.

98. The answer is B.

(Chap. 4) Malaria prophylaxis recommendations vary by region. Currently the recommended malaria prophylaxis for Central America is chloroquine. In contrast, due to chloroquine resistance of falciparum malaria, prophylaxis in India and most areas in Africa is with atovaquone/proguanil, doxycycline, or mefloquine. Table 4-2 represents the chemoprophylaxis regimens for malaria arranged by country as currently recommended by the Centers for Disease Control and Prevention.

99. The answer is A.

(Chap. 4) The causes of fever in travelers vary by geography. In general, all febrile travelers returning from malaria-endemic regions should be assumed to have malaria until ruled out or another diagnosis established, since falciparum malaria may be life-threatening and effective therapy is available. Dengue is particularly common in Southeast Asia. Most cases are self-limited and require supportive therapy. A small proportion, however, can develop hemorrhagic fever or a shock syndrome. Table 4-3 lists the most common causes of febrile illness in returning travelers by country.

100. The answer is D.

(Chap. 21) Erysipelas is a soft tissue infection caused by *Streptococcus pyogenes* that occurs most frequently on the face or extremities. The infection is marked by abrupt

onset of fiery-red swelling with intense pain. The infection progresses rapidly and is marked by well-defined and indurated margins. Flaccid bullae may develop on the second or third day. Only rarely does the infection involve the deeper soft tissues. Penicillin is the treatment of choice. However, swelling may progress despite appropriate treatment with desquamation of the affected area.

101. The answer is C.

(Chap. 109) This patient has signs and symptoms of mucormycosis. Although mucormycosis is a relatively uncommon invasive fungal infection, patients with poorly controlled diabetes, patients receiving glucocorticoids, immunocompromised patients, or patients with iron overload syndromes receiving desferrioxamine have an enhanced susceptibility to this devastating infection. The “gold standard” diagnosis is tissue culture, but a common hallmark is the black eschar noted on the palate, which represents invasion of the fungus into tissue, with necrosis. The black eschar in this scenario should prompt the clinician to do more than prescribe treatment for sinusitis. Black eschars on the extremities can be found with anthrax infection or spider bites. Given the mortality associated with this infection and the rapidity with which it progresses, it is not prudent to wait for an ENT consultation after a course of antibiotics. The infection is usually fatal. Successful therapy requires reversal of the underlying predisposition (glucose control in this case), aggressive surgical debridement, and early initiation of antifungal therapy. Voriconazole is not thought to be effective in the treatment of mucormycosis. Posaconazole, an experimental azole antifungal, has been shown to be effective in mouse models of the disease and has been used in patients unable to tolerate amphotericin.

102. The answer is A.

(Chap. 105) Although spontaneous cures of pulmonary infection with *Blastomyces dermatitidis* have been well documented, almost all patients with blastomycosis should be treated since there is no way to distinguish which patients will progress or disseminate. Extrapulmonary disease should always be treated, especially if the patient is immunocompromised. Itraconazole is indicated for non-central nervous system extra-pulmonary disease in mild to moderate cases. Otherwise, amphotericin B is the treatment of choice, especially if there has been treatment failure with itraconazole. The echinocandins have variable activity against *B. dermatitidis* and are not recommended for blastomycosis. The triazole antifungals have not been studied extensively in human cases of blastomycosis. Fluoroquinolones have activity against many mycobacterial species, but do not have activity against fungi, including *B. dermatitidis*.

in streptococcal infections, 360
in tuberculosis, 612–613, 613f
in UTIs, 278–279
Yersinia, 564, 568
- Antibacterial drugs (*Cont.*):
for salmonellosis, 527, 529–530, 529t
for sepsis/septic shock, 169, 169t
for shigellosis, 534–535, 534t
site of infection and, 364–365
for staphylococcal infections, 395–398, 396t
for streptococcal infection, 415
susceptibility of bacteria in vitro, 363
susceptibility testing, 65, 363–364, 363f, 364t
host status, 364, 365t
for tetanus, 432
toxicity of, 8
for transplant recipients, 136–142
for travelers' medical kit, 47
treatment failure, **373**, 373t
for tuberculosis, 609–610, 609t, 635–642
for tularemia, 557
for upper respiratory infections, 174–176, 177t
UTIs associated with, 274
for *Yersinia*, 568
- Antibodies, 26
to HIV, 828–829, 829f
in host-pathogen interactions, 6
production of, 28
- Antibody assays, for parasitic infections, 1048–1049, 1049t
- Antibody detection, for legionellosis, 484t, 485
- Antibody enhancement, in HIV infection, 829
- Antibody response
in detection of pathogenic agents, 62
to viral infection, 715
- Antibody testing. *See* Serologic methods
- Antibody therapy, for infectious disease treatment, 8
- Anticapsular antibody, pneumococcal infections and, 375
- Anti-CD22, for EBV infection, 135
- Anticoagulants
hemopericardium associated with, 223
for oral infections, 185
for pericarditis, 225
pericarditis associated with, 221t
- Anticonvulsants
for brain abscess, 327
for HIV patients, 856
for infectious focal CNS lesions, 328
- Anticytokine therapy, fever and, 85
- Antidepressants, for chronic fatigue syndrome, 343
- Anti-DNase B (ADB), for rheumatic fever, 415
- Antiemetics, for viral meningitis, 316
- Antifungal agents
for infections in cancer patients, 118, 127, 130
susceptibility testing for selection of, 65–66
topical, 1003
- Antigens, 26
- Antigen assays
for aspergillosis, 1025
for parasitic infections, 1048–1049, 1049t
for pneumonia, 192
- Antigen detection
encephalitis, 318
for laboratory diagnosis of infectious disease, 56
- Antigenic drifts, influenza, 777–778
- Antigenic shifts, influenza, 777–778
- Antihistamines
for acute otitis media, 181
for chronic fatigue syndrome, 343
for rhinovirus, 768
- Antimalarial drugs, adverse drug interactions with, 49
- Antimetabolites, 358
pneumococcal polysaccharide vaccination and, 26f
- Antimicrobial agents
for staphylococcal infections, 395–398, 396t
susceptibility testing for, 65

- Antimicrobial peptides, 13
 Antimicrobial stewardship, 373
 Antimicrobial susceptibility testing, for enterococcal infections, 410
 Antimonials
 adverse effects of, 1051t
 drug interactions of, 1051t
 for leishmaniasis, 1051t, 1059–1060, 1109–1110, 1109t
 pharmacology of, 1059–1060

 - entecavir for, 924–925, 926t
 - epidemiology of, 918–919
 - grading and staging in, 919t
 - HBeAg-negative, 920
 - HBeAg-reactive, 919–920
 - interferon for, 921, 926t
 - lamivudine for, 921–923, 926t
 - pathology of, 919–920
 - pegylated interferon, 923–924, 926t
 - telbivudine for, 928, 928t
 - tenofovir for, 928, 928t
 - treatment of, 921–928, 926t, 927t, 928t
 - clinical features of, 896–898, 897f, 898f, 904t, 907–910
 - complications and sequelae of, 911–912
 - diagnosis of, 716, 908, 909t, 912
 - entecavir for, 728–729
 - epidemiology of, 283, 904–905, 904f
 - escape mutants, 898–899
 - extrahepatic manifestations of, 902–903
 - extrahepatic sites, 899
 - famciclovir and penciclovir for, 727
 - fulminant, 911
 - genomic structure of, 894, 894f
 - hepatocellular cancer associated with, 714
 - in HIV patient, 816, 839t, 846–847
 - in infectious arthritis, 249
 - interferons for, 729
 - lamivudine for, 728
 - latent infection with, 713
 - molecular variants of, 898–899
 - nonreplicative phase of, 897–898, 898f
 - nucleic acid test strategies for, 65
 - occupational transmission of, 802, 883
 - pathogenesis of, 901–902
 - pathology of, 903
 - primary infection with, 713
 - prognosis of, 910–912
 - prophylaxis for, 914–916, 915t
 - proteins and particles of, 894, 895t, 896
 - replicative phase of, 897–898, 898f
 - telbivudine for, 729
 - tenofovir for, 728
 - in transplant recipient, 131, 131t, 141
 - treatment of, 912–913, 1207, 1225
 - virology of, 893f, 894, 894f, 896–899
- Hepatitis B virus vaccine, 23, 301–302, 717, 908–909, 909t, 915–916, 915t
- ACIP recommendations on, 32
 - adult immunization with, 24f–26f, 35
 - for cancer patients, 120t
 - cancer prevention with, 714
 - catch-up schedule for, 31f–32f
 - childhood immunization with, 21f–23f
 - in combination vaccines, 36
 - contraindications to, 38t
 - for developing countries, 42
 - for health care workers, 883
 - for hepatitis D, 916
 - for HIV patient, 839t, 866, 866t
 - for immunocompromised patients, 144
 - occupational exposure recommendations for, 39

Hepatitis B virus vaccine (*Cont.*):

- schedule for, 915–916, 915t
 - for travelers, 44t, 45
- Hepatitis B x antigen (HBxAg), 894f, 895t, 896
- Hepatitis C virus (HCV)
- aminotransferase in, 909
 - antivirals for, 722t–723t
 - bite-wound infections, 348
 - chronic, **929**
 - clinical features of, 918t, 930
 - epidemiology of, 929–930
 - interferon for, 930–935, 932t, 933t
 - prognosis of, 930
 - protease inhibitors for, 935
 - ribavirin for, 930–935, 932t, 933t
 - treatment of, 930–935, 932t, 933t
 - clinical features of, 900–901, 900f, 904t, 907–910
 - complications and sequelae of, 911–912
 - diagnosis of, 716, 908–909, 909t, 912
 - epidemiology of, 904f, 905–906
 - extrahepatic manifestations of, 902–903
 - fulminant, 911
 - genome of, 899–900, 900f
 - hepatocellular cancer associated with, 714
 - in HIV, 846–847
 - in infectious arthritis, 249
 - interferons for, 729–730
 - latent infection with, 713
 - nucleic acid test strategies for, 65
 - occupational transmission of, 802
 - pathogenesis of, 902
 - pathology of, 903
 - primary infection with, 713
 - prognosis of, 910–912
 - prophylaxis for, 916
 - replication of, 711
 - ribavirin for, 724
 - in transplant recipients, 131, 131t, 141
 - treatment of, 912–913
 - virology of, 895t, 899–901, 900f
- Hepatitis C virus vaccine, 717, 916
- Hepatitis D virus (HDV)
- antivirals for, 723t
 - chronic, 918t, 928–929
 - clinical features of, 904t, 907–910
 - complications and sequelae of, 911–912
 - diagnosis of, 908–910, 909t, 912
 - epidemiology of, 904f, 905
 - fulminant, 911
 - interferons for, 730
 - primary infection with, 713
 - prognosis of, 910–912
 - prophylaxis for, 916
 - superinfection with, 907
 - treatment of, 912–913
 - virology of, 895t, 899
- Hepatitis E virus (HEV)
- clinical features of, 904t, 907–910
 - complications and sequelae of, 911–912
 - diagnosis of, 909t, 910, 912
 - epidemiology of, 904f, 906–907
 - fulminant, 911
 - prognosis of, 910–912
 - prophylaxis for, 916
 - treatment of, 912–913
 - vaccine for, 916
 - virology of, 895t, 901
- Hepatobiliary disease, in HIV infection, 846–847
- Hepatocellular cancer, HBV or HCV infection associated with, 714
- Hepatocellular necrosis, leptospirosis, 661

- Hepatomegaly
 babesiosis and, 1098
 bartonellosis and, 573
 schistosomiasis and, 1158–1159
- Hepatosplenomegaly
 brucellosis with, 549
 histoplasmosis with, 1005
 leishmaniasis with, 1106
 trypanosomiasis with, 1112
 visceral larva migrans with, 1136
- Herd immunity, 29
- Hernias, with pertussis, 490
- Herpangina, 183, 941t, 943, 943f
- Herpes encephalitis, 313t, 317–322, 318f, 319t, 735–736, 735f
 antivirals for, 720t, 738t, 739
 meningitis *v.*, 310
 vidarabine for, 728
- Herpes gladiatorum, 734–735
- Herpes keratitis, 735
 antiviral drugs for, 721t
 trifluridine for, 728
- Herpes labialis, 733
 acyclovir for, 725
 famciclovir and penciclovir for, 727
- Herpes simplex virus (HSV), **730**, 767t
 adefovir for, 728
 antiviral drugs for, 718, 720t–721t
 bite-wound infections, 348
 burn-wound infections, 344
 in cancer patients, 121, 123, 127–128
Candida infection association with, 733
 CD4+ T lymphocyte count and, 835f
 cellular infection with, 709, 710
 cidofovir for, 726
 clinical spectrum of, 733–737, 734f–735f
 cytopathic effects of, 712
 diagnosis of, 716, 737
 epidemiology of, 283, 732–733
 etiologic agent of, 730–731
 famciclovir and penciclovir for, 727
 foscarnet for, 727
 ganciclovir for, 726
 herpes zoster *v.*, 743
 HIV and, 800, 816, 839t, 846, 846f, 853
 host receptors for, 10t, 11

 rash in, 88, 89t, 108f
 subacute sclerosing panencephalitis, 324–325
 treatment of, 951
- Measles immune globulin, 27, 28t
- Measles vaccines, 23, 27, 717
 adult immunization with, 24f–26f, 35
 adverse effects of, 36
 catch-up schedule for, 31f–32f
 childhood immunization with, 21f–23f
 contraindications to, 37t
 for HIV-infected patients, 39, 49
 immune globulin administration with, 36
 meningitis prevention with, 316
 occupational exposure recommendations for, 39
 subacute sclerosing panencephalitis prevention with, 324
 timing and target population of, 30
 for travelers, 43
- Measles-mumps-rubella (MMR) vaccine, 23, 27, 951, 955, 958
 adult immunization with, 24f–26f, 35
 adverse effects of, 36
 for cancer patients, 120t
 catch-up schedule for, 31f–32f
 childhood immunization with, 21f–23f
 contraindications to, 37t
 for HIV-infected patients, 39
 for HSCT recipients, 143, 143t
 immune globulin administration with, 36
 occupational exposure recommendations for, 39
 timing and target population of, 30
- Measles-mumps-rubella-varicella (MMRV) vaccine, 951, 958
- Mebendazole
 adverse effects of, 1053t
 for ascariasis, 1053t, 1064, 1141
 drug interactions of, 1053t
 for enterobiasis, 1053t, 1064, 1144
 for hookworm infection, 1053t, 1064, 1141
 for parasitic infections, 1053t, 1064
 pharmacology of, 1064
 for streptocerciasis, **1153**
 for trichinellosis, 1053t, 1064, 1135, 1136t
 for trichuriasis, 1053t, 1064, 1143–1144
 for visceral larva migrans, 1053t, 1064, 1136
- Mediastinal infection, actinomycosis, 582–583
- Mediastinal irradiation, pericarditis due to, 226
- Mediastinitis
 nocardiosis, 578
 in transplant recipient, 139–140
- Medical care, infectious disease risk in settings of, 3
- Medical kit, for travelers, 47
- Medications. *See* Drugs
- Mediterranean spotted fever (MSF), 677t, 678, **680**
 skin manifestations of, 158
- Mefloquine
 adverse effects of, 1055t
 drug interactions of, 49, 1055t
 for malaria, 46t, 1055t, 1064–1065, 1090t, 1093, 1095, 1096t
 pharmacology of, 1064–1065, 1091t–1092t
 resistance to, 1093
- Megalovirus, nucleic acid test strategies for, 65
- Megasphaera*, bacterial vaginosis, 291
- Meglumine antimonate, for leishmaniasis, 1108

- Melanism, 18
- Melarsoprol
adverse effects of, 1055t
drug interactions of, 1055t
pharmacology of, 1065
